the motor. The squirrel-cage motor is simpler and somewhat more rugged, but has the disadvantages of having a fixed slip, of requiring a comparatively large current at starting and, with high slip, of radiating a large amount of heat. Both types are in satisfactory service and local conditions of energy supply, labor, etc., should dictate the proper type to be used.

**43. The average horse power required by band mills** usually varies from 75 to 125 h.p. but to take care of heavy cuts and maintain the speed, motors of from 150 to 250 h.p. are usually supplied for each saw. These motors should preferably be of the 3-bearing belted type and with speeds from about 570 to 850 rev. per min. The following table shows the characteristics of motors which are now installed in saw mills and giving satisfactory service.

| Motor | | Band saw | |
|---|---|---|---|
| Horse power | Rev. per min. | Wheel diam. (ft.) | Width of saw (in.) |
| 200 | 580 | 9 | 15 |
| 150 | 570 | 8 | 14 |
| *150 | 675 | 9 | 14 double edge |
| 200 | 850 | 9 | ..... |
| 200 | 580 | 10 | ..... |

**44. Circular saws.** When the head saw is of the circular type, both saws are usually driven by one belted motor, and, due to the larger kerf, more power is usually required than for band mills. The following drives are in actual operation.

| Motor | | Saws |
|---|---|---|
| Horse power | Rev. per min. | Diameter |
| 250 | 580 | 2–60 in. |
| 300 | 850 | 2–60 in. with carriage and live rolls |

**45. Resaws.** Time can usually be saved by cutting planks and timber at the head saw and then resawing to the desired dimensions. Band resaws are in almost universal use, but circular resaws are sometimes installed. One 72-in. circular resaw in operation is belt-driven by a 100-h.p., 1,120-rev. per min. squirrel-cage motor. Band resaws are generally driven in the same manner as the head saws although for the smaller sizes the pulley speed is sufficiently high so that coupled motors become practicable. The following band resaws are in successful operation in saw mills.

| Motor | | Band resaw | | Drive |
|---|---|---|---|---|
| Horse power | Rev. per min. | Wheel diam. (in.) | Width of saw (in.) | |
| 125 | 850 | 72 | 10 | Belted |
| 75 | 850 | †62 | 9 | Belted |
| 60 | 850 | †54 | 6 | Belted |
| 35 | 580 | 60 | 5 | Coupled |

**46. Edgers** may in most cases be economically driven by coupled squirrel-cage induction motors. There is practically no fly-wheel effect in edgers, and motors are subjected to a severe and rapidly fluctuating load. Since one self-feed rip saw on 2-in. stock may easily require 25 h.p., it is seen that an edger with six or eight saws cutting 2-in. to 4-in. stock may at times require from 150 to 200 h.p. The actual load depends principally upon the kind of wood, feed and number of saws in the cut. The following motor-driven edgers are installed in saw mills.

* High-slip squirrel-cage motor.
† These are horizontal resaws.

| Motor | | Saws | Drive | Remarks |
|---|---|---|---|---|
| Horse power | Rev. per min. | | | |
| 200 | 850 | 6–32 in. | Belted | |
| 150 | 850 | 8–32 in. | Coupled | |
| 75 | 1,700 | 8–24 in. | Coupled | Larger motor required for stock over 2-in. thick. |
| 50 | 1,700 | 4–18 in.<br>4–24 in. | Coupled | See test below |
| 50 | 850 | 6–24 in. | Belted | Saws run 1,590 rev. per min. |
| 30 | 3,480 | 2–6 in. | Coupled | Lath edger |

Test on the above 50-h.p. coupled motor showed a friction load of 6 kw. With a feed of from 180 to 190 ft. per min., on hemlock stock, the following results were obtained:

4 cuts in 3-in. stock..... 68 kw., peaks reaching 75 and 80 kw.
2 cuts in 6-in. stock..... 68 kw., peaks reaching 75 and 80 kw.

**47. Trimmers.** The driving shafts of trimmers can be readily driven by coupled squirrel-cage motors and speeds of 680 to 850 rev. per min. are customary. The following are instances of successful applications.

| Motor | | Saws | Drive | Remarks |
|---|---|---|---|---|
| Horse power | Rev. per min. | | | |
| 50 | 680 | 20–30 in. | Coupled | |
| 50 | 850 | 21–32 in. | Coupled | Also drives transfer chains. |
| 30 | 850 | 12–24 in. | Coupled | |
| 5 | 1,120 | 2–18 in. | Coupled | Lath bundle trimmer |

**48. Slashers** are best driven by standard squirrel-cage motors coupled to the saw shafts. The speed is determined by the saw diameter since it is not desirable to use a cutting speed much higher than 10,000 ft. per min. The following are typical installations.

| Motor | | Saws | Drive |
|---|---|---|---|
| Horse power | Rev. per min. | | |
| 50 | 850 | 14–40 in. | Coupled |
| 40 | 580 | 6–36 in. | Belted |
| 30 | 850 | 5–46 in. | Coupled |
| 25 | 1,120 | 6–38 in. | Coupled |
| 20 | 850 | 4–36 in. | Belted |

**49. Hogs.** The rotating element of a hog is very heavy and the discussion of squirrel-cage versus slip-ring motors (Par. **42**) applies here also.

Diamond Iron Works' hogs

| No. | Style | Rotor | | Capacity | Horse power |
|---|---|---|---|---|---|
| | | Diam. (in.) | Rev. per min. | Cords per hr. | |
| 1 | B | 60 | 650 | 16 | 65 |
| 1½ | B | 48 | 825 | 12 | 50 |
| 2 | B | 34 | 1,000 | 10 | 40 |
| 3 | S | 48 | 825 | 16 | 75 |

Digitized by Google

Test on a No. 1 hog driven by a 75-h.p., 690-rev. per min., slip-ri coupled motor gave a friction load of 25 kw. Average load with feed fro two band mills, 40 to 50 kw. Peaks 90 kw.

Unless the hog is carefully fed the motors are subject to severe lo fluctuations.

### 50. Miscellaneous

| |
|---|
| Drop cut-off saw, 72 in. diam., 510 rev. per min.; 20-h.p. 570-rev. per mi motor, belted. |
| Swing saw, 20 in. diam.; 7.5-h.p.. 1,120-rev. per min. motor, coupled to cou ter-shaft. |
| Lath bolter, 5 12-in. saws; 40-h.p., 1,700-rev. per min. motor, coupled |
| Self-feed rip saw, 14 in. diam.; 15-h.p., 850-rev. per min. motor, belted |
| Log haul, 230 ft. total length, 100 ft. on 60 per cent. grade; 30-h.p., 1,13 rev. per min. motor, belted. |
| Log haul, 245 ft. total length, 200 ft. on 25 per cent. grade; 50-h.p., 85 rev. per min. motor, belted. |
| Burner conveyor, 14 in. wide × 200 ft. long, about 25 per cent. grade; 2 h.p., 580-rev. per min. back-geared and belted motor. |
| Conveyors in mill; 5 to 15 h.p. according to conditions, usually back-geared or belted through a counter-shaft. |
| Covel band saw grinder; 3-h.p., 1,120-rev. per min. motor, back-geared. |

## PLANING MILLS

**51. Selection of motor.** Standard squirrel-cage induction motors a satisfactorily applied to almost all machines used in planing and other woo working establishments with, perhaps, the exceptions of large band resa of great inertia, heavy planers and matchers with considerable static frict which must be overcome at starting, and in cases where each individu motor requires a large percentage of the generator capacity. For the special cases slip-ring motors are used. The data in the following paragrap give the average sizes and the power requirements of machines as suppli by several of the leading manufacturers. Nearly all of these machines ha met practical service with the motors as indicated, although for very lig or for very heavy service, smaller or larger motors, respectively, are som times used.

Automatic cup-wheel grinder, wheel 8 in. × 4½ in. 29 in. to 32 in. long, 3 h.p.

**68. Panel raiser:** hand feed, 3 h.p.; power feed 5 h.p.

**69. Door clamps:** screw feed, 3 to 5 h.p.

**70. Excelsior machines.** Lewis T. Kline 8-block horizontal machine capacity 2 tons of wood wool or 5 to 6 tons of coarse excelsior per 10 hr. average load, 30 to 40 h.p.

## TRAVELING CRANES

### BY ARTHUR C. EASTWOOD

*President, Electric Controller and Manufacturing Co., Fellow, American In stitute of Electrical Engineers*

**71. Standard electric overhead traveling cranes.** These crane are in general characterized by the fact that they travel upon an overhead structure. Usually they are supplied with three motors, one for operating the hoist, one for propelling the bridge along the runway, and one for propelling the trolley carrying the hoisting mechanism backward and forward across the bridge girders of the crane. In special cases the trolley may be equipped with two or more separate hoisting mechanisms, and in some instances two entirely separate trolleys, each equipped with its own hoisting and trolley motor, are used.

**72. Gantry cranes.** These cranes, as far as functions are concerned, are similar to electric overhead traveling cranes, but are characterized by the fact that in place of traveling on an overhead runway, the bridge member of the crane is supported on structural legs of suitable height, which are provided with wheels and suitable gearing, so that the crane may be propelled bodily along tracks on the ground.

**73. Telpherage systems** are treated fully in another portion of this section, Par. **227** to **239.**

Digitized by Google

**74. Jib cranes** comprise suitable jibs or booms, provided with motor-driven hoisting tackle. In some cases, also, a motor with suitable gearing is provided for swinging the jib into different positions.

**75. Electric locomotive cranes** comprise a jib or boom, usually carried by a turn-table which is mounted upon trucks. Frequently individual motors are provided for raising and lowering the boom, for rotating the boom, for hoisting the load, and for propelling the machine along the tracks. In other cases only a single motor is used, the different functions being set into operation through mechanical clutches.

**76. Miscellaneous.** Under this head may be mentioned charging cranes for open-hearth steel furnaces, skip hoists for elevating and dumping ore, coke, etc., into blast furnaces, also special cranes and unloaders for unloading bulk cargoes, such as ore or coal, from vessels.

**77. Types of motors.** The type of motor most commonly used for operating the various motions of cranes is the series-wound, direct-current motor. The series-wound motor is admirably adapted to the purpose because under heavy load it has the tendency to slow down, thus relieving the power station of a heavy load fluctuation; on the other hand, in the case of light loads, the motor speed increases, thus producing what is generally known as a "lively" crane. Compound-wound direct-current motors are used only in special cases. Where alternating current is available, and its conversion into direct current would entail a very considerable expense, alternating-current motors may be used. The preferable type of alternating-current motor for this service is the slip-ring type, in which resistance is introduced in the rotor circuit in order to obtain variation in speed. This type of motor affords much better results, as far as torque and speed variations are concerned, than the squirrel-cage motor, the torque of which decreases very rapidly as the voltage applied to the terminals of the primary winding is reduced. The speed range of both of these types of alternating-current motors is limited and hence they do not produce nearly so active a crane as one equipped with direct-current series-wound motors. In many large industrial plants, covering considerable areas, energy is generated and distributed in the form of alternating current. The motors which require but slight speed variation are operated directly from the alternating-current mains, while synchronous converters or motor-generator sets are installed to produce direct current for the operation of cranes, hoists, and other machines which must operate through a wide range of speed and under greatly varying load.

**78. The selection of the proper normal rating of hoist motors*** to be used is in general a difficult problem on account of wide variations in service requirements, particularly as to the matter of frequency of operation. As an illustration, two extreme cases may be taken: 1st, that of a crane installed in an engine room or pump house, the crane having been installed originally to assist in erecting the heavy machinery, being subsequently used only at varying and infrequent intervals for lifting parts of machinery when it becomes necessary to make adjustments or repairs; 2nd, the case of a traveling crane provided with a lifting magnet for handling pig-iron or other magnetic material in bulk, or equipped with a grab bucket for handling coal, sand, slag, etc. There are instances of the operation of cranes of this type four times per min., practically 24 hr. per day for indefinite periods, the lifted load being practically constant in value and almost equal to the rated capacity of the crane. It is obvious that in the first case cited, the heating of the motor windings presents a small problem, while in the latter case this item is of paramount importance. Of course the torque exerted by the hoist motor in lifting the maximum load which will be encountered, must be taken into consideration in both cases. If possible the cycle of operations should be considered as follows: 1st, the time required to hoist with maximum load; 2nd, the period of rest at the upper limit of travel; 3rd, the time of lowering; 4th, the period of rest at the lower limit of travel before the next cycle is started. The current required in lowering with a mechanical brake, or the current required in dynamic braking (Par. **83** and **464**) must also be taken into consideration. These figures known, they may be plotted in terms of time and current, so that the square-root of the mean-square current may be

* See "Horse Power of Crane Motors," *Machinery*, Dec., 1913, page 286.

Digitized by Google

determined. Since practically all series-wound motors are given fairly definite ratings in terms of current which the motor can carry continuously for 1 hr. without overheating, the proper motor may thus be selected. In many cases, however, such as in the design of cranes for ordinary machine-shop service, where the full capacity of a hoist is brought into play infrequently, the judgment of the crane designer must be relied upon to determine the proper size of the hoist motor. Many crane builders find it convenient from the viewpoint of standardization of manufacture, to build trolleys of a given hoisting capacity in duplicate. In some applications of these standard cranes the hoisting motor may have much greater capacity than is required, while in other cases the work which must be performed by the hoist may prove to be greater than was anticipated, necessitating adjustments in the field.

**79. The magnetic brake.** The hoisting motor of a crane is usually provided with a magnetic brake. This brake is so arranged that only when power is applied to the hoisting motor is the brake released. At all other times the brake is set either by means of a weight or a sufficiently powerful spring. These brakes are ordinarily designed to apply on the armature shaft of the motor at the commutator end. The series-wound brake (in connection with direct-current motors) is by all means the safest and the most reliable. Shunt-wound brakes of course are necessary in connection with alternating-current hoisting motors, because a series-wound brake would act as a choke coil and materially reduce the voltage at the motor terminals.

**80. Types of brakes in common use,** see Par. 459 to 463.

**81. Brake lining.** In present practice the friction members in all the types of brakes mentioned above are lined or faced with a composition of asbestos, woven together with bronze wire. This material affords a very much higher and much more constant coefficient of friction than do the leather, wood or metal brake facings used in the past.

**82. The mechanical brake.** After a load has been hoisted, it is usually necessary that it be lowered, at least a certain distance. If no means were provided for checking the lowering speed, the load might soon attain almost the speed of a freely falling body, and in the case of a series-wound hoisting motor, might soon attain a speed which would destroy the motor. On electric overhead traveling cranes a so-called "mechanical brake" has been employed, this brake being so designed as to prevent the load from appreciably accelerating the hoist motor, when it is running in the lowering direction, or from "overhauling" the motor, as this action is commonly designated. Many ingenious designs of such brakes have been developed. All of them, however, act upon the common principle that if the load begins to overhaul the motor, the brake is applied.

**83. Dynamic braking.** During recent years this method of retarding the speed of the hoisting motor when lowering a load has been quite generally adopted on electric cranes. The hoisting motor is driven as a generator by the lowering load, and is caused to generate energy which is either returned to the line or dissipated through a resistance, or both. This generation of energy imposes a magnetic drag on the machine and thus retards the downward speed of the load. Dynamic braking with a series-wound hoist motor is accomplished by connecting the field winding in series with a resistance across the supply mains, thus giving the machine the characteristics of a separately-excited shunt-wound generator. In some cases the armature is connected in a local circuit containing a resistance which may be varied at the will of the operator. In other cases the armature is connected across the supply mains in series with a resistance which may be varied by the operator, this latter connection being the one most generally used. See Par. 466.

**84. Motor control in dynamic braking.** Fig. 7 is a diagram of wiring connections of a face-plate type of controller arranged for dynamic braking. When the load is traveling in the lowering direction, the resistances in series with both the armature and the field of the motor may be varied by the operator by manipulation of the lever of this controller. In hoisting, the motor is connected as an ordinary series-wound motor, the controlling resistance being in series with the motor circuit and varied to vary the hoisting speed. In lowering, however, it will be seen that the

Digitized by Google

armature and the field are connected in separate circuits. On the first point of the controller, in lowering, the field is excited through a resistance which allows practically full-load current to pass through the field winding; also a considerable amount of resistance is included in the armature circuit. It will be seen that on the first lowering point the armature is shunted by the field winding and the brake winding. This naturally produces an extremely low speed. As the controller lever is moved from step to step, the resistance in the field circuit is increased, while the resistance in the armature circuit is decreased. Increase in resistance in the field circuit naturally reduces the field excitation and counter e.m.f., thus allowing the speed to increase. The resistance in the field circuit is ordinarily so proportioned that the speed can increase as much as 100 per cent. to 150 per

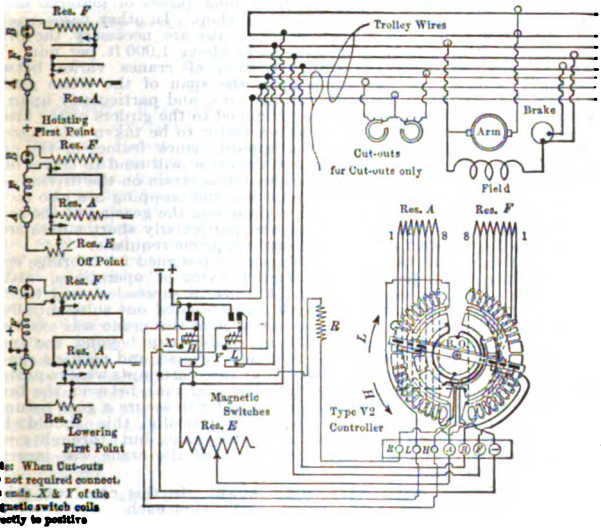

FIG. 7.—Face-plate type controller arranged for dynamic braking.

cent. above normal full-load speed. It will be seen that at all times the field is supplied with current from the mains, and at full speed this may amount to only half of the full-load current. On the other hand, the armature is also connected to the supply mains, and as soon as the counter e.m.f. reaches a value sufficient to overcome line voltage, current is actually returned to the line, so that the net current required in lowering the load is the difference between the current supplied to the field from the line and the current returned to the line by the armature. In lowering heavy loads the current returned to the line is greater than the current drawn from the line by the field, so that the lowering load is made to do useful work.

**85. Slow-hoisting motor control.** This type of control differs from the one illustrated in Fig. 7 only in the respect that a shunt is placed around the armature in order to reduce the speed, thus producing an extremely slow hoisting speed. This type of controller is frequently used in foundries where extremely slow speeds are required in lifting patterns from flasks, etc.

**86. Limit stops** are now customarily provided in connection with the hoisting motion of cranes and hoists. In the absence of a limit stop, the hoisting block, perhaps carrying a load, might be carried upward into

Digitized by Google

the mechanism of the trolley, provided the operator did not open his co troller at the proper time. Where the block of the hoist must be fr quently run up to a point very close to the mechanism of the trolley, is advisable to use a limit stop which not only cuts off the current from tl motor, but includes the motor in a dynamic braking circuit of such lo resistance that the hoist is stopped almost instantly, irrespective of tl condition of the brake.

**87. Drive of the crane bridge.** The designed speed of crane bridg varies between very wide limits. In the case of cranes used in machi shops, structural shops, and plants of like nature, it is advisable to ha the bridge of the crane driven at a speed of from 250 to 300 ft. per mi This corresponds to between 3 and 3½ miles per hr. which is a spee at which a man can walk while steadying long pieces of material carrie by the crane, and passing through a busy shop. In other cases, such the handling of bulk material, where long runs are necessary, the bridg mechanism may be geared to operate at or above 1,000 ft. per min. Th power required to drive the bridge motion of cranes varies betwee exceedingly wide limits, depending upon the span of the crane girder condition of the rails on which the bridge runs, and particularly upon th rigidity with which the end trucks are fastened to the girders of the bridg Unequal wear of driving wheels is also a factor to be taken into accoun because, if the driving wheels on the opposite truck frames of the cran become of unequal diameter, one end of the crane will tend to travel faste than the other, thus producing a severe torsional strain on the driving sha and the bridge structure. Frequent starting and stopping are also factor which should be carefully considered in designing the gearing of the bridg drive. Where many starts and stops, and particularly short moves are t be made, facility in starting and stopping is a prime requisite.

As an example, a certain crane with gearing designed for a bridge spee of 500 ft. per min. performed a regular cycle of operations, makin short moves of approximately 24 in., 24 times in succession, and then re turning to the starting-point, this cycle being carried out substantially 2 hr. per day. At the outset the performance of this crane was extremely unsatisfactory, as the operator would invariably run beyond the poin at which he was required to stop, would then reverse, and perhaps run too far in the opposite direction, so that two or three attempts were required i each case to reach the proper position. The gear ratio between the bridg motor and the driving shaft was altered in order to secure a gear reductio of three times the original reduction. Theoretically, this should have materially slowed down the operation of the crane, but through greate facility in starting and stopping, the output of the crane was increased more than 400 per cent.

**88. Bridge drive with very long span.** In this case two driving motors are frequently provided, one being placed at each end of the bridge and driving the truck wheels directly; the motors are coupled together by a line shaft carried on the girder of the crane. In such cases it is preferable to connect the two driving motors in parallel and to provide each of them with a separate reversing switch, so that each will have its own connections to the line.

**89. Safety devices.** Under this heading might be mentioned limit stops, as described in Par. **86**, and also what are known as crane switchboards. These boards usually include two solenoid-operated switches or contactors, which connect all of the circuits of the crane to the main feed wires. When these switches are open, all wiring on the crane is disconnected from the line. These switches are controlled by a plug, which, when pushed in, energizes the windings of the switch solenoids and causes the switches to close; when pulled out, it opens the switches, thereby interrupting the energy supply. The plug is also provided with attachments whereby it may be positively locked in the open position by a padlock. When a motor inspector or repairman mounts the crane he pulls open the plug and locks it positively in the open position, so that the crane cannot be operated until he has finished his work and removed his padlock. In addition the two magnetic switches are usually arranged for overload protection, and are operated by the action of overload relays in the circuit leads of each motor on the crane. In case the overload is merely temporary, the operator is simply required to reset the magnetic switches, which are conveniently at hand.

Digitized by Google

If, however, the overload relays continue to act when energy is applied, the operator must necessarily look for trouble in the mechanism of the crane.

**90. Energy supply.** In a plant in which a large number of cranes are employed, it is by no means necessary to provide generator capacity equal to the total rated horse power of all of the motors used. In a large industrial plant in which 127 cranes were installed, generator capacity corresponding to 25 per cent. of the total rated horse power of motors used on the cranes was found ample to care for the load. Where only a single crane is installed it is wise to provide generator capacity sufficient to take care of full-load on the hoist and bridge motions, leaving it to the overload capacity of the generator to take care of the current required by the trolley, in case all three motions of the crane should be operated at the same time. Naturally, the larger the number of cranes installed in a given plant where a definite cycle of operations is not carried out, the smaller may be the proportion of generator capacity to the total horse power of the crane motors.

## ELECTRIC HOISTS

**BY WILFRED SYKES**

*General Engineer, Westinghouse Electric and Manufacturing Co., Fellow, American Institute of Electrical Engineers*

**91. Drums.** Hoists are generally classified according to the shape of the drum. In general use are the cylindrical, the conical and the cylindro-conical drums, the last mentioned being a combination of the first two, part of the drum being cylindrical and part conical (Fig. 9). The object of the conical drum is to reduce the starting torque, as the load is exerted on the drum at a smaller radius when the cage is at the bottom of the shaft. The cylindro-conical drum is used with the same object. All other things being equal, the rope wear is less with the cylindrical drums than with other types of drums.

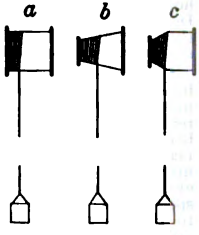

FIG. 8.—Unbalanced hoists.

**92. Flat ropes.** The above types (Par. 91) use round ropes. Flat ropes, generally about 0.5 in. thick, are sometimes used, the rope being wound upon itself on a reel, so that the radius at which the load is suspended gradually increases, the effect being similar to that of the conical drum. Flat ropes on reels are used only to a very small extent, on account of the excessive maintenance charges.

**93. Balanced and unbalanced hoists.** When running balanced the empty cage descends as the loaded cage ascends, the cages and cars balancing each other. When working unbalanced only one cage is used, and the load,

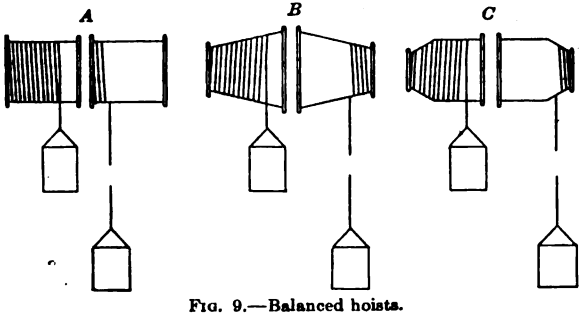

FIG. 9.—Balanced hoists.

Digitized by Google

due to the cage and the car, must be added to that due to the weight of t material hoisted in order to ascertain the load on the motor. See Figs. and 9.

**94. Power requirements.** In the case of small or medium-sized hoist it is usually difficult to determine a definite hoisting cycle, although t maximum load to be hoisted can generally be assumed. In such cas the rating of the motor required is usually determined from the followi formula:

$$\text{h.p.} = \frac{L \times V}{33{,}000 \times 0.8} \qquad ($$

Where $L$ = total unbalanced load and $V$ = speed of hoisting in ft. per mi

For large hoists, the cycle of operation is usually well defined, and t required motor rating can be accurately determined. The calculation load diagrams will be found useful in such investigation.*

**95. Mechanical efficiency.** The over-all efficiency of the mechanic parts of the equipment is assumed in general to be 80 per cent.

**96. Service affecting motor rating.** As the service is intermitte and as the motors have an opportunity to cool during the intervals betwee trips, it is not necessary that the motor should be capable of continuous carrying the load as determined above (Par. **94**). In order to preserve good balance between the maximum torque capacity of the motor and i heating capacity, at the same time keeping down the cost, intermitten rated motors are used for such hoists. Experience has shown that if a mot has sufficient capacity to carry the load, as determined above, for half a hour continuously, it will operate the hoist under ordinary condition In cases of very severe service, where the hoist operates a large portion the time, and where the peak loads due to acceleration may be high, such simple rule cannot be used.

**97. Types of motors adaptable to hoists.** Direct-current moto for small hoists are usually series-wound, but occasionally compound-woun motors are adopted, in order to simplify the control if dynamic braking required. With an alternating-current supply, slip-ring motors are use being designed for great momentary overload capacity. The high value maximum torque for which these motors are designed necessitates a lar magnetizing current, and usually such motors cannot be run continuous even at light load. For small and moderate-size hoists, motors havin speeds from 300 to 500 rev. per min. are generally used, being connecte to the drum through single-reduction gearing. Large induction moto designed for direct-connection to hoists, have been built in a few cas where the speed has been in the neighborhood of 100 rev. per min. Suc machines are very expensive and rather unsatisfactory from an operatin standpoint. The difficulty of controlling large machines by rheosta practically confines the large motors to direct-current machines used i conjunction with a fly-wheel motor-generator set, or a plain motor-generato set (Par. **100** and **104**).

**98. Direct-connected and geared motors.** Direct-current machine can be built in all sizes for comparatively slow speeds, 60 to 75 rev. pe min. being quite common for machines of 500 h.p. and upward. The use o machine-cut double-helical gears has made possible the gearing of large hois motors in many cases, and the very satisfactory operation of this type o gearing when properly built is a strong argument in favor of using moderate speed motors instead of the extremely slow-speed motors necessary fo direct-connection.

**99. Balancing systems.** The high peak loads, caused by hoists o large capacity, especially during their periods of acceleration, make i desirable in many cases to adopt some system of making the load on th line more uniform. Practically all balancing systems utilize a fly-wheel the speed of which is varied, so that it gives up or absorbs energy according to the demands of the hoist. The main requirements of a balancing system are that it should be capable of preventing sudden excessive demands fo energy from the line, it should be automatic in operation, and that th losses, due to it, should be as low as possible.

Digitized by Google

**100. Ilgner balancing system.** The arrangement now most widely used, was devised by Mr. Karl Ilgner. As arranged for alternating-current supply, it consists of an induction motor with a wound rotor, coupled mechanically to a direct-current generator, which in turn supplies energy to a direct-current separately excited hoist motor. The motor-generator set is supplied with a fly-wheel of sufficient capacity to care for the peak loads. The field of the direct-current generator is separately excited, and a controller is provided so that the excitation and the polarity of the generator can be varied as desired. The field polarity of the hoist motor remains constant, so that by reversing the armature current the direction of rotation can be changed. By varying the excitation of the generator, the voltage applied to the armature of the hoist motor can be varied, and in turn the speed of the hoist.

**101. Action of the automatic regulator.** A regulator is provided for automatically inserting resistance in the rotor circuit of the induction motor, thereby reducing the speed of the motor-generator set, which causes the fly-wheel to give up part of the energy stored in it. The rate at which the speed is changed depends upon the difference between the input that is to be maintained on the induction motor and the power required to drive the generator. When the load on the generator is reduced below the value for which the automatic regulator is set, the fly-wheel speed is increased by automatically removing resistance from the rotor circuit, energy being stored in the fly-wheel in order to enable it to carry the peak load, due to the succeeding cycle.

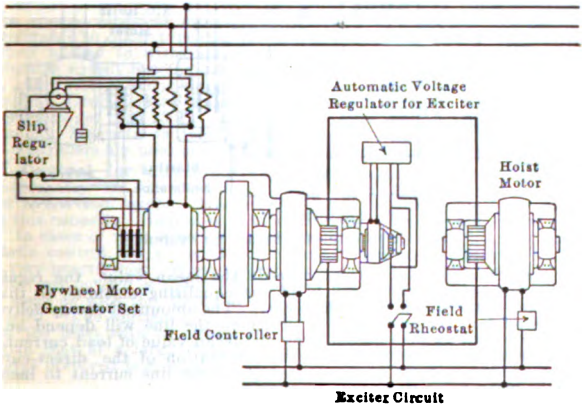

FIG. 10.—Ilgner balancing system.

**102. Details of Ilgner balancing system.** This system provides not only for power equalisation, but also for the control of the hoist motor by the manipulation of the generator excitation, thereby eliminating rheostatic losses, and the difficulty of controlling large machines. The general arrangement of this scheme is shown by Fig. 10. In practice the speed of the fly-wheel set is varied from 15 to 20 per cent. during a hoisting cycle. High-speed fly-wheels with peripheral speeds reaching 25,000 ft. per min. are used in order to minimise the weight.

**103. The losses with the Ilgner system** are comparatively high, and it is seldom that an over-all efficiency of more than 50 per cent. is realised from the combined electrical and mechanical equipment. This efficiency decreases when the hoist is operated below its normal capacity, due to the constant no-load loss of the fly-wheel motor-generator set. However, for important hoists, the advantage of equalising the input, and

Digitized by Google

the perfect control possible with this type of apparatus more than compensates for the increased power consumption.

**104. Converter balancing system.** Another system has been devised, which provides for equalising the input, but does not provide for the control of the hoist motor. This is shown in Fig. 11. In order to render the demand on the line constant, the equalising system is connected in parallel with the generating station. It consists of a synchronous converter and a direct-current machine which is coupled to a suitable fly-wheel.

**105. Operation of the converter balancing system.** The synchronous converter acts only as a connecting link between the alternating-current system and the equalizing set, which consists of a compound-wound direct-current machine coupled to the fly-wheel (Fig. 11). The field of this machine is controlled by a regulator, operated by a series-wound solenoid connected in the main-line. At the beginning of a trip the fly-wheel is running at full

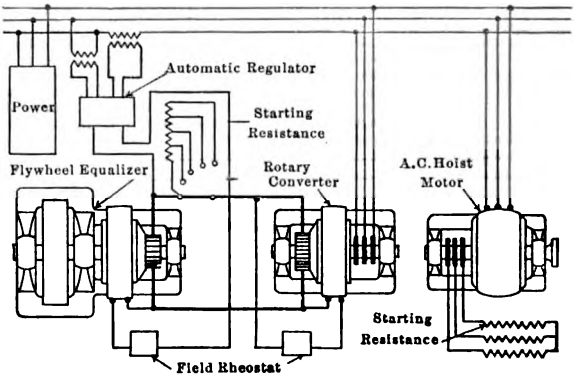

FIG. 11.—Converter balancing system.

speed, and when the load current exceeds the mean value, the regulator automatically strengthens the field of the equalizing machine, so that it acts as a generator driven by the fly-wheel. The amount of energy delivered to the synchronous converter and thence to the line will depend on the excess of momentary load-current over the mean value of load current, for the regulator will continue to raise the excitation of the direct-current machine as long as there is any tendency for the line current to increase above the mean value.

When the current demand drops below the mean value, the regulator will weaken the field, thereby causing the machine to run as a motor, which, taking energy from the line through the synchronous converter, will accelerate the fly-wheel. As before, the rate at which the resistance is introduced in the field depends upon the excess of the mean current value over the momentary current demand. In this way energy is stored in the fly-wheel and the line load is kept approximately constant. The synchronous converter changes either direct current to alternating current, or *vice versa*, depending upon whether the fly-wheel is delivering or receiving energy.

**106. Comparison of Ilgner system with converter system.** It will be seen that the fly-wheel speed variation in the converter method is obtained by field regulation of the direct-current motor, so that the loss is negligible. With the Ilgner system the loss is from 7.5 per cent. to 10 per cent. of the input to the driving motor. This is a very important feature in equalizing systems using direct-current machines, as a much greater fly-wheel speed variation can be economically obtained with the converter method, it being the usual practice to allow from 20 per cent to 25 per cent.,

Digitized by Google

and consequently the fly-wheels can be comparatively light. The machines of the converter equalising equipment need be only large enough to deal with the load variations from the mean value, and under ordinary circumstances, the capacity need not be more than about one-half that of the motor-generator set for the same duty. The equalising equipment is quite independent of the hoisting motor, so that it may be out of service without cessation of hoisting. However, in this event the peak loads will be felt on the line. With the Ilgner system the hoist is directly dependent upon the motor-generator set.

**107. Significance of the starting method.** The main difference between the two systems is that the Ilgner method provides for starting the hoist motor by voltage control without any rheostatic losses while the converter system makes no provision for doing so. When considering the economy of both systems, this difference must be taken into account as starting losses are often a large proportion of the total input. The question of starting is very important with large hoists, and on this account the Ilgner system is preferred for heavy work.

**108. Control for alternating-current motors.** Magnetic-switch controllers are used to a considerable extent. Liquid controllers for the rotor circuit are also used, and these have the advantage of providing smoother acceleration and of being simpler in construction.

**109. Types of switches in use.** For the control of the primary, both oil and air-break magnetic switches are in use. For circuits of 550 volts and under ordinary magnetic switches are quite satisfactory. For 2,200-volt motors, special air-break switches are in use, and when properly designed are preferable to other types on account of the accessibility of the contacts and their ability to withstand hard service. Oil switches are used to a considerable extent but for very severe service they must be very liberally rated, otherwise there is danger of explosion, due to the heat generated in the oil. Drum controllers can be used only for small hoists requiring motors not larger than 75 h.p., and are not at all suitable for severe operating conditions. Magnetic-switch controllers can be used for all sizes, but liquid controllers are used only for motors of about 300 h.p. and above.

**110. Control for direct-current hoist motors.** Drum controllers are satisfactory for direct-current motors under 100 h.p., providing the service is not too severe. Magnetic switches should be used for motors above this capacity. Liquid controllers are not satisfactory for direct current. In cases of very large hoists with peak loads of 1,000 h.p. and above, rheostatic control, for either direct-current or alternating-current motors is not very practicable. When power equalization is not required, a motor-generator set is used without a fly-wheel. In every respect the operation is the same as with the Ilgner system, except that the speed of the set is not varied. The efficiency of such an arrangement is often greater than that of the hoist with rheostatic control, and the maintenance is usually less than that of a large rheostatic controller, although the amount of apparatus involved is greater.

## ELEVATORS

### BY DAVID L. LINDQUIST

*Chief Engineer Otis Elevator Company; Associate, American Institute of Electrical Engineers*

**111. Classification of electric elevators.** There are two general classes of electric elevators, namely, those with winding drums, and those with traction sheaves. The drums of the former type are spirally grooved, the cables winding or unwinding as the elevator is raised and lowered. With elevators having winding drums it is advisable to restrict service to car speeds under 200 ft. per min. and for travels less than 100 ft. For elevators of the latter class, the sheaves are straight grooved for receiving the cables, the car being raised or lowered because of friction existing between sheave and cables. Elevators of this class, are especially adapted to service requiring car speeds of from 200 ft. per min. to 700 ft. per min. inclusive, regardless of length of travel.

**112. Roping and counterbalancing of elevators with winding drums.** Necessary connections are usually made between drum and car and counter-

Digitized by Google

balance by means of two ropes for each connection, thereby decreasing size of ropes required, the increased flexibility permitting the use of smaller diameter drums and sheaves. Fig. 12 indicates the roping arrangement followed when a single or back drum counterbalance only is used; while Fig. 13 portrays similarly the arrangement necessitated by the use of a double counterbalance. With this latter arrangement, one counterbalance constitutes the back drum weight, while the other is attached directly to the car.

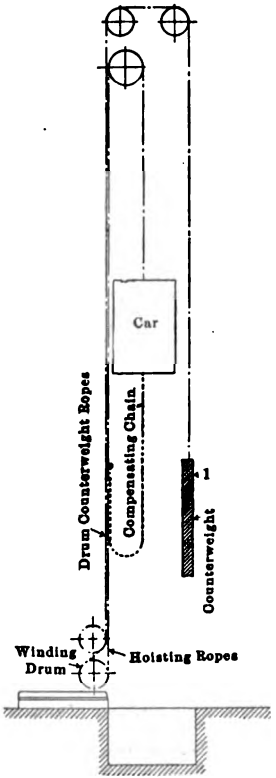

FIG. 12.—Roping arrangement for use with single (back drum) counter balance.

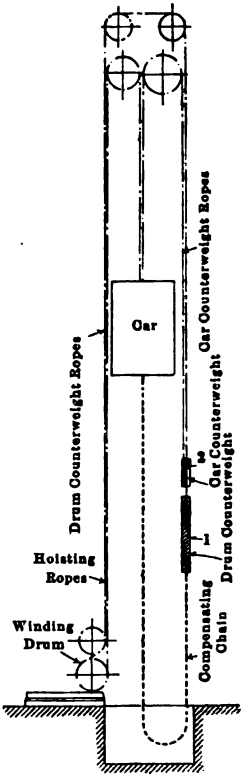

FIG. 13.—Roping arrangement for use with double counterbalance.

The total counterbalancing should be proportioned to the average load to be carried, which usually range from 30 to 40 per cent. of the rated maximum load. When only one counterbalance is used, therefore, its weight should equal that of the car plus from 30 to 40 per cent. of the maximum load in the car. With the double counterbalance, sum-total weight should also be equal to the weight of the car plus from 30 to 40 per cent. of the maximum load in the car. In this event, the counterbalance attached to the car is

Digitized by Google

proportioned to approximately 70 per cent. of the actual weight of the car, the weight of the back drum counterbalance being equal to the difference between the total weight and that of the car counterbalance. Either method of counterbalancing imposes on the motor a net maximum load of approximately two-thirds the rated capacity of the elevator.

For car travels in excess of 100 ft. it is advisable to compensate variation of load on motor, produced by change in position of cables during run, by means of a compensating chain attached from the car to the middle point of the hatchway, as shown in Fig. 12, or attached from car to counter-balance as indicated in Fig. 13. The following formulas derive total compensating weight required, where $h$ = weight of hoist ropes per ft.; $dw$ = weight of drum counterbalance ropes per ft.; $cw$ = weight of car counterbalance ropes per ft.; $c$ = weight of compensating chain (or ropes) per ft. With compensating chain attached to car and middle point of hatch: $c = 2(h + dw + cw)$. With compensating chain attached to car and counterbalance: $c = (h + dw + 2cw)/2$. For installations employing the single counterbalance only; $cw = 0$.

**113. Roping and counterbalancing of elevators with traction sheave** From Fig. 14, which clearly indicates roping required by what is known as the 1 : 1 traction-sheave type, it will be noted that the single length of ropes used are directly connected to car and counterbalance at either end. By the use of a secondary or idler sheave these ropes are passed over the traction sheave a second time as a means for increasing rope contact, which, under the influence of the combined weight of car and counterbalance, provides the adhesion requisite to elevator service.

The foregoing arrangement corresponds to that used for the 2 : 1 traction-sheave type with the exception that the ropes, instead of being directly connected to car and counterbalance, are passed under traveling sheaves located at the upper end of both car and counterbalance; from this point they are extended vertically to the top of the hatchway and there securely and permanently anchored. This latter roping produces a decrease in car speed with a consequent increase in the lifting capacity. Fig. 15 represents the 2 : 1 roping arrangement.

One of the striking advantages resulting from this arrangement of ropes and method of driving them, is the total loss of traction obtained if either car or counterbalance is obstructed in its descent, or bottoms on its respective oil buffer, causing complete cessation of all car motion even though the driving member may continue to revolve. This property of the traction-sheave elevator constitutes an extremely important and effective safeguard by enabling the absolute fixing of the car travel between two given limits, inasmuch as with proper roping the car will be brought to rest on its oil buffer before the counterbalance comes into contact with the overhead work and *vice versa*. A further advantage of the traction-sheave elevator lies in the fact that the faces of the sheaves are entirely independent of the height of the building.

Counterbalancing must in all cases be proportioned for an equal margin of safety to counteract the tendency to slip on both up and down direction of travel under maximum load conditions. Where there is a considerable surplus of traction, however, the weight of the counterbalance should be made dependent upon the average loads in the car, which, for this type of elevator, usually range from approximately 33 to 45 per cent. of the maximum. Ordinarily, the total weight of the counterbalance should equal that of the car plus from 33 to 45 per cent. of the maximum load in the car.

Elevators with traction sheaves should in all cases be provided with rope compensation and with connections arranged in accordance with Fig. 14; the weight per hatchway ft. of the compensating ropes should equal approximately the weight of the hoist ropes per hatchway ft. minus one-fourth the weight per ft. of the electric control and lighting cables.

**114. Electric elevator machines.** The machines used for driving the two types of electric elevators mentioned are distinguished by their methods of power transmission between motor and winding drum or traction sheave, namely, (a) worm gear; (b) worm and spur gear; (c) helical or herring-bone gear; (d) 1 : 1 gearless traction; (e) 2 : 1 gearless-traction machines. All of these machines are preferably arranged for location over the hatchway in each and every case, although, under certain conditions, they can be arranged for location at the base of the hatchway.

**115. Worm-gear machines.** These machines are used for both passenger and freight service and may be arranged with either winding drum or

Digitized by Google

traction sheave. For the smaller sizes, known as dumbwaiter machi duties ranging from 500 lb. at 100 ft. per min. to 100 lb. at 500 ft. per min. possible, while in the larger sizes duties rarely exceed from 10,000 lb. at ft. per min. to 4,000 lb. at 400 ft. per min.

In order to preserve alignment, all parts should be assembled on a rib bedplate extending underneath the entire machine. The armature sl

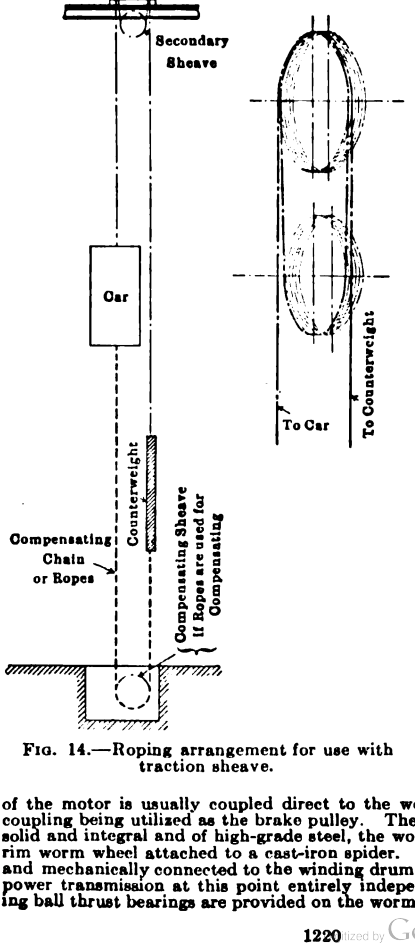

FIG. 14.—Roping arrangement for use with traction sheave.

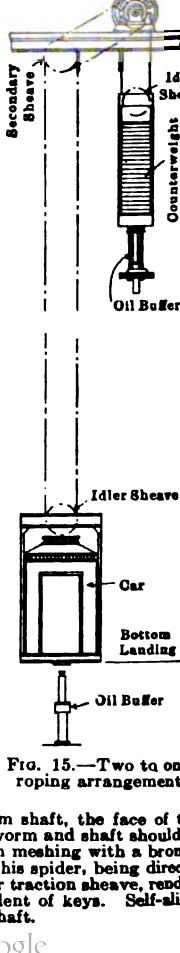

FIG. 15.—Two to on roping arrangement

of the motor is usually coupled direct to the worm shaft, the face of t coupling being utilized as the brake pulley. The worm and shaft should solid and integral and of high-grade steel, the worm meshing with a bron rim worm wheel attached to a cast-iron spider. This spider, being direc and mechanically connected to the winding drum or traction sheave, rend power transmission at this point entirely independent of keys. Self-ali ing ball thrust bearings are provided on the worm shaft.

Digitized by Google

**116. Worm and spur-gear machines.** The two types may be classified as safe lift machines and geared freight machines, the former being a special adaptation of the worm-gear machine when it is desired occasionally to lift loads greater than the normal and at considerably reduced speeds. This type is generally installed in office buildings, where, with the special arrangement applied to one or more of the ordinary passenger elevator machines, the handling of safes averaging from 4,000 lb. to 9,000 lb. in weight at a slow rate of speed, is greatly facilitated. To accomplish the increase in lifting capacity, a special provision is made for placing necessary gears in mesh between the armature and worm shaft, thereby reducing the car speed and increasing the lifting capacity in direct proportion to the ratio of the gearing inserted. By this method, therefore, and usually with a slight addition in counterbalance, the safe-lift loads are carried without requiring more current from the line than during normal operation. Geared freight machines differ from the worm-gear type by the addition of a single spur-gear reduction between the worm gear and the winding drum, thereby constituting them essentially slow-speed machines with relatively large lifting capacities.

**117. Helical gear or herringbone gear machines.** These machines, which can be arranged for use with either winding drums or traction sheaves, are provided with a single gear reduction to the motor by means of the helical or herringbone type of gear, usually made in accordance with the Wuest method. Such gears permit a larger ratio of reduction with greater efficiency than can be obtained with ordinary spur gears. The motor speeds usually range from 300 to 600 r.p.m.

**118. Gearless traction machines, 1:1 ratio.** This machine represents a combination of extreme simplicity, maximum economy and highest efficiency. Briefly, it is a two-bearing electric machine, the armature, traction sheave and brake pulley being contained on the same shaft, all parts being compactly grouped on a cast-iron bed. The motor is of the plain shunt-field, slow-speed type of about 60 r.p.m. transmitting energy direct to the traction sheave. Contrary to general belief, these motors have the remarkably high efficiency and a distinctive procedure has been to arrange design with a view to realising the highest efficiency (about 90 per cent.) at half rated capacity. This figure corresponds with the average loads for this class of service, the full-load efficiency being approximately 87 per cent. Frequently these machines are provided with ball bearings as a means for further increasing the efficiency and decreasing the space required.

Machines of this type should be located over the hatchway whenever it is at all possible. They are used for car speeds of from 500 to 750 ft. per min. with loads ranging from 2,000 to 3,500 lb. inclusive. To date only machines employing direct-current motors have been produced.

By means of a special arrangement, the regular machines can be converted so as to enable the lifting of safes weighing from 5,000 to 8,000 lb. This arrangement includes the placing of a second magnet brake in operation and also the adding of extra weight to the regular counterbalance. When lifting safes, maximum field strength of motor is utilized, producing a proportionately slow car speed.

**119. Gearless traction machines, 2:1 ratio.** All mechanical features of these machines correspond to those of the 1:1 gearless-traction type. They have been designed for traction sheave elevators requiring lower car speeds than obtained with the 1:1 machine without the necessity of gear reductions the car speed reduction being produced by the 2–1 roping arrangement previously described. The machines have been designed for direct-current service only, using shunt-field motors of from 80 to 140 rev. per min., with resultant car speeds of from 250 to 450 ft. per min., and they have been installed for capacities up to 11,000 lb. passenger load. By an arrangement similar to that with which the 1:1 gearless-traction machines are equipped, these machines can also be used for safe lifting.

**120. A common characteristic of all elevator motors** is that they must be specially constructed to withstand repeated stresses produced by frequent starting and stopping. In general, however, the performance of alternating-current and direct-current motors differ to such an extent as to necessitate their separate consideration.

**121. Direct-current motors.** This class of motors must be designed for sparkless commutation at starting, stopping and reversal of rotation under

Digitized by Google

all fluctuations of load within their rated capacity, and be capable of exer a heavy starting torque with minimum requirements as to starting curr especially where frequent starts and stops are made, in order to reduce energy consumption and the reaction on the generating plant. Becaus these requisite features, commercial motors are rendered generally una able. As a means for reducing starting currents, those motors used driving geared elevator machines, and usually operating at from 300 to rev. per min., are arranged to start as compound-wound motors havin heavy series field which should be cut out, usually by a short-circuiting p ess, as the motor speed increases. At full speed, therefore, the mo operates as a plain shunt-field type.

Because of the high self-induction of the field winding required by mo used for driving the 1 : 1 and 2 : 1 gearless-traction machines, which gener operate at from 60 to 140 rev. per min., when at full speed, the fields connected permanently across the supply lines, with reduced current w machine is at rest; this procedure shortens the length of time required bring the field to full strength on starting. Such a method of field con tion materially reduces motor starting current. For direct-current type motors, starting torque and starting current are usually twice the ra torque, and not in excess of 125 per cent. of the current at rated capacity.

**122. Polyphase slip-ring induction motors.** This type represents yond question the most satisfactory alternating-current motor for eleva service. The rotor, which is polar wound, is connected to a series of s rings, thereby permitting the insertion of an external resistance in the ro circuit, resulting in large starting torque with reasonably low starting c rent. Since the resistance of a slip-ring motor is external, it may be adjus for several values of starting torque, and good elevator practice, therefor to provide a larger external-rotor resistance than is required for neces starting torque at full-load, thus limiting first inrush of current to a p determined amount, with connections so arranged that if motor fails to st the imposed load, rotor resistance will be gradually short-circuited u required starting torque is obtained. As elevator loads are frequen considerably under full-load values, the maximum starting resistance all the elevator to start with a current much lower than that required with f load in the car. With the external rotor resistance it is possible to us rotor winding of extremely low internal resistance, and since the exte resistance is completely short-circuited when motor attains full speed, res ant slip and temperature rise are reduced to a minimum, and high runn efficiency is obtained. The speed variation of this type of motor is v small, and it fulfills the best obtainable balance between the three value starting current, slip and running efficiency, which are of extreme importa when applied to elevator motors.

**123. Two-speed polyphase slip-ring induction motors.** For speeds in excess of 200 ft. per min., and where conditions demand accur floor stops, it is advisable to use two-speed motors. These motors, wh have been used successfully, contain double windings on both the stator a rotor. The switches governing them are mounted on the controller pa being electrically and mechanically interlocked in order to prevent c fliction. Starts are always made with the high-speed winding, and conn tions to the slow-speed winding, which is used for stopping purposes only, so arranged that the motor is electrically retarded to a predetermined s speed of usually ½ to ⅓ of full speed.

**124. Polyphase squirrel-cage induction motors.** Squirrel-cage i tors are generally undesirable for elevator service except in the smaller si With motors of this type, the rotor winding is permanently short-circuit thus preventing the employment of external resistance at starting. In or to prevent the possibility of starting currents becoming excessively high is therefore necessary to wind the rotor with self-contained resistance, t method resulting in high slip, comparatively low efficiency and a high te perature rise, especially when the motor is operating frequently. Si rotor resistance is permanently fixed, the motor starting current rises t maximum, with each start, irrespective of load. Motors of this class sho only be used on a power line, where the high starting current required is objectionable and where the service is sufficiently light to eliminate possibility of danger from overheating.

Digitized by Google

**125. Single-phase motors.** Up to the present a type known as the repulsion-induction motor alone has proven successful and in sizes up to and including 15 h.p. These motors, which start as one of the repulsion type, are provided with a centrifugal governor, usually located within the armature core, so designed and adjusted that at about 80 per cent. of full speed the rotor winding is automatically short-circuited, and the motor operates as if it were of the simple induction type. These motors cannot be reversed while operating, as induction motors. Devices are required to prevent change of connections until speed has dropped below that point at which the repulsion connections are re-established in order that reversal of rotation may become effective. Although starting currents are comparatively high, this condition is not objectionable in the smaller sizes, and in the larger sizes the starting current may be appreciably reduced by an external resistance in the stator circuit so connected that it is effective at the moment of starting and during the first period of acceleration.

**126. Brakes.** All elevator machines are equipped with brakes for the purpose of assisting in stopping and holding the car securely at a landing, under any and all conditions of loads up to and including the maximum specified. The brakes, which must be so designed as to be equally effective for either direction of rotation, generally consist of two separate and independent shoes, lined with leather or asbestos preparations, and actuated by heavy helical steel springs. Brake release should be obtained by means of an electromagnet, as this method enables the making of such connections that the brake will be instantly and positively applied on failure or interruption of current supply. See Par. 459 to 463.

**127. Methods of control.** The controlling apparatus of an elevator constitutes one of its most important features, including devices for establishing direction, for producing proper acceleration, retardation, and speed regulation, and also including the necessary safety appliances. Usually slate panels bolted to floor standards are provided, the switches being mounted on its face with connections to these switches, and all resistances located on the rear. All contacts of the various safety devices are usually connected in circuit with the holding coil of what is known as a potential switch, and, since all current to the controller and machine is carried through the contacts of this switch, the operation of any one safety feature immediately interrupts all current to the equipment. This switch also constitutes a no-voltage circuit breaker and an excessive drop in voltage will cause the switch contacts to open. The motor circuits are completed by the reversing switches, two in number, one for the "up" and one for the "down" direction, respectively. The brake circuits are made simultaneously with the closing of either direction switch. In order to prevent conflict, reversing switches are generally electrically or mechanically interlocked.

**128. Automatic starting.** It is advisable, with direct-current elevators, to arrange the stepping-out of the armature starting resistance entirely independent of the operator, and by this process eliminate the damage which would result from a reduction of this resistance at too high a rate. As a means for reducing energy consumption, however, starting resistance should be stepped-out as rapidly as the load on the motor permits; this is accomplished by means of either series relay magnets or magnets dependent on the counter-electromotive force of the motor for operation. See article on "Motor Control" elsewhere in this section.

**129. Dynamic braking.** Except with the small-capacity machines, the wiring of direct-current controllers invariably includes a dynamic-brake circuit which is obtained by introducing a resistance across the armature terminals on stopping. The stopping field in some cases is obtained by having the shunt field (permanently in series with a limiting resistance) connected directly across the supply line. In other cases it is obtained by providing an extra low-resistance shunt field; in the smaller machines the residual magnetism of the field poles is sufficient. Although connecting the field permanently across the supply line slightly increases energy loss, an important safety feature is gained, for with such connections it becomes impossible to attain excessive car speeds either up or down should, for any reason, the machine brake fail to apply. By various methods stopping resistance is automatically stepped-out as the load on the motor permits, thereby strengthening the dynamic-braking effect. As explained, single-

Digitized by Google

speed alternating-current motors cannot readily produce a dynamic s and the machine brakes must be relied upon entirely in bringing the to rest.

**130. Elevator speeds.** Direct-current elevators are generally arran with one speed only for car speeds up to 150 ft. per min., except in the c of automatic push-button-controlled elevators which are provided with t speed control for car speeds above 100 ft. per min. With car speeds abo 150 ft. per min., two or more speeds, under control of the operator, are p vided for convenience in making accurate landings. Alternating-curr elevators are generally arranged for one speed only up to 200 ft. per mi except for automatic push-button-controlled elevators where two speeds m be used with car speeds exceeding 100 ft. per min. The foregoing appl with equal force to winding-drum and worm-gear traction-sheave machin but where accurate stopping is essential two speeds may be provided w car speeds lower than those specified above.

The methods of operation from the car are given in Par. 131 to 133.

**131. Car switch—magnet control.** This method is suitable for all speeds and consists of a master switch, located within the car, electrica connected to the operating coils of the magnetically actuated switches on t control panel. Connections are so arranged that after direction has be established the proper sequence of switches is obtained for the desired celeration and retardation. The car switch should be so designed that it automatically return to centre or stop position should the operator's hand, any cause, be momentarily removed.

**132. Automatic push-button control.** By means of a special type magnet controller, elevators can be operated by a selective arrangement co sisting of a call button located at each floor and a series of buttons, cor sponding to the floors to be served, located within the car.

**133. Hand-rope control.** The contacts of the reversing switches operated by the revolving of a small sheave, to which they are directly indirectly attached, the revolving of the sheave being accomplished by a p on an endless rope connected to it and installed in the hatchway in order to available from the car. For convenience this rope is occasionally connect to a hand wheel or revolving lever device located within the car. Hand ro control becomes difficult to manage as the speed of car is increased and f this reason is generally limited to car speeds below 150 ft. per min.

**134. Automatic terminal stopping device.** With machines of t winding-drum type this consists of a series of contacts usually located abo the drum and positively operated either directly or indirectly by an rangement on the extended drum shaft at the gear-case end. These conta are so connected in the controller circuits that car speed is automatica reduced at predetermined distances from the terminal landings, and fina brought to rest approximately near either terminal landing, provided t operator, for any reason, has neglected to centre his controlling device.

Since with traction-sheave machines no fixed relation exists between t traction driving sheave and the position of the car in the hatchway, becau of the creeping action of the hoist ropes, a machine-driven automatic t minal-stopping device cannot be used. With the worm-gear traction-shea elevators it has become the practice to locate a series of switches in t hatchway, properly spaced, operated by a cam mounted on the car, for pr ducing the necessary slow-down and stop at the terminal landings. Becau of the increased number of speed-reducing steps required with the higher-spe gearless traction-sheave elevators, the switch arrangement in the hatchw would present wiring complications and increase the difficulty of adjustmen and for this reason it has become advisable to carry the switches on the c completely enclosed in a metal case for protection, operated by one cam locat at the top and one at the bottom of the hatchway.

**135. Slack-cable switch.** This device is used with winding-drum el vators only for the purpose of stopping the machine and preventing t unwinding of hoist ropes in case the car is obstructed in its descent. T contact of the slack-cable device is connected in series with the holding c of the potential switch or circuit-breaker which, on opening, interrupts current to the machine. Slack-cable switches are not required with tractio sheave elevators for, as previously described, the obstructing of either car

Digitized by Google

counter-weight immediately causes sufficient loss of traction to prevent further motion of the car and counterbalance.

**136. Final hatchway-limit switches.** To guard against the possibility of damage through disarrangement of the automatic terminal-stopping device, final limit switches are located, one each, beyond the terminal landings, and are operated by a cam on the car, in case the car overtravels to a point at which these switches become operative. The contacts of these switches are also placed in series with the holding coil of the circuit-breaker, causing immediate interruption of current to the machine when opened.

**137. Governor switches.** With high-speed elevators, regulating devices are usually provided, these being operated by a speed governor. These devices control car speed by means of field regulation of the motor, and are usually applied when the car speed exceeds normal by certain predetermined amounts. One or more speed-regulating switches are used, the number depending upon the average speed of the car, and, by their use, maximum speed variation is retained within certain predetermined limits. Governors should preferably be provided with a breaking contact adjusted to open at a car speed slightly lower than that at which the car safeties are set to operate. Therefore, connecting this contact in series with the holding coil of the potential switch or circuit-breaker, usually stops the elevator by interrupting all current to the motor, without the necessity of applying the car safeties.

**138. Car safety switch.** All electric elevators should be provided with a small enclosed switch, located within the car and so connected in the controlling circuits that current to the machine will be interrupted when it is opened. This switch is furnished for emergency purposes only.

**139. Car-safety devices.** The expression "car safety" is usually applied to that form of safety which is designed to bring the car to rest by locking it to the guide rails, in case excessive speed has been attained, irrespective of the cause. All elevators should be equipped with a device of this nature. The application of car safeties should be made dependent upon on a centrifugal or inertia governor, adjusted with a definite and fixed relation to the speed of the car and arranged to operate at approximately from 30 to 50 per cent. above normal car speed. The general practice is to support the safety device within the lower member of the car frame, with the governor substantially supported at the top of the hatchway, although, in some cases, specially designed governors are mounted on the car. With the governor located over the hatchway, it is driven by an endless rope attached to the car and safety mechanism in such a manner that, in case of excessive speed, the governor holds or grips this rope and the safety is applied, usually by means of a drum, sheave or lever arrangement.

Under certain building conditions, namely: where a room or vault is located directly underneath the hatchway, it is advisable to furnish a guide grip safety for the counterbalance as well as for the car, in order to prevent damage such as might otherwise occur through the breaking of the ropes. On all of the recent higher class installations counterbalance safeties have been furnished even where the foregoing condition has not existed.

**140. The number of elevators required** in a building depends on several conditions, namely: height of building, relation of area of building to its height, net rentable area in sq. ft. per floor, character of elevator service required by prospective tenants and relative location of building. In average office buildings it is not considered good practice to attempt to serve more than from 18,000 to 24,000 sq. ft. of rentable floor area per elevator. The mileage of each elevator in a modern office building ranges from 15 to 40 miles per day, depending on the character of service and type of elevators used.

**141. General consideration of energy consumption.** Usually, it is safe to assume that the loads distributed by an elevator to the different floors of a building are the same, approximately, as those loads returned to the starting point, and with such load conditions the work done consists merely of overcoming the friction. Of greater importance, therefore, in the energy consumption, is the power expended in imparting the kinetic energy required to bring the masses up to speed, and the machine which will register the lowest power consumption must have a low moment of inertia together with a low value of friction.

Digitized by Google

The machine at present fulfilling the foregoing requirements to the most satisfactory degree, is the 1 : 1 ball-bearing gearless traction-sheave machine, and this fact is clearly evidenced by the following comparison between a 1 : 1 traction machine with motor running at 74 rev. per min., and a herringbone-gear traction-sheave machine driven by a 600-rev. per min. motor, both of these machines being designed for a lifting capacity of 2,500 lb. at a speed of 700 ft. per min. It was found that the kinetic energy required to bring the 1 : 1 traction machine up to speed, without the car, counterbalance or ropes, was 3,600 ft-lb., while, under the same conditions, the herringbone-gear traction machine required the expenditure of 17,900 ft-lb. in attaining full speed. The total number of starts and stops of an elevator, therefore, constitute an important factor in the resultant power consumption per mile of car travel.

**142. Influence of number of stops on energy consumption** (*Test data*)

| Specification type of machine and control | Load in car | Average speed, ft. per min. | Number of stops between terminal landings per mile of travel | Energy cons. in kw-hr. per mile of travel | Running efficiency (line to full load) |
|---|---|---|---|---|---|
| Worm-gear drum machine | | | | | |
| Direct-current motor | | | 0 | 2.04 | |
| Magnet control | | | 76 | 3.31 | |
| Duty | 2,150 | 326 | | | 52.5 per cent. |
| Maximum load 2,500 lb. | | | 152 | 4.33 | |
| 2,000 lb. at 300 ft. per min. | | | 380 | 7.34 | |
| Rise, 69 ft. 6 in. | | | | | |
| Overbalance 650 lb. | | | 0 | 1.48 | |
| | | | 76 | 2.47 | |
| | 1,350 | 320 | | | |
| | | | 152 | 3.35 | |
| | | | 380 | 6.21 | |
| 1 : 1 traction direct duty motor | | | 0 | 1.3 | |
| Magnet control | | | | | |
| Duty 2,500 lb. at 600 ft. per min. | 1,500 | 600 | 50 | 3.03 | 68 per cent. with maximum load. |
| Rise 537 ft. 0 in. overbalance 1,125 lb. | | | | | |

**143. The line to load efficiency** is determined by ascertaining the total electrical input, and the net work done on the load.

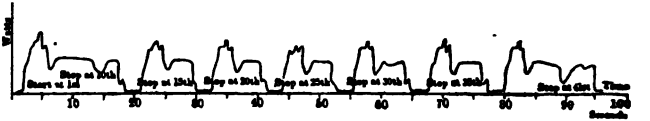

FIG. 16.—Graph of recording wattmeter.

**144. Required power is best determined** by means of a recording wattmeter writing a graph which shows the existent relation between watts and time, the energy consumption in kw-hr. being represented by the area surrounded by the graph and the axis of time. Fig. 16 is a reproduction of such a graph taken in one of the largest office buildings in New York City.

**146. Testing of electric elevators.** When an elevator is completed usual test consists of carrying the rated load at full speed, setting the safety by overspeeding, and a trial operation of all electrical or mechan safety features to determine their effectiveness. A more complicated comprises determinations as to friction, line to load efficiencies with differ loads in the car, the energy consumption with various net loads on the mo and number of stops, and the speed characteristics and the kinetic ener

**147. Energy calculations.** As previously explained the kinetic ene $W$ required to accelerate the masses of the speed $V$ has an important bear on the power requirements. Its determination is made accurate and c paratively simple by application of the formula:

$$W = \int_{0}^{T} f v \delta t = 0.7373 \int_{0}^{T} P_v \delta t \qquad \text{(watt-sec.)}$$

in which $f$ is the accelerating or retarding force in lb. and $v$ the velocity ft. per sec. at the time $t$. $T$ is the total time in sec. for the body to come rest from velocity $v$.

In the foregoing formula $fv$ represents the work per sec. performed the accelerating or retarding force, is equal to 0.7373 $P_v$ if $P_v$ is expres in watts. Consequently $P_v$ represe the accelerating or retarding watt the speed $v$ and time $t$, and the quant under the integral sign is the a contained between the accelerating retarding watt-time curve and the of time. This curve is readily tained, for if sufficient load be pla in the car so that the weight on hoist ropes equals the weight on counterbalance ropes, the watts in into the armature necessary to dr the elevator at the speed $v$, minus

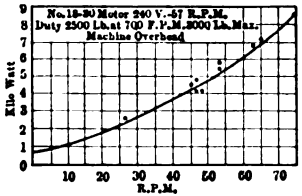

FIG. 17.—Watt input—speed curve.

$I^2R$ losses, must equal the retarding watts, if, at the speed $v$, the armat current be interrupted.

Under this method, a watt input-speed curve, Fig. 17, is first secur following which a retardation cur Fig. 18, is obtained; this latter curv a speed-time curve giving the relat between speed and time if, at the sp $v$, the armature circuit is interrup and the elevator system allowed

# POWER PUMPS

**BY FRED J. POSTEL**

*Consulting Engineer, Assoc. Mem. A. I. E. E., Member Western Soc. Eng.*

## GENERAL

**148. Classification of power pumps.** Power pumps for all practical purposes can be divided into two general classes—displacement pumps and centrifugal pumps. Displacement pumps may be further divided into reciprocating pumps and rotary pumps, while centrifugal pumps may be divided into turbine and volute pumps. As will be shown later, the two classes of displacement pumps differ radically in design and are really distinct classes, while the difference between turbine and volute pumps is a difference of detail of construction, rather than a difference of type.

**149. Calculation of the horse power required,** is based upon a consideration of the opposed head (expressed in ft. or lb. per sq. in.) the pump delivery (expressed in gal. per min. or cu. ft. per sec.); and the efficiency of pump and mechanical transmission. Pump efficiencies vary with the different types, sizes, and working conditions. See Par. **154, 157, and 165.**

The head will include the static head pumped against and also the head of pipe friction. A calculation of required horse power should always consider the latter component of total head if the pipe is of considerable length. **Friction head** may be calculated with reasonable accuracy by means of Eq. 3. Accuracy within 6 per cent. may be expected for new, smooth pipes, while accuracies within 20 per cent. may be secured by its use on practically all pipes met in common practice. This expression is a modification of the well-known "Exponential" formula for straight smooth pipe.*

$$h_f = 1.6 \frac{G^{1.87}}{d^5} \left(\frac{L}{1{,}000}\right) \qquad (3)$$

where $G$ is the delivery in gal. per min.; $L$ is the total length of the pipe in ft.; $d$ is the inside diameter of the pipe in in.; and $h_f$ is the friction head, expressed in ft., for the *whole* pipe length. The horse power required to pump a certain quantity of water through a given length of pipe of known diameter against a given head is expressed as follows:

$$\text{h.p.} = \frac{G \times H}{3{,}950 \times \text{Efficiency}} \qquad (4)$$

where $G$ is the delivery in gal. per min., and $H$ is the sum of the static head and the friction head, both expressed in ft.

For use in these formulas it is well to note that 1 cu. ft. per sec. corresponds to 448.8 gal. per min.; also a pressure of 1 lb. per sq. in. corresponds to a head of 2.304 ft., for water weighing 62.5 lb. per cu. ft.

## DISPLACEMENT PUMPS

**150. Slip.** In all displacement pumps, the volume of liquid pumped is always less than the piston displacement, or, in the case of the rotary pump (Par. **156**) the displacement of the rotating element. This difference is due, partly, to leakage past the piston (in the case of the reciprocating pump), or the rotating element (in the case of the rotary pump), and partly due to leakage through the valves. The difference between the displacement of the moving part (piston or rotating element) and the volume of water discharged, is called the slip, and is usually expressed in per cent. of the total displacement. This slip may vary from 2 per cent. in a new pump to 50 per cent. in a badly worn pump. Generally speaking, anything under 5 per cent. may be considered fairly good performance for pumps that have been in service any length of time.

**151. Effect of speed on capacity of displacement pumps.** Neglecting slip, the capacity of all types of displacement pumps varies directly with the speed, regardless of the head pumped against. For constant head, the horse power required varies almost directly as the speed and, therefore, as the capacity. This, of course, is not strictly true, for the pump efficiency

* Moritz, E. A. *Eng. Record*, Dec. 13, 1913.

Digitized by Google

will be slightly greater and the slip in per cent. slightly less as the pump approaches rated capacity. These characteristics and the service to be performed will determine the type of motor to be installed.

**152. Displacement pumps under constant head require practically constant driving torque at all speeds** and, therefore, at all capacities. This characteristic has a very direct bearing on the type of motor to be selected in cases where it is required to operate the pump at variable capacity and, therefore, at variable speed. From this, it is evident that no saving of power will result if variable speed of the pump is obtained by inserting resistance in the armature circuit of a direct-current motor, or in the rotor circuit of an induction motor. To effect a saving of power, it is necessary to use field control, in the case of the direct-current motor, or a pole-changing device for an alternating-current motor, or any similar device in which the torque of the motor remains constant, for reduced power consumption at the motor service switch. In considering the question of head, it should be kept in mind that the total head on a pump includes both the static head and the friction head in the pipe connections. Where this friction head constitutes a large proportion of the total head, another factor must be taken into consideration. The velocity in the discharge pipe varies directly with the quantity discharged, while the friction head varies as the square of velocity, consequently a pump under these conditions, running at reduced capacity, will not be discharging against a constant head, even though the *static* head is constant, but instead, the head against which the pump operates will be less at partial loads.

**153. Starting torque with displacement pumps.** Displacement pumps operating at constant speed against a variable head will have a constant rate of discharge. The torque and horse-power input will vary (neglecting minor losses) directly with the head. In starting these pumps against the normal working pressure, the motor must exert full-load torque. As this requires very heavy starting currents, especially in the case of induction motors, the expedient of by-passing the pump in starting is usually employed wherever this is practicable. Where the by-pass is installed, the head at starting, and therefore the starting torque, can be reduced to a negligible quantity. After the pump is up to speed, the by-pass is closed.

**154. The efficiency of reciprocating pumps** is generally higher than the efficiency of any other type of pump for the same service. This assumes the pump to be in good condition and the slip comparatively small. The curves in Fig. 20 illustrate the efficiency that can reasonably be expected of triplex pumps of good manufacture. It should be understood that these curves do not represent the performance of a single pump, but rather the efficiency of a series of pumps, each designed for a particular point on that curve, or for a given capacity and head. These pumps are ordinarily designed to operate at a piston speed of from 30 ft. per min., for pumps of 6-in. stroke, or less, to 75 or 80 ft. per min., for pumps of 16-in. stroke or over. These low piston speeds, in turn, require extremely low shaft speeds, as compared with the ordinary motor speeds. This condition is met by installing a slow-speed motor with belt or silent-chain drive, by a double gear reduction, or by a combination of the two. This reduction in speed, especially when accomplished by the double gears, necessarily involves a considerable loss of power, and this loss should be considered in comparing pump efficiencies. The

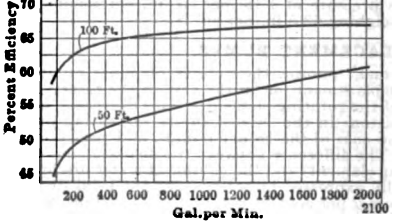

FIG 20.—Efficiency curves of triplex pumps under various heads.

Digitized by Google

efficiency increases with the capacity of the pump, for the same reason that the efficiency of similar pieces of apparatus increases with the size.

**155. Reciprocating-pump types.** Most displacement pumps are of the reciprocating type. In very small sizes, they are generally single-cylinder pumps, while in the larger sizes they are more frequently triplex pumps. While most manufacturers of this type of pump build duplex pumps, the latter have not found favor to the same extent that the other two types have. All simplex, duplex and triplex pumps are built in both the single-acting and double-acting pattern, *i.e.*, built to discharge only during one stroke of each revolution or during both strokes. It should be noted that in the case of the single-acting pump, the simplex pump gives one impulse, the duplex two and the triplex three impulses per revolution, while in the case of the double-acting type, the simplex gives two, the duplex four and the triplex six impulses per revolution. Where uniformity of discharge and absence of pulsations is of primary importance, this feature will have a very direct bearing on the type of pump selected.

**156. Rotary pumps** in their essential parts consist of two rotating elements, sometimes called impellers or cams, enclosed in a casing. These two elements "mesh" in much the same manner as a pair of gears, bearing on each other in line contacts. Consequently, any wear that occurs cannot be compensated for by packing or by adjustment of the moving parts. The slip in this type of pump is caused by the leakage through the line contact of the impellers and through the clearance space between the ends of the impellers and the pump casing. While these pumps do not require priming, they frequently have a small connection from the discharge pipe back into the pump casing to "seal" the joints between the impellers, as well as the small clearance space between the impellers and the casing.

These pumps are primarily designed for low-head work and show their greatest efficiency at low heads. When used for high-head work, it is generally for intermittent service, such as fire-pump service. They probably find their greatest field, however, in pumping heavy oils, liquid tar, syrup and liquid food products of various kinds. The speeds are usually so low that motors of ordinary speed must be geared or belted to the pump shaft.

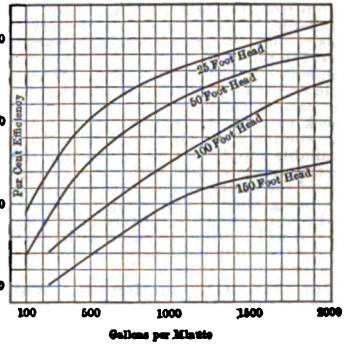

FIG. 21.—Efficiency curves of rotary pumps under various heads.

**157. Efficiency of rotary pumps.** Typical efficiency curves of this type of pump are shown in Fig. 21. These curves, like the curves in Fig. 20, do not represent the performance of a single pump, but rather the efficiencies of a series of pumps, designed for definite conditions of capacity and load, plotted in a single curve.

## CENTRIFUGAL PUMPS

**158. Mechanical construction.** Centrifugal pumps for low heads are almost always of volute type, but manufacturers and designing engineers apparently differ as to the best practice to be followed for pumps discharging against higher heads. The turbine and the volute types of pump use substantially the same type of impeller. The difference between the two types lies in the design of the water passages of the casing. The volute pump, as its name implies, has these water passages built in the form of a volute, increasing in size toward the discharge opening. For the lower heads, the velocity of the water is comparatively slow and there is little or no "churning" and "eddying." Moreover, as this type of pump is cheaper to build than a tur-

Digitized by Google

bine pump, the reason for its popularity for low heads is evident. For higher heads, however, the velocity in the pump casing is necessarily great, and this increases the tendency to form eddies with resultant loss of efficiency. To meet this situation, some builders resort to diffusion vanes. These vanes are a part of the pump casing and simply act as guides to direct the flow of the water and prevent eddies. To be effective and not cause loss of head, they must be of a design which will provide water passages with long easy curves and will change the velocity head of the water leaving the impeller, to pressure head without shock. When these vanes are added, the casing is no longer built of volute shape and the pump is then called a turbine pump.

**159. The importance of suction lift in the selection of a pump.** One of the fundamental factors in the relative performance of displacement pumps and centrifugal pumps is that the former are capable of creating a partial vacuum in the suction connection without priming (Par. **160**), while the latter are not. This one characteristic at once eliminates the centrifugal pump from consideration in all cases where the pump must necessarily be located above the level of the water, and where it is not practicable to prime the pump at starting. Where, for other reasons, it appears desirable to install a centrifugal pump under conditions where it must "lift" its supply, some provision must be made to prime the pump and its suction connections, *i.e.*, to fill them with water and expel all of the air that may have accumulated.

**160. Priming.** In large centrifugal pumps, this priming is usually accomplished by actually "lifting" the water through the suction pipe and the pump from the source of supply by some auxiliary device. Where steam is available, a steam syphon is a very satisfactory means of accomplishing this result. Where condensing apparatus is used, the water may be "lifted" into the pump by means of a connection from the vacuum chamber of the condenser to the pump casing. Where no such auxiliary devices are available or their installation impracticable, a hand pump may be installed. In the case of small pumps, this result is usually accomplished by installing a check valve in the suction line or, better still, a foot valve at the bottom of the suction line. In addition, a "priming" connection is made to some available supply so that by opening the valve or connection, the pump and suction line are filled with water, a vent cock being usually provided in the top of the casing to allow the escape of air while the pump and suction line are being filled. The pump is then started, but *not* until the suction line and pump casing are entirely filled with water. Once the pump is in operation, it will continue to pump with practically no danger of losing its priming, unless the suction lift becomes abnormally high or air leaks into the suction pipe or pump casing.

**161. Attainable suction lift.** With all air leaks eliminated, almost any good centrifugal pump may be depended on for a suction lift of 15 ft. (after it has been primed and started). Under favorable conditions, this may be increased to 20 ft. suction lift. While there are centrifugal pumps operating under greater than 20 ft. suction lifts, this requires the best of conditions, both as to pump and connections, and even then it must be understood that these same pumps would be much more reliable and dependable if the suction lift were reduced to 20 ft., or less. This same characteristic makes a centrifugal pump much more sensitive to air leaks in the suction connection than a displacement pump. An air leak in the suction line of a centrifugal pump which is not even sufficient to cause a displacement pump to "knock" may cause a centrifugal pump to "lose its suction" or "priming."

**162. Multi-stage pumps.** A pump designed to deliver 100 gal. per min., against a head of 75 ft., will require exactly the same h.p. to deliver 100 gal. per min., against 80 ft. head, with the supply flowing to the pump under a head of 5 ft., as it will to deliver 100 gal. per min., against 125 ft. head, with the supply flowing to the pump under a head of 50 ft. This characteristic is taken advantage of in designing pumps for heads higher than can be satisfactorily met by single-stage pumps, by using two or more pumps in series. These may be entirely separate and distinct pumps, the discharge of one connected into the suction of the other by pipe, or all of the pumps or stages may be housed in one casting. For ordinary motor speeds, centrifugal pumps are usually built single-stage for heads up to 100–150 ft., depending on the capacity of the pump and, therefore, the size of the impeller. As

Digitized by Google

the peripheral speed of the impeller increases, either on account of larger diameter or of higher rotative speed, the allowable head per stage increases correspondingly. When several centrifugal pumps are installed in the same station, they may be so connected that by the operation of a few valves, the pumps can be operated in series against a head aggregating the combined working heads of all the pumps, the capacity remaining the same as for one pump; or they may be operated in parallel, giving the total combined capacity, the limiting head in this case being the same as for a single pump.

**163. The up-keep expense of centrifugal pumps** is usually small for the reason that the only moving parts in contact are the shaft and bearings. The clearance between the impeller and casing is almost always greater than the permissible wear of the bearings, so that there is little likelihood of the two coming into contact. Even if they did, this would probably be detected and the pump shut down before any damage was done.

High-head conditions require high impeller velocity, which gives high velocity to the water leaving the impeller. In order to obtain good efficiency these conditions demand high velocities in the diffusion chamber (if there be one) and in the volute. High velocity of water results in rapid corrosion of cast iron, the usual material used for volute pumps. This corrosion occurs wherever the water at high velocity comes in contact with the iron, and particularly so wherever a sudden change in direction of flow occurs which will cause shock and the formation of eddies. However, it is often found that the efficiency of centrifugal pumps increases slightly after they have been in service for a time and this is due to the scouring action of the water on the surface of the water chambers.

**164. Piping connections.** From the principle of operation of centrifugal pumps and especially of turbine pumps, the velocity in the pump casing is very likely to be higher than good practice would permit for velocity of water in pipes, consequently the size of the pipe connection should be calculated on the basis of allowable velocity in the pipe rather than simply to make the connection of the size of the suction and discharge openings of the pump. To avoid shock, due to sudden change of section of the pipe, this change in size of pipe should be made by means of a standard "increaser" or "reducer," and this fitting should be installed at the pump opening. As already pointed out, the suction connections must be absolutely air tight if satisfactory operation is to be obtained. Incidentally, also, the packing glands must be drawn up tight, but only tight enough to prevent leakage, care being taken to avoid excessive friction on the shaft at this point. Some pumps have a connection from the discharge chamber to the glands in order to keep them under a **"water seal"** at all times. When this connection is provided, the glands should be loose enough to permit constantly a slight leakage.

**165. Characteristics of centrifugal pumps.** Fig. 22 shows typical curves of efficiency of standard centrifugal pumps designed for various heads and capacities. These curves may be compared with the curves of Fig. 20 of reciprocating pumps. Figs. 23 and 24 show the characteristic curves of typical centrifugal pumps. Attention is called to the slope of the so-called "capacity-head" curve in the two cases. In Fig. 23, the highest head is the "shut-off pressure" and the curve falls from this point on. In Fig. 24, the pressure rises at first above the "shut-off pressure" and then falls as the capacity is increased. While the shape of the curve depends primarily on the shape of the impeller vanes, it will be found in general, although by no means in every case, that volute pumps will show a curve similar to Fig. 23 and turbine pumps a curve similar to Fig. 24. With a head-characteristic curve similar to that in Fig. 23, the horse-power curve usually reaches a maximum slightly above normal capacity and then drops off. This feature is very important in the selection of a pump for service where the head is likely to be materially reduced at times, as it will prevent the motor from being overloaded. A pump with the characteristics shown in Fig. 24 should be used only where there is no likelihood of its being operated at heads greater than, equal to, or approaching the "shut-off pressure," or where the head is likely to be reduced to a value considerably below the normal working head. At heads equal to, or greater than the "shut-off pressure," there are two capacities corresponding to each condition of head. At these points, the operation becomes unstable with a probability that the pump will discharge intermittently, the water surging up and down in the discharge pipe. With

Digitized by Google

heads below normal, the capacity and the horse power keep increasing with the result that the motor is likely to become dangerously overloaded. In general, the characteristic curve of the volute pump, and at least within the "working limits," the curve of the turbine pump, show that for constant speed, the capacity increases as the head decreases and *vice versa*, with but little change of power required.

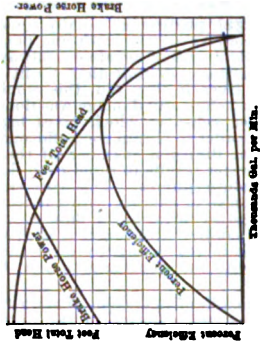

FIG. 23.—Characteristic curves of a typical volute pump at constant speed.

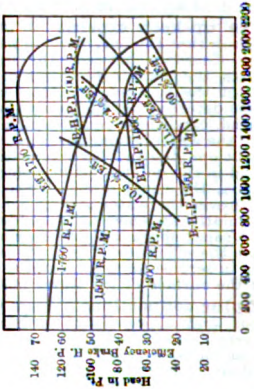

FIG. 25.—Head-delivery and power characteristics of a centrifugal pump at different speeds with curves connecting points of constant efficiency.

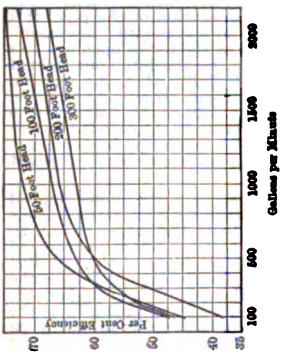

FIG. 22.—Efficiencies of centrifugal pumps designed for various head and capacities.

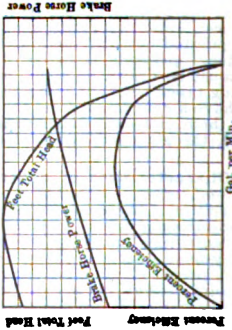

FIG. 24.—Characteristic curves of typical turbine pumps at constant speed.

**166. Performance under variable speed.** Fig. 25 shows the effect of operating a given pump at variable speed. It will be noted that the efficiency, the head and the capacity all fall off rapidly as the speed is decreased, so that there is little or nothing to be gained by the use of a variable speed motor except, perhaps, in special cases. These curves also show that the power required at starting is very low, permitting the pump to be started even against normal head without the use of a by-pass and without requiring heavy starting currents in the motor—a most desirable feature.

# AIR COMPRESSORS

BY JOSEPH H. BROWN, JR.

*Asst. Manager, Sullivan Machinery Co.*

**167. Rating.** The rating of air compressors is made on the basis of the piston displacement of free air per min., and in designing a motor drive, the first problem which arises is the determination of the power output required of the motor for the compressor operating under the desired conditions.

**168. Measurement of discharge.** The relation between the piston displacement and the amount of air actually delivered, has been taken, in the past, from indicator cards, but this method is extremely inaccurate, since slippage due to leakage past the piston rings and leakage back into the cylinder through discharge valves, cannot be detected. As a matter of fact, these leakages tend to make an apparently better card and to increase the apparent volumetric efficiency. Recent tests have been made by discharging the compressed air through orifices and calculating the quantity of free air delivered per min. by Fliegner's formula (Par. 169).

**169. Fliegner's formula** may be stated as follows: $G = (0.53AP)/(\sqrt{T})$, where $G$ = flow in lb. per sec., $A$ = area of orifice in sq. in., $P$ = absolute pressure (in lb. per sq. in.) of air behind the orifice, and $T$ = absolute temperature (deg. Fahr.) of the air behind the orifice.

**The weight of 1 cu. ft. of air** is found by the following formula: $W = 1.325B/T$, where $W$ = weight of 1 cu. ft. of air, $B$ = barometer reading in in. of mercury, and $T$ = absolute temperature (deg. Fahr.) at the compressor intake.

**The delivery of cu. ft. of free air per min.** then equals $G \times (60/W)$.

**170. Efficiency.** In practice it is found that compressors with mechanically operated rotary inlet valves show volumetric efficiency, varying from 91 per cent. at 100 rev. per min. to 88 per cent. at 188 rev. per min. Piston inlet machines at 100 rev. per min. give 88 per cent. efficiency, and at 188 rev. per min., 79 per cent.

The above figures may be used in determining the actual amount of air delivered by the compressor. The power required per cu. ft. of air depends upon the type of compressor, whether single-stage or multi-stage, and upon the method of driving, whether direct-connected, belted or geared (Par. 173 and 174).

**171. Two-stage compression** should be used for capacities over 200 or 300 cu. ft. per min., where the pressure is between 40 and 200 lb. per sq. in. Not only is there a saving in power of approximately 10 to 20 per cent., but the reduced terminal temperature permits better lubrication.

**172. Theoretical power required to compress air.** For the ordinary working pressure of 100 lb., the theoretical power required for isothermal compression of 1 cu. ft. of free air per min. is 0.131 h.p. To this must be added the power lost in friction and that given off as heat, during compression (Par. 175).

**173. Test of a direct-connected compressor.** In a test made in New York City in January, 1912, the power input to the motor was 23.26 h.p. per 100 cu. ft. of free air per min. compressed to 100 lb. per sq. in. gage pressure and actually delivered through orifices. The compressor tested was direct-connected to a 400-h.p., 188-rev. per min., self-starting synchronous motor with belted exciter. The low-pressure cylinder was 26 in. in diameter, the high-pressure cylinder 15.5 in. in diameter, stroke 18 in., and the displacement capacity 2,070 cu. ft. at 188 rev. per min. The volumetric efficiency at this speed as shown by the orifice test was 88 per cent. The horse-power input at full-load was 425, and the indicated horse power of the air cylinders was 350. The overall mechanical efficiency including motor, exciter and compressor was 82.3 per cent.

**174. Comparison of direct-connected compressor with belted compressor.** For the purpose of comparison with a belted compressor where the power is usually specified as that delivered at the compressor pulley, the efficiency shown in Par. 173 may be divided into 91.5 per cent. for motor and exciter and 90 per cent. for the compressor. This gives a motor output of 389 h.p., or 21.4 h.p. per 100 cu. ft. of air delivered. Compared

Digitized by Google

with isothermal compression, the overall efficiency, exclusive of motor an exciter, is 61 per cent., and with motor and exciter included, the overa efficiency is 56 per cent. In a belt drive there will be a further loss of fro 5 per cent. to 10 per cent., depending upon the efficiency of the belt drive.

**175. Computation of required horse power.** The figures in Par. 17 may be used in computing required horse powers from tables showing pow used in isothermal compression at other pressures, and will be found approx mately correct for machines of over 100 h.p. rating. In the case of machine of less than 100 h.p. rating, allowance should be made for reduced mecha ical efficiency of both compressor and motor. In comparing these figur with those obtained from other sources, it should be noted that these result are calculated from actual delivery, and not from piston displacement.

**176. Advantages of direct connection.** The ideal motor-drive fo air compressors is direct connection, and this should be used wherev possible on machines of 100 h.p. and above. No power is wasted in the be transmission, the upkeep cost of the belt is eliminated and there is a gre saving in floor space. Compressors are now designed to give good volumetr efficiency at speeds below 225 rev. per min. by the use of mechanicall operated rotary inlet valves, unobstructed air passages and ampl discharge valve area. Self-starting synchronous motors can be obtaine which will operate at the desired speed, and this type of motor is admirabl adapted for such service. The exciter is usually belt-driven from a pulle on the compressor shaft, and may be mounted on the bed plate, or tie-piec between the frames, making a self-contained unit.

**177. Use of fly-wheels with synchronous-motor drive.** The roto of standard synchronous motors do not give the necessary fly-wheel effec and this defect should be compensated for by the use of a fly-wheel on th compressor shaft, otherwise there will be wide variations in current with eac stroke of the machine. Furthermore, in isolated plants, a momentary dro in voltage may cause the compressor to stop unless the proper fly-whe effect is supplied.

**178. Belt-drive** is used on small compressors, also in the case of large installations of a temporary nature, where economy of power and floor spac is not imperative, or where first cost and delivery must be considered In this connection, however, it is important to note that on the New Yor City tunnel of the Catskill Aqueduct, where the compressors were in servic only from 2 to 3 years, the great majority were of the direct-connecte type.

**179. The short belt-drive** has come into active use and makes a ver desirable arrangement for small installations. The motor and compresso shafts are brought closely together and, by use of an idler pulley which ride on the belt, sufficient arc of belt contact is secured on both driving and drive pulleys, and the results are entirely satisfactory. For this purpose the bel should be made endless, in order that no lacing will be required. The econ omy of floor space obtained by this arrangement has practically done awa with **gear-drive** for air compressors except in the case of very small machine of the portable type. The only redeeming quality of the gear-drive was it compactness, and it was always objectionable on account of noise and wea even when the drive was of the most improved type.

**180. Regulation of air discharge.** Since the demand for air is almos always intermittent, and the compressor must operate at constant speed some method of regulating the amount of air compressed and delivered mus be employed. Various devices are used. With some types of mechanic ally operated inlet valves provision is made to hold them open during th whole or part of the compression stroke, but any mechanism of this natur has the objection of complicated moving parts, and furthermore the com pressor must be limited to comparatively slow speed to allow for prope operation.

**181. Regulation by clearance control.** In this method clearanc spaces are provided which communicate with the cylinder through valve controlled by the governor. The compressed air, instead of being delivere to the line, passes into this clearance space and on the return stroke of th piston, returns to the cylinder and expands again behind the piston. A par of the work of compression is recovered in this re-expansion, but this metho

Digitized by Google

of control is inefficient because a considerable amount of power is wasted in heat which cannot be regained, and there is also some leakage.

**182. Regulation by use of an unloading valve.** The most satisfactory and economical method of regulation is the combination of an unloading valve on the intake cylinder and an **atmospheric relief valve** on the discharge, or high-pressure cylinder. The unloading valve on the intake is connected to the air receiver, and a rise in pressure causes it to close. All air is then cut off, and as soon as the system is pumped out, the low-pressure piston operates in a vacuum. But there will be a slight leakage past the valve and around the piston-rod stuffing box, and provision must be made for allowing this air to escape. If this is not done, a small amount of air will be carried over into the high-pressure cylinder and compressed over and over again, resulting in dangerously high temperatures and waste of power. An atmospheric relief valve is therefore provided which is operated automatically after the unloading valve is closed. This relief valve shuts off communication between the pressure line and the high-pressure cylinder, and at the same time opens a free exhaust from the high-pressure cylinder to the atmosphere.

When the pressure in the receiver falls slightly, the intake unloader opens, then the relief valve closes, and the work of compression is again taken up. This cycle is secured without shock, as the operation is comparatively gradual and as an appreciable space of time is taken to fully load or unload. With this method of control the machine is either operating at its most efficient point (full-load) or else no work is being done except that necessary to overcome the friction of the moving parts.

**183. A load factor** of 60 per cent. may be taken as an average figure for compressor operation. In the test referred to above (Par. **173**), the compressor was equipped with combination unloading valves and the power required at 60 per cent. load factor was 3.1 kw-hr. per 1,000 cu. ft. of free air actually delivered at 100 lb. pressure. A compressor of the same capacity and type, but fitted with clearance control, was also tested at the same time, and at 60 per cent. load factor the power required was 3.5 kw-hr. per 1,000 cu. ft., or 12.9 per cent. greater.

**184. Starting.** No special difficulties are encountered in starting, since the compressor is started without load and the load is not thrown on until the machine is up to normal speed.

**185. Automatic starting and stopping.** In cases where the demand for air is very intermittent and no air is required for long intervals, the compressor may be automatically stopped and started. The main switch is controlled by the air pressure and is thrown out when the pressure rises, and thrown in when the pressure falls. The unloading valve is controlled by a solenoid which holds the valve open when the compressor is running, but allows it to drop and close when the main circuit is opened. The compressor always starts unloaded since the solenoid is not energised until the motor is up to speed and the last contact has been made in the starter. On account of the effect of repeated starting on the electrical supply line, automatic starting is not recommended for large units, or for installations where the starting and stopping is at all frequent.

## FANS AND BLOWERS

### BY MERTON S. LEONARD

*Chief Engineer, B. F. Sturtevant Co., Member American Society of Mechanical Engineers*

**186. Definitions.** Fans will here include only **centrifugal fans** having inlet at centre and discharging at the periphery, either directly or through a casing which directs the air to the outlet; and **propeller fans** which move the air in an axial direction by propulsive force, similar to the propeller of a ship. **Blowers** will here include only **positive rotary blowers**, which, by the action of a rotating impeller or impellers in a very closely fitting casing, create pressure by direct compression.

**187. Characteristics of fans and blowers.** Fans and blowers, like pumps and unlike most other machines, may operate with equal efficiency

Digitized by Google

at any speed which their mechanical strength safely allows. They may also discharge, in practice, through orifices varying in area from that of their full discharge, to a very small per cent. of the full outlet. The efficiency varies with different orifice areas, but not according to any fixed law for all designs.

The **horse power** for any fan or blower, if the area of the discharge orifice remains unchanged, varies directly as the cube of the speed; also, if the area of the discharge orifice remains unchanged and the speed is constant, the horse power varies directly with the density of the gas being handled.

**188. The horse power of a centrifugal fan,** if the speed remains unchanged, generally decreases as the area of discharge orifice is decreased. In some designs the horse power with rated orifice is not over one-third of the horse power with orifice equal to area of fan outlet, and in other designs it is very little less at rated orifice than with unrestricted orifice.

**189. The horse power of a propeller fan,** if the speed remains unchanged, increases as the area of the discharge orifice is decreased. In some designs the horse power with rated orifice is not over one-quarter of the horse power with complete restriction.

**190. The horse power of a positive blower,** if the speed remains unchanged, increases as the area of the discharge orifice is decreased. Owing to the fact that the clearances in these machines are as small as possible, the horse power increases tremendously with decrease of orifice.

**191. Types of motors adapted to various fans.** For driving centrifugal fans, with direct-current supply, shunt-wound motors should be used. For driving propeller fans either shunt-wound or series-wound motors can be used, with direct-current. The series-wound motor is preferable, if readily obtainable. For driving positive blowers, with direct-current supply, shunt-wound motors should be used. Induction motors are commonly used, with alternating-current supply, for all types.

**192. Starting torque.** As the torque required to start any fan or blower is only that required to overcome the friction of the bearings, which are usually two in number, and the inertia of a comparatively light rotating part, no special consideration need be paid to this feature.

**193. Method of control (direct-current).** When a fan or blower is required to operate at only one speed under all conditions of service, a starting rheostat with no-voltage release should be used. If there is a possibility of a condition arising in the system which will increase the horse power above the capacity of the motor, as in the case of a centrifugal fan so arranged that all air resistance may be removed by the changing of dampers or opening of doors, or in the case of a propeller fan which may have its delivery entirely blocked by a shutter, or in the case of a positive blower which may have its delivery restricted by the closing of blast gates, an overload release should also be provided.

A starting and regulating rheostat with no-voltage release should be used where a fan or blower is required to operate under varying conditions at speeds below normal, but operates the greater part of the time at normal speed. Such equipment should also be used where speed varying below normal is required, and the cost of energy is not important. See Par. 446.

When a fan or blower is required to operate at varying speeds, and operates the greater part of the time at less than its maximum speed, or where varying speed is required and economy of operation is more desired than low first cost, a starting rheostat with no-voltage release should be used in combination with a field controller. The speed, with this arrangement, is adjusted by variation of resistance in the field circuit. From 10 per cent. to 25 per cent. speed increase by field control and 50 per cent. decrease by armature regulation, are very common specifications for fan motors in high-grade installations.

**194. Remote control.** Any of these devices (Par. 193) may be arranged for remote control, or for automatic speed control to maintain constant volume or constant pressure of air from the fan or blower, or to maintain constant steam pressure at the boilers in the case of mechanical draft fans. Automatic speed control of fan and blower motors is not recommended,

Digitized by Google

since it is very likely to give trouble on account of its complexity and refinement.

**196. Method of control (alternating-current).** Any method of control which is adaptable to alternating-current motors in general is suitable for alternating-current fan motors. However, such motors are usually arranged to operate at only one speed, and are provided only with a starting device. If it is necessary to vary the volume or pressure of the fan or blower, it may be accomplished by throttling the air with a damper.

**196. Methods of direct connection.** Whenever feasible it is best to mount the fan wheel directly upon the motor shaft. This can usually be done with small centrifugal fans and with propeller fans up to about 60 in. diameter; however, the deflection and the critical speed of the shaft should be investigated to determine whether or not this is safe.

When it is not feasible to mount the fan wheel upon the motor shaft, it is best to provide the fan with two bearings and connect the motor by means of a flexible coupling. It is more common, however, on account of low cost and space economy to provide the fan with one bearing and connect the motor by means of a solid-flange coupling. If this is done, care must be taken properly to align the bearings, and to maintain the alignment.

**197. If a fan handles hot gases,** means must be provided for the protection of the motor from the heat. This is accomplished by cooling the shaft or the bearings with water, or by separating the motor and the fan with a long shaft extension, or by driving the fan with a belt or chain.

**198. Suppression of noise.** If there is danger of noise being transmitted through the air ducts, as in auditoriums, theatres, schools, churches and hospitals, it is often better to drive the fan by belt from the motor. This is particularly true of alternating-current motors.

**199. Belt drive for fans.** It is often possible to use a smaller and less costly motor by use of belt-drive, when the fan speed is lower than necessary for a motor of the same horse power. It is generally preferable to belt alternating-current motors, because the most desirable speed of a standard fan for a given duty is seldom the same as the available motor speed, making it necessary to build a special fan, and thus increasing the cost, if direct-connected.

It is desirable to drive by belt, when the required fan speed or the fan horse power is in doubt, as an inexpensive change in size of pulley will correct the error, if one is made.

**200. Method of motor application to blowers.** Blowers are essentially slow-speed machines. It is, therefore, almost always desirable to belt or gear the motor. If geared, the motor and the blower should be mounted on the same base to assist in maintaining alignment.

**201. Approximate horse power of centrifugal fans.** The horse power required to drive any centrifugal fan may be represented by the following formula:

$$\text{h.p.} = K\left(\frac{T}{1000}\right)^3 DW\left(\frac{w}{0.075}\right) \qquad (5)$$

Where $K$ (Par. **203**) is a constant depending upon the design and upon other conditions, $T$ is the peripheral velocity or the tip speed of the blast wheel in ft. per min.; $D$ is the mean diameter of the blast wheel in feet; $W$ is the mean width of the blast wheel in feet; $w$ is the absolute density of the gas handled, in lb. per cu. ft.; 0.075 is the weight of standard air at 65 deg. fahr. in lb. per cu. ft.

**202. Approximate horse power of propeller fans.** The horse power required to drive any propeller fan may be represented by an expression of the form,

$$\text{h.p.} = K_1\left(\frac{T}{1000}\right)^3 A\left(\frac{w}{0.075}\right) \qquad (6)$$

Where $K_1$ (Par. **204**) is a constant depending upon the design and upon other conditions, $T$ is the peripheral velocity or the tip speed of the wheel in ft per min.; $A$ is the gross area of the wheel in sq. ft.; $w$ is the absolute density of the gas handled in lb. per cu. ft.; 0.075 is the weight of standard air at 65 deg. fahr. in lb. per cu. ft.

**203. Table of constants for centrifugal fans**
(B. F. Sturtevant Company)

| Type of fan | $K$ |
|---|---|
| Paddle-wheel with 6 to 10 straight blades and $W = 0.45D$. . . . | 0.0060 |
| Steel pressure with 24 backward curved blades and $W = 0.15D$ | 0.0050 |
| Slow speed conveying with 18 forward curved blades and $W = 0.25D$. | 0.0100 |
| Single-inlet multiblade-drum with 60 narrow curved blades, inclined forward and $W = 0.50D$. | 0.0350 |
| Double-inlet multiblade-drum with 60 narrow curved blades, inclined forward and $W = 0.25D$. | 0.0250 |
| Double-inlet multiblade-drum with 60 narrow curved blades, inclined forward and $W = 0.50D$. | 0.0400 |
| Double-inlet multiblade-drum with 60 narrow curved blades, inclined forward and $W = 1.00D$. | 0.0350 |

**204. Table of constants for propeller fans**
(B. F. Sturtevant Company)

| Type of fan | $K_1$ |
|---|---|
| Sturtevant propeller | 0.0006 |
| Multiblade disc | 0.0012 |
| Blackman propeller | 0.0012 |
| Davidson propeller | 0.0015 |

**205. Horse power of positive blowers.** The horse power of a posi blower at any speed varies over such a wide range, depending upon the p sure, that any rule for the approximate horse power would have to take account the volume and the pressure of the air and the displacement of blower, all of which are so difficult of determination that it is thought not to attempt to state a rule here. For estimating purposes, the efficie of such machines may be taken as 60 per cent.

## COAL AND ORE HANDLING MACHINERY

**BY C. D. GILPIN**

*Electrical Engineer, Wellman-Seaver-Morgan Company*

**206. Definition.** The term "coal and ore handling machinery" is tended to cover the apparatus used in re-handling coal and iron ore betw the mine and point of ultimate consumption. Such apparatus consist

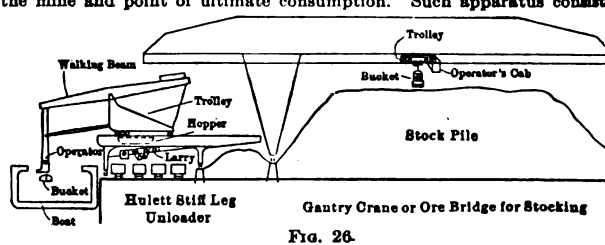

FIG. 26.

Digitized by Google

the main of unloaders, bucket-handling gantry cranes, car dumpers, self-propelled transfer cars and belt conveyors. Fig. 26 represents a stiff-leg unloader, with a gantry crane for stocking such ore as is not to be immediately loaded into cars. Fig. 27 shows a gravity-type unloader and a gantry crane.

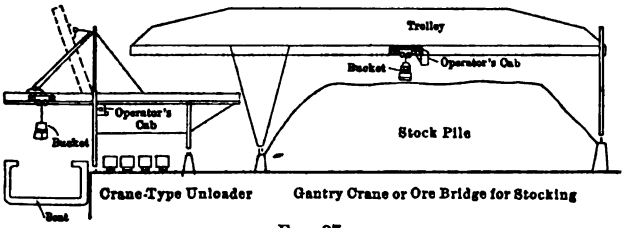

FIG. 27.

**207. Motors for severe service** are usually of the mill type with large shafts, fire-proof insulation, heavy frames, small moment of inertia of armature and great commutating capacity. Shafts are generally tapered at the pinion end to allow for easy removal of the pinion, and axle bearings are often used where a gear ratio of about five-to-one is desired. The frames are generally entirely enclosed, although many of the larger sizes are constructed with part of the upper frame cut away in order to facilitate the dissipation of heat. It is probable that in the future, forced ventilation will become common practice, as is already the case in electric locomotives.

**208. Motors for light service** where direct current is available, and of 25 h.p. or under, are usually of the crane type. This construction is much cheaper than the mill-type construction, yet is quite satisfactory for intermittent service where no severe overloads occur. The frames are entirely enclosed, as heating is not a consideration.

**209. Motors for car dumpers,** where there is usually abundant space available, and where the electrical apparatus is well protected from the weather, are often of the open type with commutating poles. The speed of rotation is preferably lower than for the mill motor, owing to the greater radius of gyration of the armature.

**210. Motors for transfer cars** are commonly either of the railway or mine type, the latter often being preferable on account of their low speed, high torque and large gear reduction. Standard drum-type controllers are ordinarily furnished with these motors.

**211. Mill motors,** where alternating current only is available, may be obtained for 3-phase, 25-cycle, 220-volt or 440-volt circuits. For a frequency of 60 cycles it is necessary to use an open type of frame, an outboard bearing being desirable for sizes above 25 h.p. Alternating-current motors should be of the slip-ring type, except for belt conveyors with light starting requirements, where squirrel-cage motors may be used. They should be of sturdy mechanical construction, and should be wound for high torque. Low rotor speeds are desirable as tending to keep the acceleration load at a minimum.

**212. Controllers for heavy duty** are always of the contactor or magnetic-switch type with overload and automatic acceleration relays. Dynamic braking for lowering buckets, etc., is now almost universal; not only is the energy of the lowered mass dissipated in resistors instead of brake friction, but the operator is given a very delicate control by means of his master controller instead of having to manipulate an air or hand brake. Where direct current is not available, dynamic braking is obtained by means of a small low-voltage generator set, which provides direct current for exciting the stator winding of the motor lowering the load, thus allowing it to become an alternating-current generator. Since only part of the winding can be used for this purpose, and since an induction motor possesses inherently a limited torque, this system of dynamic braking is not as reliable as where

Digitized by Google

direct-current motors are used. See article on "Motor Control" elsewhere this section.

**213. Distribution systems.** The standard source of energy, especially on the lower lake docks (Lake Michigan and Lake Erie) and in the great steel plants, is a 250-volt direct-current circuit. A metallic return circuit is generally used, but there is a tendency at present to install a ground return. In purchasing energy, part of the charge is usually based on the peak loads, and where these peaks are figured on the basis of five seconds or less, the cost of energy can often be substantially reduced by the introduction of a fly-wheel balancer set in connection with the rotary converter.

**214. A fly-wheel balancer set** consists of a direct-current machine of very high commutating capacity mounted on the same shaft with a fly-wheel and so arranged that when the station load exceeds a certain amount, the field of the balancer machine will be automatically strengthened so that energy will be given out by the fly-wheel as it decreases in speed. When the demand ceases, the balancer field is weakened and the machine becomes a motor, thus accelerating the wheel to normal speed. Such balancers are commonly rated at from 200 kw. to 300 kw. of continuous capacity, with a commutating capacity for 200 per cent. overload; the fly-wheels vary from 25,000 lb. (11,350 kg.) to 50,000 lb. (22,700 kg.) with rim speeds of about 16,000 ft. per min. (4,880 m. per min.) for cast steel wheels and 28,000 ft. per min. (8,540 m. per min.) for laminated plate wheels. A very careful study of load conditions and the power contract is desirable before installing one of these balancer sets.

**215. The power requirements of coal and ore handling apparatus** may be considered under two classes: (*a*) those in which a fixed force or constant torque predominates, such as gravity or friction, and (*b*) those in which acceleration or variable torque is the main feature. To the first class belong the hoist motions, where the speed is comparatively low and the requirement for acceleration is a small part of the total power. For this type of motion a compound-wound motor has been commonly used, the compound winding being originally provided to facilitate dynamic braking. Later developments of control have made dynamic braking practicable for series motors, and the tendency now is toward the use of that type of winding. The control should include at least one "power point" in the lowering direction and should be so arranged as to provide dynamic braking or armature shunting at all times while lowering, so that it will be impossible for the load to overhaul the mechanism at a dangerous speed. An emergency spring-closing switch is often desirable; this should be so arranged as to connect the armature in series with the field and a small amount of resistance, in case of failure of the line current. The motors should be provided with magnetic brakes, the shunt type of winding being generally preferable.

**216. The approximate motor loads may be obtained as follows.** The hoisting h.p. equals the hoisted load in lb. multiplied by the hoisting speed in ft. per min., divided by 33,000 and again divided by the efficiency expressed as a decimal. The nominal lowering h.p. equals the lowered load in lb. multiplied by the hoisting speed in ft. per min. divided by 33,000 and multiplied by the efficiency. In this case the lowering h.p. really represents current or torque as read on the characteristic curve of the motor. Variations in lowering speed are obtained by changing the dynamic braking resistance and thereby the motor voltage for the same current value. The approximate heating of the motor can be determined as shown in Par. **224.**

**217. The power required by a belt conveyor is,** normally, almost constant. The size of motor is commonly obtained by referring to the manufacturer of the conveyor. The motor should have a continuous rating and may be of the variable speed type. **Electrical weighing devices** are sometimes used to weigh the material as it passes a given point. Such a device consists essentially of a magneto generator driven by the conveyor, connected in series with a resistance which varies inversely with the instantaneous weight of the material at that point on the conveyor. It is obvious that the output of the generator depends both on the speed of the conveyor and on the amount of material which it carries; an indicating wattmeter will therefore show the rate at which the material is being handled, and a watt-hour meter will record the total amount of material handled during a given time.

Digitized by Google

**218. Power required by transfer cars.** In the case of transfer cars and the trolleys of unloaders and bridges, acceleration is the predominant factor. For loads of this kind, two motors are used as a rule, in order to obtain good traction; in such cases, series-parallel control is generally preferable. If the motors are permanently connected in parallel, it is safer to provide a separate set of reversing contacts for each armature. Armature-shunting points are occasionally employed to obtain very low speeds, and dynamic braking is sometimes provided in the case of a gantry crane or unloader trolley. To obtain dynamic braking for a series-wound trolley motor, it is necessary to connect the field in series with a resistance across the line, so that the characteristics of a shunt generator may be obtained. An air brake is generally preferable for trolley service, except when the operator is located at some distance from the mechanism, in which case the motor should be provided with a magnetic brake, preferably of the disc type, and the controller should give dynamic braking on or near its central position.

**219. The frictional resistance of the ordinary trolley** may be taken at 25 lb. per ton; for a transfer car with standard trucks, 15 lb. per ton is ample. The horse power for the final assumed speed should first be figured as follows: h.p. = friction force at rim of wheel multiplied by the speed in ft. per min. and divided by the efficiency (expressed as a decimal) and by 33,000. About twice the result should be taken as the nominal horse power required, this value being based on a rise of 75 deg. cent. in 1 hr. The performance of the trolley or car can then be easily worked out by means of the motor curves, the step-by-step method being used as explained in Par. **226.** It will sometimes be found that the motor chosen is too small; where there is any doubt, the moment of inertia of the armature should be obtained and should be translated into its equivalent weight at the trolley speed. The calculations should then be gone over more carefully; for slow trolley speeds, the inertia of the armature becomes a very considerable part of the whole.

**220. The longitudinal drive of an unloader** or bucket-handling gantry partakes of the nature of a trolley drive, but owing to the much lower speed and higher friction, inertia plays a smaller part, and dynamic braking is unnecessary. Friction may be taken at about 40 lb. per ton, although this figure is quite uncertain. The heating is not a factor in this class of service, but sufficient commutating capacity should be allowed to take care of a wind-pressure equivalent to one and one-half times the friction; this is merely a general rule, but is one which works well in practice. In some cases long gantry cranes are driven by independent motors at each end; this scheme is quite successful, even with series motors, although an automatic device should be provided to prevent one end from leading the other. With this type of drive, the motors should be provided with magnetic brakes, the disc type being preferable because the shock when stopping is less than with the post brake. For the ordinary gantry or unloader, one motor is generally connected by bevel gears to both trucks; a mechanical foot brake which is held in the released position by the weight of the operator is preferable to a magnetic brake in this case, since it can be applied more gently.

**221. The gear efficiency** of one reduction of cut spur gears in this class of work may be generally taken as 95 per cent.; for cut bevel gears, 90 per cent. For important motions, the cut herringbone gear is becoming popular; it should have an efficiency of at least 97 per cent. if properly erected. The **coefficient of friction** for the ordinary bearing will average about 0.05, while for sheaves it is better to allow a value of 0.07. These figures may be safely followed except in special cases, such as in gearing for longitudinal drives where there is decided likelihood of poor alignment of shafts and gears.

**222. The calculation of power house or substation capacity** for a dock is a long and tedious process, since it is a matter of some conjecture as to just how the peak loads, which are usually violent, will coincide. A 10-ton stiff-leg ore-unloader having a total capacity of 400 h.p. in five motors will show a momentary peak load of 1,200 amp. and an average load of 400 amp. Two such machines working together will occasionally take 1,800 amp. for 1 or 2 sec. One 15-ton stiff-leg ore-unloader with seven motors totalling 700 h.p. and requiring an average load of about 500 amp. will draw a peak of 1,800 amp. The maximum current for four such machines, however, will not exceed 4,000 amp. Gravity-type unloaders are likely to show a higher proportional peak load because practically all the work is done by

Digitized by Google

the hoist and the trolley; operators of this type of machine are gener cautioned not to work too nearly in synchronism with the other unloade the power house capacity is limited. If possible, it is much better to ob data from an installation similar to the one contemplated. In any case generators or converters should have a high commutating capacity and circuit-breakers should have time-limit relays. The tendency of lat distinctly toward the purchase of energy where possible; in many cases excellent rate can be obtained owing to the fact that work is carried on night as well as by day. A better rate is sometimes obtainable by redu the demand during hours of normal central-station peak load.

**223. Example of calculations for typical ore-handling gantry cra** The hoist-motion calculations are given in Par. **224**, the trolley calculat in Par. **225**, and the bridge calculations in Par. **226**. The following calc tions relate to the case of a typical 15-ton ore-handling gantry crane. estimated average duty is to lift one bucket of ore 30 ft. every min., average distance to be trolleyed being 200 ft. Assuming that 10 per cent the total time is lost in moving the crane longitudinally, etc., the spe must be such as to perform the given cycle in 54 sec. Estimate time in which the trolley will not be working, as follows: Closing buc 6 sec.; hoisting clear of ore pile, 2 sec.; opening bucket, 4 sec.; lowering buc after trolley comes to a standstill, 2 sec.; total, 14 sec. Time available trolley trip in one direction, 20 sec. Average speed of trolley, 600 ft. min. Assume a maximum trolley speed of 900 ft. per min. and a hois speed of 180 ft. per min.; the latter speed is not required for the assu cycle, but will be useful when making long hoists with a short trolley tra

**224. Calculations for hoist motion (Par. 223).** The hoist motio assumed to be of the type in which each of two motors is geared through reductions to its own drum, each of the two drums carrying one of the sets of cables necessary for operating a clam-shell bucket. No. 1 m closes the bucket; Nos. 1 and 2 hoist the bucket together; No. 1 opens bucket; and No. 2 lowers it, No. 1 running down with practically no-l The efficiency may be assumed roughly as 90 per cent. The ore will w 33,600 lb.; assume the bucket weighs 30,000 lb., making a total of 63,600 The hoisting horse power per motor $= (63,600 \times 180)/(33,000 \times 0.90)$ $= 193$; or say 200 h.p. The lowering horse power for No. 2 m $= (30,000 \times 180/33,000) \times 0.90 = 147$ h.p.; or say 150 h.p. Assume average closing load for No. 1 motor is 150 h.p., and for opening, 50 The root-mean-square or effective horse power for No. 1 motor will the $[(150^2 \times 6 + 200^2 \times 10 + 50^2 \times 4)/60]^{\frac{1}{2}} = 95$ h.p. The mean effective h power for No. 2 motor $= [(200^2 \times 10 + 150^2 \times 7)/60]^{\frac{1}{2}} = 96$ h.p., assum that actual lowering takes place in 7 sec.

The smallest motor which suggests itself for this service is one having entirely enclosed frame and a mill rating of 150 h.p.; the mill rating is ba on the power the motor can develop for 1 hr. with a temperature rise no exceed 75 deg. cent. Investigation of the manufacturers' data shows t the 150-h.p. mill-rated, fully enclosed motor will not have sufficient h ing capacity if the crane is to be operated at full speed continuously, altho the commutating capacity is ample. This same motor, however, if b with a semi-enclosed frame will have a mill rating of approximately 165 and a root-mean-square rating of about 130 h.p., which is ample for service. If the semi-enclosed motor cannot be adequately protected, enclosed frame may be used, and forced ventilation may be resorted Another method would be to use a larger totally enclosed motor; suc motor, however, would be higher in cost and in weight, the latter bein particular importance when the span of the crane is long.

**225. Calculations for trolley motion (Par. 223).** Assume that trolley with bucket and ore weighs 170,000 lb., and is driven by two mot each geared through two reductions to one of the four axles. Take frictional resistance per motor at $25/2{,}000 \times 170{,}000 \times \frac{1}{4} = 1{,}060$ lb. F h.p. $= (1{,}060 \times 900)/(33{,}000 \times 0.90) = 32$. Assume two 80-h.p. [temperat rise of 75 deg. Cent. for 1 hr.] series-wound motors; from the characte tic curve it will be found that at 32 h.p. the motor speed equals 820 rev. min. and the torque equals 205 lb. at 1 ft. radius. Therefore the gear r must be such that the desired trolley speed of 900 ft. per min. is equivalen

Digitized by Google

a motor speed of 820 rev. per min.; then ft. per min. = (900/820) × rev. per min. = 1.1 × rev. per min.; also the force at the rim of the wheel will have the same ratio to the motor torque as the friction force has to the friction torque; or, force = (1,060/205) × torque = 5.17 × torque. Assume effect of armature weight equal to 1,500 lb. at 0.7 ft. radius; equivalent weight of one armature at trolley speed = [1,500 × 0.9 × (2π × 0.7 × rev. per min.)²]/(ft. per min.)² = ([1,500 × 0.9 × (2π × 0.7 × rev. per min.)²]/(1.1 × rev. per min.)² = 2,160 lb.; or say 5,000 lb. including gearing. Total weight per motor for acceleration = 85,000 + 5,000 = 90,000 lb. Assume that acceleration while short-circuiting the resistance is 2.5 ft. per sec. per sec., which is as high a value as the operator can endure with comfort; this initial rate of acceleration is determined by the rapidity with which the starting resistance is cut out. Since the force of acceleration = $F_a$ = (wt. in lb./$g$) × acceleration in ft. per sec. per sec., then $F_a$ = (90,000/32.2) × 2.5 = 7,000 lb. Since the friction force is 1,060 lb., the total force = 7,000 + 1,060 = 8,060 lb. Motor torque = $T$ = 8,060/5.17 = 1,560 ft-lb. From the characteristic curve, when $T$ = 1,560, h.p. = 119; rev. per min. = 402. Therefore ft. per min. = 402 × 1.1 = 442, and ft. per sec. = 7.4. This is the speed which is attained at the instant the last section of resistance is cut out. The time = $t_1$ = speed/acceleration = 7.4/2.5 = 3.0 sec. The distance = $d_1$ = average speed × time = (1/2) × 7.4 × 3.0 = 11 ft. After the starting resistance is cut out, the trolley will continue to accelerate at a diminishing rate, as long as the force supplied by the motors exceeds the friction force. Assume that the horse power has decreased to 60; then from the motor curve, rev. per min. = 560. Since ft. per min. = 1.1 × rev. per min., the ft. per min. = 616, or ft. per sec. = 10.3, and the increase = 2.9 ft. per sec. The average speed = (10.3 + 7.4)/2 = 8.85 ft. per sec. Referring again to the curve, $T$ = 560, therefore $F$ = 2,900 lb.; $F_a = F - F_f$ = 2,900 − 1,060 = 1,840 lb., acceleration = $A = g F_a$/90,000 = 0.66, average $A$ = (2.5 + 0.66)/2 = 1.58, $t_2$ = (increase in speed)/(average acceleration) = 2.9/1.58 = 1.8 sec., $d_2$ = 8.85 × 1.8 = 16 ft., total time up to this point = $t$ = 3 + 1.8 = 4.8 sec.; total distance up to this point = $d$ = 11 + 16 = 27 ft. Assume the horse power has dropped to 35; then rev. per min. = 760, ft. per min. = 836, ft. per sec. = 13.9, increase = 3.6, average speed = 12.1 ft. per sec.; $T$ = 240, $F$ = 1,240, $F_a$ = 180, $A$ = 0.06, average $A$ = 0.36, $t_3$ = 10.0 sec., $d_3$ = 121 ft., $t$ = 14.8 sec., $d$ = 148 ft. Assume trolley coasts for 1 sec. at 13.9 ft. per sec.; $t_4$ = 1, $d_4$ = 14 ft., $t$ = 15.8 sec., $d$ = 162 ft. Assume retardation = 2.5 ft. per sec. per sec.; $t_5$ = 13.9/2.5 = 5.6 sec., $d_5$ = 39 ft., $t$ = 21.4 sec., $d$ = 201 ft. The time originally allowed for a trip one way was 20 sec., but since the trolley will return light at a somewhat higher speed, the gear ratio originally assumed is close enough. If the heating is figured for the loaded trip and for one-half the cycle, the results will be on the safe side. Mean effective h.p. = $\{[(119^2 \times 3) + (119^2 \times 1/2 \times 1.8) + (60^2 \times 1/2 \times 1.8) + (60^2 \times 1/2 \times 10) + (35^2 \times 1/2 \times 10)]/[60 \times 4]\}^{\frac{1}{2}}$ = 52. A fully enclosed mill motor can keep up this cycle for about 3 hr., but not indefinitely. If the crane will not operate for over 3 hr. at any one time, 80-h.p. mill-rated entirely enclosed motors should be used. For continuous operation use the same motors with the semi-enclosed frames, which will have a mill rating of about 90 h.p. and root-mean-square rating of about 70 h.p.; or if convenient, forced ventilation may be used with the totally enclosed motors. In any case, the armature, fields, etc., will be the same, the difference in rating being due to the different methods of cooling. The maximum loads to be commutated should not exceed those shown on the motor curve.

**226. Calculations for bridge drive (Par. 223).** Assume that the total crane weighs 1,200 tons, and that a 2-motor longitudinal travel drive is desired. Friction force per motor at 40 lb. per ton = 40 × 1,200 × ½ = 24,000 lb. Assume that a speed of 75 ft. per min. is desired, and that each motor has one spur-gear and two bevel-gear reductions. The efficiency would be approximately 77 per cent. The friction load per motor = 71 h.p. If 80-h.p. mill-rated motors were used, the friction torque read from the curve would be about 720 lb.-at 1 ft. radius. Assuming the wind load = 36,000 lb. and acceleration at 0.25 ft. per sec. per sec. = 9,300 lb., the total maximum load = 69,300 lb. and approximate maximum torque = (69,300/24,000) × 720 = 2,080 ft-lb., which is well within the commutating limit of an 80-h.p. mill motor.

## TELPHERAGE SYSTEMS

BY H. McL. HARDING

*Consulting Engineer, Associate American Institute of Electric Engineers*

**227. Classification.** There are two main divisions of telphers, automatic telphers and man-telphers. **Automatic telphers** are those which are driven by electric motors, the control being apart or remote from the telpher. The original telphers were automatic, the telpher being placed in the middle of the train. The chief use of the automatic telpher is for coal, ore and bulk material. **Non-automatic or man-telphers** are those which are controlled by an operator who travels with the load, and who operates both the telpher and the hoists from a cab or cage which is attached to the telpher or the carriage. It is employed for bulk material, like the automatic telpher, and is also used for the hoisting and conveying of miscellaneous material, boxes, cases and barrels, the package freight of railways and the mixed cargoes of steamships, see Fig. 28.

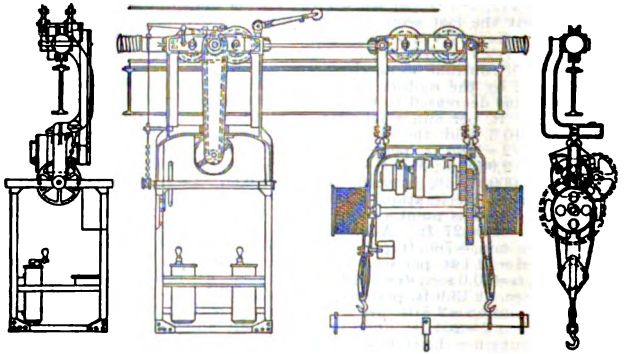

FIG. 28.—Telpher train.

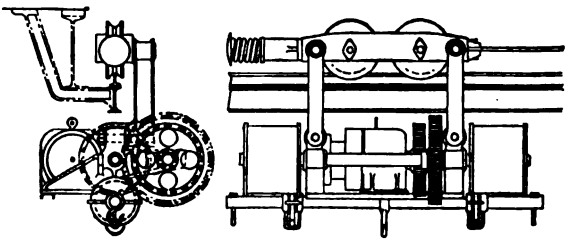

FIG. 29.—Carriage hoist.

**228. Suspension.** A telpher is suspended from one or more wheels in tandem, of which one or all are driven by the electric motor or motors.

**229. Clearances.** In the minimum-headroom 2-ton (4,000 lb.) type designed for railway and steamship terminals (Fig. 29) the vertical space from the underside of the roof girders to the bottom of the hoist-hook is 4 ft. 9 in. (144.8 cm.). The width of the hoist is 3 ft. 3 in. and 4 ft. 8 in. to the limit line for 10-deg. swing. From the centre of the rail to the inner limit of the telpher and hoist is 16 in.

Digitized by Google

**230. Energy supply,** in the form of either direct or alternating current is communicated to the motors by conductors which lie parallel to the track, the contact being made by shoes or wheels. Sometimes storage batteries, suspended from the telpher or the carriage, are employed. On steep grades the telpherage traction, in some installations, has been assisted by supplementary cables, either fixed or movable.

**231. Motors.** The sizes of motors for telphers and hoists will depend upon the class of work to be done; the motors for telpher-tractors vary from 5 to 15 h.p., and for the hoists from 3 to 75 h.p., the loads being from 500 lb. to 30,000 lb. The load factor for the tractor motor is 0.25 and for the hoisting motor 0.16. The driving wheels and the motors may be connected by gears or by chain drive. The maximum service efficiency of the motors is that corresponding to the efficiency obtained between one-half and three-quarters full-load. The motors are of slow or medium speed.

Direct-current, 250-volt or 500-volt, series-wound motors are preferable for tractors and hoists although alternating-current motors afford satisfactory results. The motors should be dust and weather proof, and should have a 50 per cent. reserve in their rating. The average combined efficiency of the motors and gearing, for the tractor and hoist, is from 65 per cent. to 75 per cent.

**232. Brakes.** The telpher brake is of the mechanical type, and the hoist brake is of either the electro-mechanical or electro-dynamic types. Spur gears and chain drive on the tractor transmit the power from motor to track wheels, and either spur or worm gear is used to transmit power to the hoisting drum.

**233. Trackage.** Telphers either run in one direction on a closed track circuit (Fig. 30), or to and fro over a single line. On the single line the automatic telphers reverse themselves on completing their trips. The spacing between the cars is automatically regulated by a block system, and the cars are also automatically controlled at switches and crossings. The track consists of either a cable, or a T-rail supported on a wooden stringer, or upon the top or lower flange of an I-beam. There are also track rails of special section. The radii of the curves are from 8 ft. to 20 ft.

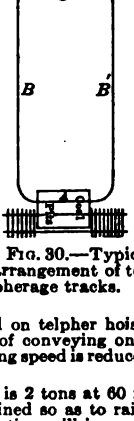

FIG. 30.—Typical arrangement of telpherage tracks.

**234. Track supports.** The track is supported on brackets attached to buildings, or is supported on "A" bents. Supports under straight track are spaced 20 ft. apart, and on curves the spacing is 8 ft. For long spans cables or trusses are used.

**235. Tracks may be fixed or movable.** In Fig. 30 the side tracks *B.B'*, are fixed, but *C* is movable, being attached to a travelling bridge. The speed of this bridge is from 300 ft. to 900 ft. per min. The motor driving this bridge would have a load factor of 0.16.

The telpher train passes from these side tracks *B'*, by means of a gliding switch, upon the movable track *C*. This track therefore may be placed anywhere over the area between the fixed side-tracks. The telpher returns by means of the track *B'*, to its starting-point. By the operation of this movable track, all the space can be served; this operation is called **transferage.** The minimum allowable radius of curves is 8 ft.

**236. Performance.** The loads hoisted and conveyed on telpher hoists have been as high as fifteen tons. The maximum speed of conveying on a straight level track is about 1,000 ft. per min. The running speed is reduced at curves, according to their radii.

**237. For terminal work,** the capacity of each hoist is 2 tons at 60 ft. per min. (18.288 m. per min.). Two hoists can be combined so as to raise 4 tons. The motors being series-wound, the speed of hoisting will increase as the load is diminished.

**238. For freight handling,** from two to four carriage hoists constitute a train which has a total maximum carrying capacity of 8 tons. Such trains are used for assorting as well as for distributing, according to con-

Digitized by Google

signments. Many telphers can be operated in one installation, the num being limited only by the design of the track layout. As the speed of m telphers is greater than that of automatic telphers and the loads heav the capacity is greater for a given length of track.

**239. Installation costs.** The overhead trackage, made part of attached to the building structure, costs the same in proportion as ot structural steel. The weight, including the brackets, averages about 50 per lineal foot. The steel is fabricated at the mill.

## STEEL MILLS

### BY WILFRED SYKES

*General Engineer, Westinghouse Electric and Manufacturing Co., Fel American Institute of Electrical Engineers*

**240. Classification.** Rolling mills are usually named after the mate produced by them, although they are sometimes classified according to layout of the mills. The principal types of mills are as follows:

(a) **Blooming mills,** rolling ingots, as cast, to blooms or billets. material rolled in a steel mill must pass through the blooming mill or equivalent, to be reduced to proper dimensions for handling in the finish mills. The mills are built either two-high reversing, or three-high runn continuously in one direction.

(b) **Slabbing mills** (modification of the two-high blooming mill) prod slabs with finished edges, which are afterward rolled into plates. Vert rolls are provided for finishing the edges.

(c) **Billet mills** are usually of the continuous type, with rolls in tand and roll material from the blooming mill to a suitable size of billet for finishing mills. Material passes directly from one stand to the other, speed of the rolls being arranged to correspond to the reduction in area a each pass.

(d) **Plate mills** may be either two-high reversing, or three-high runn continuously in one direction, and roll slabs to plates of various thickness They are sometimes provided with vertical rolls for finishing the edges the plates and are then known as universal mills.

(e) **Structural mills** are usually three-high and are used for roll girders, heavy angles, channels, etc. In small plants such material may rolled by the reversing-blooming mill.

(f) **Merchant mills** are used for rolling small angles, channels and types of profiles. They are usually three-high, with the finishing st sometimes two-high.

(g) **Bar mills** are usually three-high, and generally consist of rough stand and a separate finishing stand. These are used for rolling bars all sections and sizes.

(h) **Rod mills** are special types of bar mills, and are used for rolling sm sections at high speeds.

(i) **Rail mills** generally roll blooms or heavy billets to rails of vari sections, and are made two-high or three-high, according to the layout

(j) **Sheet mills** roll 0.5-in. to 1-in. bars to sheets of all gages; they always two-high, and generally have separate roughing and finishing stan

In addition to the foregoing types, there are several other forms of c struction, used for rolling certain sections of material, but their use is genera confined to one particular installation.

**241. Arrangement of mills.** The simplest type of mill, having m than one stand, is arranged on one axis, all stands being driven by one of pinions in the middle or at one end of the mill (Fig. 31). This type mill is generally used for rolling small sections only, but is occasions used for heavy sections when transfer tables are provided to move the me from one stand to the other.

The usual arrangement for rolling light sections is shown by Fig. the roughing stand runs at a slower speed than the finishing stand, usually has larger rolls to obtain greater strength, in order that large red tions can be made. The metal is roughed down to such size that it be readily handled by the higher-speed finishing stands. The moto generally direct-connected to the finishing stands, the roughing stands be rope driven. A better arrangement is to drive the roughing and finish

Digitized by Google

stands separately, so that the speed of each can be adjusted for different products to give the maximum output.

Occasionally the various stands are arranged on one axis, the finishing stands being separately driven to give the proper speed adjustment. The object of driving the finishing stands at different speeds than the roughing stands is to increase the capacity of the mill, and to finish the material at such a rate that it does not become too cool; this difference in speeds also makes it possible to work without an exceedingly large loop from one pass to the other.

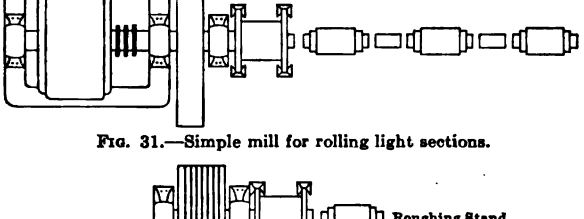

FIG. 31.—Simple mill for rolling light sections.

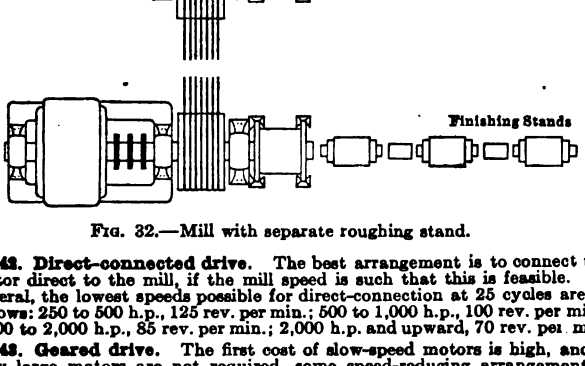

FIG. 32.—Mill with separate roughing stand.

**242. Direct-connected drive.** The best arrangement is to connect the motor direct to the mill, if the mill speed is such that this is feasible. In general, the lowest speeds possible for direct-connection at 25 cycles are as follows: 250 to 500 h.p., 125 rev. per min.; 500 to 1,000 h.p., 100 rev. per min.; 1,000 to 2,000 h.p., 85 rev. per min.; 2,000 h.p. and upward, 70 rev. per min.

**243. Geared drive.** The first cost of slow-speed motors is high, and if very large motors are not required, some speed-reducing arrangement is generally used for slow-speed mills. The low power-factor of the slow-speed motor is a serious objection. Gearing has been used extensively for connecting motors to mills, and the use of cut double-helical gears makes possible pitch-line speeds previously impracticable. Although the maintenance is increased, gears permit the installation of high-speed motor of good performance at low cost. The use of gears introduces losses and offsets the increased efficiency of high-speed motors, but the advantage of high power-factor is important. An important advantage of gear drive is that in the case of very slow-speed mills, the fly-wheel (Par. **247**) can be located on the pinion shaft and run at such a speed that comparatively small weight is required. This is of particular importance in sheet mills, which run at approximately 30 rev. per min., as sufficient fly-wheel effect cannot be obtained to equalize the input properly if the fly-wheel is located on the mill shaft.

When connecting the motor to the mill, the fly-wheel (Par. **247**) should be so placed that the shocks from the rolls are not transmitted to the motor.

Digitized by Google

The best location is on the mill shaft, but with very slow-speed mills, it may be necessary to place the fly-wheel on the pinion shaft for the reason above mentioned.

When the fly-wheel is mounted on the pinion shaft, the gear must be proportionately larger, as it transmits the peak loads. When the fly-wheel is mounted on the mill shaft (Fig. 33), the gear need only be large enough to transmit the motor load. In practice, pitch-line speeds up to 1,500 ft. per min. are used with plain spur gearing, and up to 2,500 ft. per min. with double-helical gears. The best practice is to mount the gears in a substantial case and to run them in oil, which decreases the noise and reduces maintenance.

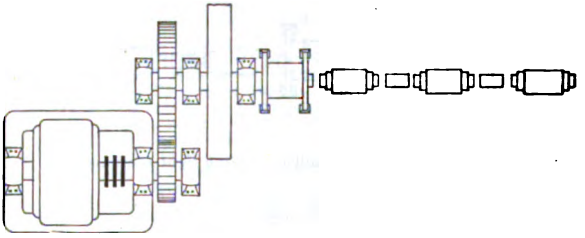

FIG. 33.—Gear drive, fly-wheel on mill shaft.

**244. Rope drive** is extensively used in steel mills where the mill-speed is suitable. Rope speeds up to 6,000 ft. per min. are used, the rope wheel acting as a fly-wheel for the mill. General practice does not differ from that of rope drive in other industries. Large fly-wheels are generally required to prevent rapid fluctuations in the amount of power transmitted from the motor and consequent whipping of the ropes. Belt drives are used only to a small extent in steel mills, usually where a number of stands are arranged in tandem to be driven from one source of power, the belt being passed around several pulleys. The present practice is to substitute gears for belts in this type of mill.

**245. Reversing blooming mills** cannot be driven directly by alternating-current motors, due to the difficulty of control, and to the unsuitable characteristics of such machines. Direct-current motors are used for driving the rolls, and are supplied with power from fly-wheel motor-generator sets, the field of the generator being varied and reversed to control the speed and the direction of rotation of the roll motors. The roll motors are always excited with the same polarity, and the reversal of the armature current of the generator reverses the rotation of the roll motor. The fly-wheel is used to equalise the input to the motor-generator set, and, in practice, limits the load in the line to about one-fourth of the maximum output of the generator.

**246. Reversing rolling mills** have been built with motors which exert as much as 16,000 h.p. on the rolls for short periods.

**247. Fly-wheels.** The function of the fly-wheel is to give up energy during the period when the load on the rolls is in excess of the capacity of the motor, and to store energy when the rolls are idle between passes. In rolling-mill practice, a speed variation of from 15 to 20 per cent. is permissible.

The energy available from the fly-wheel is:

$$\frac{W(V_1^2 - V_2^2)}{2g \times 550} \quad \text{(h.p. sec.)} \qquad (7)$$

where $W$ = weight of fly-wheel in lb., $V_1$ = maximum velocity of wheel at radius of gyration in ft. per sec., $V_2$ = minimum velocity of wheel at radius of gyration in ft. per sec., $g$ = acceleration due to gravity = 32.2 ft. per sec. By properly arranging the control of the motor, the rate at which the energy is given up by the fly-wheel can be regulated, so as to limit the load on the motor to the average value, providing sufficient fly-wheel effect is available.

The majority of fly-wheels used on rolling mills are built of cast iron, and

Digitized by Google

is a general practice, the limit of peripheral speed in such cases is 6,000 ft. per min., because higher speeds are not considered safe, owing to the uncertainty of the shrinkage stresses. By special construction to avoid such stresses, cast-iron wheels for a peripheral speed of 10,000 ft. per min. have been built with success. For moderately high speeds, cast-steel wheels are commonly used, the usual limit of peripheral speed being 12,000 ft. per min.; but in special cases cast-steel wheels run at speeds up to 22,000 ft. per min. Such speeds are dangerous if the material is not homogenous and free from initial stresses, but with proper design and annealing, they have proved successful. For speeds up to 30,000 ft. per min. fly-wheels have been built from discs cut from single plates, the plates being riveted together to form a solid wheel.

**248. Factors affecting power requirements.** The power required by rolling mills depends upon the following factors: (a) volume of metal displaced in a given time; (b) manner in which the section is changed; (c) temperature of metal during rolling; (d) class of material; (e) size of rolls. The determination of the best arrangement of motor and fly-wheel for any particular mill necessitates the analysis of the power required for each pass. The

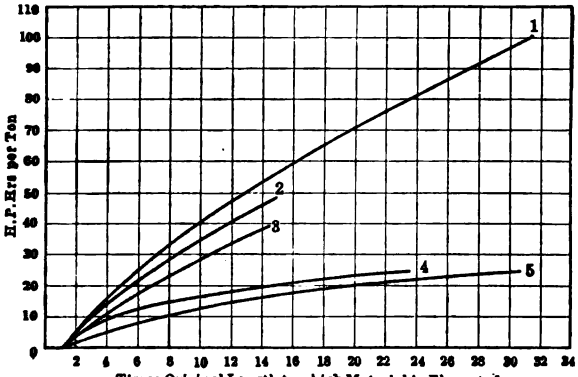

FIG. 34.—Curves showing average energy consumption of different types of mills.

Curve No. 1, rolling small billets of high-carbon steel to rods.
Curve No. 2, rolling billets to light rails.
Curve No. 3, rolling billets to flats and squares.
Curve No. 4, rolling ingots to billets.
Curve No. 5, rolling slabs to plates.

Average output required can be obtained from Fig. 34, which shows **average energy consumption for different classes of materials.** The figures given are h.p. hr. per ton of metal rolled, plotted against elongation. To these figures should be added the friction of the mill, in order to obtain the motor load. The size of the motor may be determined from these curves, provided that the tonnage taken corresponds to the maximum that the mill will roll if working continuously, and that there is sufficient fly-wheel effect available to equalise the peak loads.

**249. Motor rating and temperature rise.** Rolling-mill motors are usually rated on a temperature rise of 35 deg. Cent. and they have a continuous overload capacity of 25 per cent. with 50 deg. Cent. rise and a 1-hr. overload capacity of 50 per cent. with 60 deg. Cent. rise. With the knowledge now available of the power requirements, a standard temperature rise of 40 deg. Cent. with a 25 per cent. overload capacity for 2 hr. is satisfactory, if the conditions are properly analysed.

| Billet mill | 4×4 | 1¼×1¼ | 50 | 20 |
| Rod mill | 1¼×1¼ | ½ Round | 20 | 60 |
| Bar mill | 4×4 | 1×1 | 15 | 48 |

**252. Types of motors adaptable to rolling-mill practice.** Alternating-current motors are used almost exclusively for driving rolling mills, direct-current machines being adopted only in a few installations of comparatively small capacity, or where there are special speed requirements.

Special types of direct-current and alternating-current auxiliary motors for steel-mill service have been developed, the principal characteristics of these machines being high overload capacity without injury, and great mechanical strength. Accessibility is also an important factor in order to facilitate rapid repairs. Mill motors are built from 5 to 150 h.p., being usually rated on a temperature rise of 75 deg. Cent. after 1 hr. operation. They are equipped with heat-resisting insulation, because they are often located near furnaces where the temperature of the motor even without load may be very high. The maintenance cost of such motors is approximately one-fourth that of the modified railway motors previously used. Full particulars of these motors can be obtained from the publications of the manufacturers.

**253. Control.** It is becoming general practice to use hand-operated controllers only for auxiliary motors up to about 30 h.p., larger machines being provided with magnetic-switch controllers. The principal characteristics of steel-mill controllers are simplicity, reliability in operation and ability to stand abuse. The special construction necessary to meet these conditions increases appreciably the cost of steel-mill controllers as compared with controllers for ordinary industrial service.

For motors driving main rolls, magnetic-switch controllers are generally used, the resistance being so arranged that various running points up to 15 per cent. slip may be obtained, in order that the motor will slow down on heavy loads and allow the fly-wheel to give out a part of the energy stored in it. Automatic slip regulators are now being adopted, in order to regulate the rate at which energy is delivered by the fly-wheel, thereby obtaining better equalization of the load on the motor. Liquid regulators are used on account of their simplicity and small maintenance, as well as quickness in action and sensitivity.

## CEMENT MILLS

**BY CHESTER W. DRAKE**

*Commercial Engineer, Westinghouse Electric and Manufacturing Co., Associ American Institute of Electrical Engineers*

### PORTLAND CEMENT MANUFACTURE

**255. Materials.** The necessary ingredients, lime, silica and alumina, generally obtained from two raw materials, in one of which the lime p dominates and in the other the silica and alumina. The materials used this country are: (a) cement rock and limestone; (b) limestone and sh or clay; (c) marl and shale or clay; (d) blast-furnace slag and limesto In 1913 about 84 per cent. of all Portland cement was made by combinatio (a) and (b) but the amount made from blast slag is rapidly increasi although its manufacture is confined to the steel-mill territory. The proce using combination (c) generally employs the wet or slurry system of grindi since the marl is dredged from swamps or under water.

**256. Process.** Briefly stated, the process of manufacture consists reducing the raw materials to a fine powder, mixing the ingredients in t correct chemical proportions as shown by analysis, burning to a clink and again reducing to a fine powder which is Portland cement. In a m using the dry process, the buildings, departments and machines are arrang in approximately the following order, although there are many different typ of machines in use to do the same work.

| Departments | Machines |
|---|---|
| Quarry | Hoists, air compressors, pumps. |
| Raw mill | Crushers, dryers, intermediate grinders, automat scales, fine grinders. |
| Coal mill | Crushers, dryers, fine grinders. |
| Kiln building | Kilns, blowers or fuel feeding apparatus. |
| Clinker storage | Cranes, cableways, conveyers. |
| Finishing mill | Intermediate grinders, fine grinders, or pulveriser |
| Packing house | Automatic sacking machines, conveyers. |

Also numerous elevators and conveyors in all departments.

**257. Power requirements.** Extensive tests and investigations ha shown that the average power demand per bbl. of cement per day depen on many items, but is usually within the limits of from 0.75 h.p. to 1.5 h at the switchboard. On this basis the energy consumption will be from 1 to 27 kw-hr. per bbl. Even with energy at 1 cent per kw-hr. it will seen that the cost of energy is a very large part of the total value of t cement, which, for the United States in 1913 averaged about $1 bbl. at the mill. In 1913 about 92 million barrels of cement were man factured in the United States, although the capacity of the kilns installed about 25 per cent. greater. A total capacity of more than 200,000 h.p. motors is installed in cement plants and the percentage of electric power us is rapidly increasing and is already over 50 per cent. With the excepti of the quarry and the crushers, and sometimes the coal house, all of t machinery in a cement plant is in continuous operation and at a nearly co stant load; the load factor would be very nearly unity were it not for the

Digitized by Google

rtions of the plant, and is often from 80 to 85 per cent., based upon the tio of average to maximum demand.

**258. Motor characteristics.** Induction motors only should be con-dered; already over 90 per cent. of the motors installed are of the alternating-rrent type, and the percentage is steadily increasing. The simplicity and ggedness of the squirrel-cage motor make it admirably adapted for the vere and dusty service of cement mills. The bearings should be made st proof. Ball and tube mills and others of similar type are very difficult start, and motors which drive these machines should have a starting rque of not less than twice the value of full-load torque; friction clutches e unnecessary if proper motors are used. Slip-ring motors are often ed for large gyratory crushers, which may become choked with rock and pose very severe starting conditions. Speed variation is sometimes ired on the kilns and dryers, but this requirement can be met easily by e use of slip-ring motors with resistance which will reduce the speed to e-half of normal.

**259. Type of drive.** For satisfactory service and long life, a motor ould not be subjected to severe vibration. Either belts or flexible coup-gs are able to absorb the vibration of the grinding machinery, but the dust uses rapid deterioration of belts and, therefore, the best practice is direct-nnection wherever possible. The countershafts of ball and tube mills tate at about 160 rev. per min. and, on 25-cycle circuits, motors at this eed are connected through flexible couplings. Motors may often be placed a separate room, the shafting extending through into the mill proper. or Fuller mills, or for other vertical-shaft mills, special belted vertical otors can be obtained which are more satisfactory than horisontal motors ith quarter-turn belts.

**260. Jaw crushers** are often used for secondary crushing, or upon linker, and the following are typical ratings.

Superior Jaw Crushers—Blake Type
(Power and Mining Machinery Co.)

| Size of jaw opening (in.) | Weight of crusher (lb.) | Capacity per hr. according to size | | | | Driving pulley | | | Horse power (aver.) |
|---|---|---|---|---|---|---|---|---|---|
| | | Tons | In. | Tons | In. | Diam. (in.) | Face (in.) | Rev. per min. | |
| 10× 7 | 7,550 | 6 | 2 | 2½ | 1 | 24 | 7½ | 250 | 7½ |
| 15× 9 | 12,000 | 16 | 3 | 8 | 1½ | 30 | 8½ | 250 | 10 |
| 20×10 | 21,500 | 38 | 4 | 19 | 2 | 36 | 13 | 250 | 20 |
| 24×15 | 38,000 | 60 | 5 | 25 | 2½ | 42 | 16½ | 250 | 25 |
| 36×24 | 68,000 | 130 | 6 | 70 | 3 | Pulleys to suit conditions | | 250 | 75 |
| 42×40 | 130,000 | 225 | 8 | 130 | 4½ | | | 250 | 100 |
| 60×48 | 205,000 | 290 | 9 | 180 | 5 | | | 200 | 150 |
| 84×60 | 400,000 | 450 | 11 | 280 | 7 | | | 100 | 200 |

Champion Crushers (American Road Machinery Co.)

| Size no. | Size of jaw opening (in.) | Weight of crusher (lb.) | Tons per hr. according to material and feed | Driving pulley | | | Horse power |
|---|---|---|---|---|---|---|---|
| | | | | Diam. (in.) | Face (in.) | Rev. per min. | |
| 3 | 7½×13 | 5,500 | 8 to 12 | 38 | 8 | 170 | 12 |
| 4 | 9 ×15 | 8,800 | 12 to 18 | 48 | 9 | 155 | 15 |
| 4½ | 10 ×20 | 12,500 | 16 to 24 | 50 | 10 | 150 | 18 |
| 15 | 11 ×22 | 12,000 | 18 to 26 | 48 | 9 | 150 | 20 |
| 5 | 11 ×26 | 20,000 | 24 to 35 | 60 | 9½ | 140 | 25 |
| 20 | 18 ×50 | 60,900 | 70 to 100 | 72 | 12½ | 105 | 50 to 60 |

Digitized by Google

**261. Gyratory crushers.** The following table gives the ratings of Gates crushers; other makes of similar size have approximately the same power requirements.

Gates Gyratory Crusher—Style "K"

| Size no. | Size of openings (in.) | Weight of breaker (lb.) | Capacity per hr. in tons (2,000 lb.), varying with material | Driving pulley | | | Horse power |
|---|---|---|---|---|---|---|---|
| | | | | Diam. (in.) | Face (in.) | Rev. per min. | |
| 4 | 8×30 | 22,000 | 15 to 40 | 32 | 12 | 400 | 14 to 21 |
| 5 | 10×38 | 32,800 | 30 to 70 | 36 | 14 | 375 | 22 to 30 |
| 6 | 12×44 | 48,000 | 50 to 90 | 40 | 16 | 350 | 28 to 45 |
| 7½ | 14×52 | 68,000 | 80 to 120 | 44 | 18 | 350 | 50 to 75 |
| 8 | 18×68 | 103,000 | 130 to 150 | 48 | 20 | 350 | 70 to 110 |
| 9 | 21×76 | 155,000 | 250 to 300 | 56 | 20 | 300 | 100 to 150 |
| | | Several larger sizes are manufactured | | | | | |

**262. Rotary dryers.** For the average size of dryer, 5 ft. diam. by 50 or 60 ft. long, revolving at 2 to 5 rev. per min., from 10 to 20 h.p. is required. This varies with the construction of the dryer, the method of the drive and the speed of rotation.

**263. Ball mills**

Gates Ball Mills

| Size no. | Weight without charge of balls (lb.) | Weight of charge of balls (lb.) | Cap. on Portland cement clinker to 20 mesh | Horse power |
|---|---|---|---|---|
| 7 | 29,500 | 3,000 | 12 to 16 bbl. per hr. | 30 to 40 |
| 8 | 41,100 | 4,500 | 18 to 24 bbl. per hr. | 40 to 50 |

The F. L. Smidth Co. Kominuters are similar to ball mills, and the three sizes, No. 53½, 66, and 88 require approximately 30, 75 and 100 h.p. respectively.

**264. Williams mills.** These are of the swinging-hammer type, and are made in various modifications for pulverising coal, clay, clinker, etc. The ratings of the coal and cement crushers are as follows:

Coal crushers

| Size no. | Pulley dimen. (in.) | Rev. per min. | Horse power |
|---|---|---|---|
| 1 | 20×15 | 1,000 | 20 |
| 2 | 20×15 | 1,000 | 30 |
| 3 | 20×15 | 1,000 | 50–60 |
| 4 | 24×18 | 1,000 | 75 |

**266. Kent mills.** This mill (made by the Kent Mill Co.) is in very tensive use both as an intermediate and a fine grinder. Being of the l and ring type it can be started with comparative ease, and a 40-h.p. otor is usually supplied to drive the mill with its elevator and screen. he pulleys on the mill are 36 in. × 8 in., and 64 in. between centres, running about 200 rev. per min. Motors with double-extended shafts make a mple and satisfactory drive.

**266. Tube mills** of 5, 5.5 and 6 ft. diam. by 22 ft. long are now in common e in cement mills. The required power varies with the charge of pebbles d the feed, but averages 100, 150 and 200 h.p., respectively, for the above ills. For belt drive, motors from 480 to 690 rev. per min. are used, while r coupled drive 160 rev. per min. is customary. The F. L. Smidth No. 16 d 18 tube mills are usually driven by 100-h.p. and 150-h.p. motors, re-ectively. When "cylpebs" (short cylindrical pieces of steel) are added a tube mill the power required is increased 20 to 30 per cent.

**267. Fuller mills.** The Lehigh Car Wheel & Axle Works have on the arket three sizes of Fuller mills, known as the 33 in., 42 in. and 54 in. The aller mill is used principally for coal, while the two larger sizes are adapted pulverising either raw material or clinker. The power requirements are ven in the following table.

| Size of mill (in.) | Pulley | | | Horse power |
|---|---|---|---|---|
| | Diam. (in.) | Face (in.) | Rev. per min. | |
| 33 | 33 | 10 | 210 | 25–40 |
| 42 | 54 | 18 | 160 | 75–90 |
| 54 | 75 | 21 | 125 | 150–200 |

ertical belted motors make the best drive for these mills.

**268. Griffin mills.** These mills, also of the vertical type, are manu-etured by the Bradley Pulveriser Co. Since the driven pulley is above the ill, they are seldom individually driven, but such drive is made feasible proper mounting of the motor.

| Size | Pulley | | Horse power |
|---|---|---|---|
| | Diam. (in). | Rev. per min. | |
| 30 in. | 30 | 190–200 | 30 |
| 36 in. | 40 | 135–150 | 40 |
| Giant | 42 | 160–170 | 60–75 |

**269. Bonnot pulverizer.** Although this is a vertical mill, it has a orisontal pulley running at about 215 rev. per min. Only one size of mill manufactured; this requires from 75 to 85 h.p. Either a belted or a upled motor may be used.

**270. Aero pulverizers.** These reduce crushed coal to an impalpable wder, and blow it into the kiln, mixed with the correct amount of air for mbustion.

Aero pulverisers

| Size no. | Weight (lb.) | Height (in.) | Floor space (in.) | *Normal capacity of soft coal (lb. per hr.) | Rev. per min. | Horse power |
|---|---|---|---|---|---|---|
| A | 1,800 | 28½ | 61½ × 27½ | 600 | 2,000 | 10 |
| B | 3,500 | 38½ | 77½ × 29 | 1,000 | 1,600 | 15 |
| C | 4,200 | 51½ | 78½ × 29 | 1,500 | 1,500 | 20 |
| D | 4,400 | 44½ | 78½ × 29 | 2,000 | 1,400 | 30 |
| E | 5,600 | 46½ | 97 × 33 | 2,800 | 1,400 | 40 |

* The capacity may be increased 25 per cent. or decreased 50 per cent. ithout material loss of economy.

Digitized by Google

**271. Kilns.** The size of kiln in greatest favor at present is about 6 8 ft. in. diam. by 125 to 135 ft. long. However, many shorter kilns ar use and a number have lengths of 150 ft. or longer. Pulverised coa used as fuel in 75 per cent. of the kilns, oil in about 17 per cent., and nat gas in the remainder. To burn the clinker properly, a speed adjustm ratio of 2 to 1 is usually necessary, and slip-ring motors with control are required. For 7-ft. × 100-ft. kilns an average of 15 h.p. is requi and from 20 to 30 h.p. is required for 8-ft. × 125-ft. kilns.

## COAL MINING

**BY GRAHAM BRIGHT, E.E.**

*Engineer, Mining Dept., Westinghouse Electric and Manufacturing*
*Member, American Institute of Electrical Engineers*

### DEVELOPMENT OF POWER PRACTICE

**272. Haulage and hoisting.** The early mines in the United St generally consisted of a hole in the side of a hill extending back a few hund feet into the hillside. The coal was mined entirely by hand, a process kn as "pick mining," and the small cars were pushed to the entrance where coal was dumped on loading platforms. As the distance became greater adverse grades were encountered, it became necessary to obtain a new so of power, and the time-honored mule was found most satisfactory. At present time this method of traction has practically disappeared from m haulage work, and is also being rapidly replaced by mechanical processes gathering. When shaft mines were developed, a power system was ne sarily employed in the hoisting of coal, men and material. Steam was used and a few compressed-air hoists followed later. Electric hois practice has, however, found a firm footing, and a great many old mines to-day electrifying their hoists. (Par. 91).

**273. Pumping (Par. 288).** Very few mines can be laid out to be draining, and pumping becomes necessary as soon as they are opened. early power pumps were steam-operated, and this type appears in a g many of the pumps of to-day. The inherently poor economy of steam o pumps, and the large losses in long pipe lines make this type of installa compare very poorly with electrically driven pumps.

**274. The ventilating systems (Par. 289)** were operated by steam many years. The electric motor is, however, rapidly supplanting the st engine and is establishing for itself a remarkable record in regard to flexibi continuity of operation and the economical use of power.

**275. Mining machines (Par. 290).** Originally coal was all pick-mi but it soon became evident that power must be used to mine the coa an insufficient amount of labor was available to care for the rapidly increa output. The first mining machine was the compressed-air puncher-t followed later by the compressed-air chain-type. Various kinds of ele mining machines are in use to-day, and many new types are being develo The particular design of machine which should be used to meet a partic set of conditions, can be determined only by experience.

**276. For auxiliary power outside of the mine (Par. 287),** suc power for shops, pumps, etc., steam engines have been largely used; an substitute an electric motor is usually a comparatively simple matter.

**277. Safety specifications.** Various countries and each of the mi states of this country have mining codes which deal with the manne installing electrical apparatus in mines and give general safety rules. reference, Mr. H. H. Clark, of the Bureau of Mines has written a paper fo April, 1913, meeting of the American Institute of Electrical Engi entitled "Safeguarding the use of Electricity in Mines."

### ENERGY SUPPLY

**278. The generators** are generally of the direct-current, 250-volt or volt types. These generators should be compounded about 10 per cent. should be capable of withstanding momentary overloads of from 50 to per cent. Standard machines are built for 225-volt to 250-volt service, for volt to 275-volt service and from 500-volt to 550-volt service. The h

Digitized by Google

voltage of 500 has an advantage over 250 volts in that very much less copper is needed and greater distance can be covered. The danger is, however, considerably greater, and many states are legislating against the use of over 300 volts underground. Compounding is necessary due to the long lines that are required in reaching the workings. The type of load is such that heavy short-time peaks frequently occur.

**279. Predetermination of generator capacity.** When a mine is small and electric power is used for only one or two locomotives, the capacity of the generator will be determined entirely by the peak loads. For instance, if the load were to consist of two 10-ton locomotives each having two 50-h.p. motors, the conditions will be as follows: 1-hr. rating of motors, 200 h.p.; continuous rating of motors about 80 h.p.; maximum load with both locomotives starting 300 h.p. To compensate for the line drop and efficiency, 1 kw. should be allowed at the switchboard for every horse-power at the machine.

It will be seen from the above that on a heating basis, an 80-kw. generator can be used. This machine, however, could not take care of a load of 300 kw. The generator should have a capacity of not less than 150 kw. If old second-hand generators and engines are installed, it will be necessary to provide for a capacity of from 200 to 250 kw., as there would be a lack of overload capacity. The efficiency of power generation will not be very high, since the unit will be carrying a small load a considerable portion of the time. Excellent examples of load diagrams showing the low average and the high peak loads obtained at a coal mine power plant are shown in a paper presented before the A. I. E. E., April, 1913, by Wilfred Sykes and Graham Bright.

If we were to add to the above a third locomotive, a pump load of 50 h.p., a fan load of 50 h.p., and a cutting load of four 25-h.p. cutters, we would have the following conditions:

| | |
|---|---|
| One-hour rating of motors..... | 300 + 50 + 50 + 100 = 500 |
| Continuous rating of motors..... | 120 + 50 + 50 + 40 = 260 |
| Maximum load of..... | 400 + 50 + 50 + 100 = 600 |

For the maximum locomotive load, two locomotives can be considered as starting, each developing 150 h.p., and one running taking 100 h.p. There will, no doubt, be a diversity among the machines, so that the actual peaks will not be over 550 h.p. The generator capacity should be 300 kw., preferably divided between two units of 150 kw. each. From these figures it will be seen that, for the larger plants, the generators can be operated more nearly at their continuous capacity.

At larger mines, or where one company operates a group of mines, a central alternating-current generating system is frequently installed. Energy is generated at 2,200 volts, 3 phase, 60 cycles, and is either transmitted to substations at 2,200 volts, or stepped up to 6,600 volts or 11,000 volts. Motor-generator sets or rotarics are used at the substation to transform the alternating current to direct current. Motor generator sets are generally to be preferred to rotaries, as compounding is more easily obtained. In determining the capacity of the central plant, the machine and line losses must be taken into account in determining the size of the main generating units. These losses will average from 15 to 20 per cent. The capacity of the central plant will not be the sum of the individual substations, as there will be considerable diversity. The diversity factor will range from 1.2 to 1.5 to 1.

**280. Design and advantages of mines using purchased energy.** When central-station power is used, the power application is very much simplified. For haulage, cutting and inside pumping, a motor-generator set or synchronous converter is used. The motor-generator sets are generally of the synchronous type, owing to the high power-factor which can be obtained with the synchronous motor. This high power-factor will compensate for the lower power-factor obtained on the induction motors used for driving fans, pumps, and tipple or breaker machinery. The substation can be a very simple structure and, in a great many cases, the old generating room can be used. The care of a substation is an extremely simple matter when compared with an isolated plant. For fans, compressors, outside pumps, tipple and breaker machinery and machine or blacksmith shop drive, the squirrel-cage motor is best adapted, as regards first cost and upkeep. This apparatus can be operated at all times independent of the motor-generator set which, in many cases, operates only 8 or 10 hr. per day.

Digitized by Google

## MOTOR CIRCUITS

**281. Permissible voltage drop** for haulage, gathering and cut (for good operation), should not exceed 20 per cent. to 25 per cent. at m mum load.

**282. Diversity in peak-load calculations.** **See Par. 279.** Wh several locomotives and cutting machines are supplied from one feeder, maximum load is obtained by estimating the number of machines that r be running at one time. It is seldom that two locomotives will start at same time where only three or four are in use. In practice, a locomotive not operate at full-load more than one-fifth of the time. The same is tru mining machines, and the maximum load should be estimated from the l conditions that exist at each mine.

**283. Construction methods and costs.** Trolley and feed wire sho be installed in a substantial manner and protected from contact with men, mules at cross-overs. The total cost, including labor and materials erecting a 0000 trolley wire in an anthracite mine will range from $1,00 $1,400 per mile, and from $650, to $900, in a bituminous mine, depend upon the nature of the roof. Outside of the mine, the cost per mile range from $1,200 to $1,600. Number 0000 feed wire will cost, erected, f $900 to $1,200 per mile inside of the mine, and from $1,000 to $1,500 out of the mine for an anthracite mine. The cost of 0000 feed wire in a bitumin mine will be about the same as for the trolley wire. The rail return is g erally much neglected. The bonding should be frequently checked wit bond-testing instrument and cross bonds should be installed at about ev 200 or 300 ft. All switches, frogs, and cross-overs should be bonded aro and cross-bonds should be placed on each side. Any water, or air p should be well bonded to the rail, especially near the main entrance, in or to obtain the benefit of an extra return circuit and to prevent electroly The total cost of bonding a track (rails varying from 30 to 50 lb. yd.) with No. 00 bonds including cross-bonding, will be about $350 mile, including labor and material. The total cost using No. 0000 bo will be about $400 per mile.

The haulage and cutting circuits should be kept separate where possi but should be arranged to connect together in order to help out one anothe emergency cases. In the larger mines, the feeders can be separated in or that local line trouble will not shut down the entire mine. However, in s large mines, it is the practice to connect everything solidly, and in cas trouble the circuits are held closed and the source of trouble removed literally burning it out.

**284. Lighting circuits** both inside and outside are generally taken f the haulage or cutting feeders. Incandescent lamps for either 110 or volts are used, with as many in series as necessary.

## MOTOR APPLICATIONS

**285. Compressor motors.** See Par. 167 to 188. Where compressed is used, motor-driven compressors can be applied to advantage. For small c pressors, the best type is that used by street railways for supplying compre air for brake systems. For larger compressors a synchronous-motor d is most used because of the high-power factor obtainable thereby. C pressor motors are often operated at 80 per cent. leading power-factor in or to compensate for the lower power-factor due to the induction motors wh are used to drive fans, pumps and tipple or breaker equipment. With a s chronous motor drive, an unloading device must be used on the compres this prevents the motor from being loaded until it has reached synchronous sp

**286. One great advantage of electrically driven air compressor** that they can be installed at the most convenient location. Small auxil compressors can be easily located inside of the mine at the end of long p lines where it is difficult to maintain normal pressure.

**287. Types of adaptable motors.** For tipples, breakers and sh considerable power is often required for crushers, screens, elevators, was and machine tools. When direct current is employed, a compound-wo motor is best adapted, and is sometimes built totally enclosed in orde avoid the effects of coal dust. The motors should be continuously ra as the load is fairly constant. A shunt-wound motor is best adapted for s purposes, as its speed is more nearly constant under varying loads. W

Digitized by Google

power is purchased, all outside motors can be of the alternating-current type, so that the motor-generator sets, or synchronous converters, need only supply the haulage, cutting, inside lighting and pumping. Where very heavy starting loads obtain, the wound-rotor induction motor with drum type controller should be used. Where only moderately heavy starting torques are required, the squirrel-cage motor is best adapted. The rotor characteristics of this motor will depend upon the character of the load. This is by far the simplest and most rugged motor built, the control also being very simple. Where starting requires a low torque, a low resistance end-ring can be used; where high starting torques are required, a fairly high-resistance end-ring should be used. The cast end-ring has solved all end-ring troubles which were once so prevalent.

**288. Pumping.** For inside pumping the reciprocating duplex or triplex pump is most used for the smaller sizes. The centrifugal pump will probably average a higher efficiency, but is not so well adapted for moving about and for use under various heads. The capacity of the motor can be readily determined by the amount of work to be done. See Par. 148 to 166.

**289. Ventilation.** Mine fans are inherently low-speed machines and are very well adapted for direct connection to a steam engine. For economy in first cost and operating cost an electric motor is inherently a high-speed machine, usually requiring some speed-reducing device in such an application. Belting seems to be the most popular method, although gearing, chain drive, and even rope drive, are used occasionally. See Par. 186 to 205.

**290. Machine mining.** Pick mining is a rather slow and laborious process of mining coal, although a large portion of the coal is still mined by this method. Machine mining has become a necessity owing to the increasing demand for coal and the limited supply of labor. Punchers and chain machines are the two types generally used. **Punching machines** were first driven by compressed air, and most of the machines of this type are still operated in this manner. The electric puncher is coming in rapidly; this machine consisting of a motor-driven compressor attached to the cutting mechanism, so that compressed air really is used to operate the puncher. This machine has the advantage of electric transmission, but is heavier and more expensive than the straight-air puncher.

The **chain machine** is the most rapid of all mechanical cutters. The chain cutter will require a motor having an intermittent rating of from 20 to 30 h.p., while the pneumo-electric machine will require a motor rated from 10 to 15 h.p. As a rule direct-current compound-wound motors are used to operate coal-cutting apparatus. Alternating-current motors are being introduced for both punching and cutting machines and have been very successful. They, however, require a separate power circuit consisting of two feed wires with track return. They possess the advantages of simplicity of construction and less danger of the workmen coming in contact with live parts.

## LOCOMOTIVES

**291. Locomotives for main haulage and gathering** are of the direct-current type, designed to operate on 250- or 500-volt circuits. The series type of motor is invariably used as it has the best speed-torque characteristics for the service. The service is somewhat similar to street-railway conditions and the same general methods are used to determine the weight and capacity of the equipment.

Mine locomotives are built in weights ranging from 3 tons to 30 tons and gages ranging from 18 in. to the standard of 4 ft. 8.5 in. The wheels may be cast iron with chilled tread, steel tired, or rolled steel. Gathering locomotives are built to replace mules; these weigh from 3 to 8 tons with equipment varying from two 10-h.p. motors to two 40-h.p. motors.

**292. Locomotive-adhesion and weight calculations.** The cast-iron wheel will afford a running coefficient of adhesion of 20 per cent., and a starting coefficient of 25 to 30 per cent. when sand is used. The steel-tired or rolled-steel wheel will have a running coefficient of 25 per cent. and a starting coefficient of 30 to 33.33 per cent. with sand. The above figures are conservative and can be easily obtained with fair rail conditions. The weight of locomotive is determined by the following formula:

$$T(30+20G)+20GW = 400W. \text{ for cast-iron wheels,}$$
$$= 500W. \text{ for steel wheels.}$$

Digitized by Google

Where $T$ = weight of trailing load in tons. The item 30 is the friction in per ton for the trailing load on the level and is the average value obtai by test for small mine cars. The expression $20G$ is the pull necessary overcome gravity, $G$ being the grade in per cent. $W$ = weight of locomo in tons. The item 400 is 20 per cent. of 2,000 lb. for cast-iron wheels. item 500 is 25 per cent. of 2,000 lb. for steel wheels.

A margin over 20 and 25 per cent. for starting with sand is availabl take care of the extra tractive effort necessary for accelerating the load locomotive when starting. See Par. 242, also see Sec. 16.

**293. The track-curve resistance** can, as a rule, be neglected, since length of the average mine trip is many times that of any of the cur For gathering, the cu may have a vital influe In general, *each* 1 *de of curvature adds* ½ *lb. per to the friction.* The ab of a locomotive to negot a curve depends upon wheel base and size of wh The curves of Fig. 35 s a minimum radius of c that any locomotive wi certain wheel base and of wheel can negoti These values are conse tive and are based on st ard wheel flange and t play. With a liberal spr the value of wheel base be safely increased from to 50 per cent.

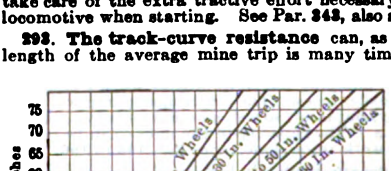

FIG. 35.—Relation of wheel base to radius of minimum curve.

**294. Braking.** In s cases the problem of b ing becomes most important and the weight of the locomotive is determi by its ability to hold back a loaded trip on a certain grade. If a runa would result in serious damage, then a smaller coefficient should be assu than would be appropriate for pulling a load up a grade. With cast- wheels the coefficient for braking should not be over a value from 15 t per cent. and for steel wheels 18 to 20 per cent. Care should be taken wheels do not become too hot; this may break a cast-iron wheel, or cau steel tire to slip. For, retarding a trip down a grade, the formula of Par. will be changed to:

$$T(20G-20)+20GW = (300 \text{ to } 360)\,W. \text{ for cast-iron wheels,}$$
$$= (360 \text{ to } 400)\,W. \text{ for steel wheels.}^{*}$$

**295. The friction of the average mine car** is about 30 lb. per ton. cars in good condition may have a resistance very much less than 30 lb., the friction increases with the age of the car, and may reach 40 to 50 lb. ton. Roller bearings when kept in good condition will have a fairly resistance, but unless good care is taken of them, their frictional resist will rise rapidly.

**296. Selection of proper rail weight.** For each given weight of

| Weight of locomotive (tons) | Weight of rails (lb. per yard) |
|---|---|
| 4 to 6 | 16 |
| 6 to 8 | 20 |
| 8 to 10 | 25 |
| 10 to 13 | 30 |
| 13 to 15 | 40 |
| 15 to 20 | 50 |

there is a corresponding maximum weight of locomotive which should no

* The car friction should be taken at 20 lb. for descending trips.

Digitized by Google

exceeded for satisfactory operation. The following table has been prepared by the Baldwin Locomotive Works and represents the best modern practice. If a heavier locomotive is desired than is shown in this table, tandem units are often applied.

**297. Rating of locomotive motors.** Although the motors of a mine locomotive are given a 1-hr. rating, it is the average heating that determines the capacity for all-day service. This heating is proportional to the square of the current. The average of the square of the current will give a squared value, the square-root of which is really the capacity of the motor for all-day service. This value is known as the square-root of the mean-squared current. It is obtained by finding the different values of the current for one motor throughout a round trip. These current values can be obtained from the characteristic motor curve of the particular motor used. After the weight of the locomotive has been determined, one of the standard motors for this weight is selected and calculations made to determine if it is of the proper capacity. The total tractive effort per motor is determined for each grade, allowing 20 lb. per ton for the friction of the locomotive. For each total tractive effort the current and speed are obtained from the curve, and the time is calculated. By squaring each current value and multiplying by the time, we have the sum of the products of various squared values of the current, multiplied by the time. This summation should be increased by from 5 to 10 per cent. to make allowance for acceleration and switching movements at each end. The final value is then divided by the total time, and the square-root extracted. The characteristic curve gives the continuous current capacity, which can be compared with the final result obtained.* The capacity of the equipment should not be based on h.p. per ton weight of locomotive, since the 1-hr. rating of the motor is no indication of what its performance will be under certain given conditions.

**298. An electric reel** is sometimes applied to a gathering locomotive so that it can be taken into rooms where no trolley wire is erected. This reel may be chain driven from one of the axles or motor driven from a small independent special motor which maintains a constant pull on the cable. This cable may be single-conductor or double-conductor, depending upon the track conditions. A No. 4 A.W.G. cable is generally used.

**299. A traction reel** can also be supplied on a gathering locomotive. It consists of a small motor-driven crab with from 300 to 400 ft. of steel cable. This type of reel is used where the room grades are very steep, and are driven to the dip.†

**300. The storage-battery locomotive** is rapidly coming to the front for gathering purposes. Until recently the storage battery was not rugged enough to stand the rough service that exists in mining conditions. Two types of battery are now available for this work, the lead-cell and the Edison. The iron-clad Exide is the most satisfactory type of the lead cells. The efficiency between battery and locomotive wheels will range from 60 to 66 per cent. In order to calculate the proper battery to use, the entire trip should be divided into as many sections as there are different characteristics. The car friction should be taken at 30 lb. per ton, and the tractive effort 30 lb. per ton for each per cent. of grade. The total tractive effort multiplied by *three* will give the watt-hours per train mile. The total watt-hours per round trip can thus be obtained. The total watt-hours divided by the voltage of the battery will give the ampere-hours of the battery. For a lead cell the voltage per cell will be 2, and to calculate the number of positive plates per cell, the ampere-hours should be divided by 31.5. The proper size of Edison cell can be selected from the ampere-hours required. Batteries for this kind of service are rated on a 4.5-hr. basis. The size of either type

* For a more detailed explanation of the determination of weight and equipment of a mine locomotive see article, *Electric Journal* of March, 1912, entitled "The Determination of Weight and Equipment of a Mine Locomotive," by Graham Bright. (This article gives an example with complete set of calculations.) Also see *Coal Age*, issues of March 6 and March 20, 1915.

# REFRIGERATING PLANTS

**BY AUGUSTUS C. SMITH**

*Sales Engineer, The Cataract Power and Conduit Co.*

**302. Motors adaptable to refrigerating service.** Ammonia compressors and auxiliary apparatus in refrigeration plants may be driven either by direct-current motors or by induction motors. The flexibility of speed control of the direct-current motor offers an advantage, but the possibilities of speed control of the induction motor together with the characteristic advantages of this type are sufficient reasons to justify its selection where alternating current is available.

**303. Motor speeds and speed control.** Motors for the operation of ammonia compressors should be of the variable-speed type, so that where the operating conditions require it, suitable speed control can be secured. Compressors of 50 tons capacity, and over, are operated usually at about 70 rev. per min., so that a motor speed of 500 rev. per min. or less, is desirable.

**304. Multispeed motors.** With the two-speed motor, the compressor can be operated at full speed and at half speed; while with the three-speed motor, it can be operated at full speed, two-thirds speed and one-third speed. This method of speed control, however, provides for changes in the compressor at fixed and predetermined steps only, and does not, therefore, provide for the flexibility in speed control necessary to meet the usual requirements in the operation of refrigeration machines.

**305. With the slip-ring type of motor** and resistance speed control flexibility of operation equivalent to that of the steam compressor is attainable. The power-factor of this motor remains practically constant at all speeds, but the efficiency falls off with the reduction in speed; operating the compressor continuously, at reduced output, with this type of motor, is therefore uneconomical from a power-consuming standpoint.

**306. Plant duplication.** In plants where it is necessary materially to reduce the output, during certain periods of the year, it is desirable to employ more than one compressor unit. This is especially true in large refrigeration plants, where the total compressor capacity should be divided among indi-

Digitized by Google

vidual units, properly proportioned according to the required operating conditions.

**307. The standard rating for ammonia compressors** is based on 15 lb. suction pressure, 185 lb. condensing pressure, and condensing water at 70 deg. Fahr. (21 deg. Cent.). The power necessary to drive a compressor varies directly with the operating pressure, the horse-power being determined by indicator card.

**308. Power requirements per ton.** Ammonia compressors operated at 15 lb. suction pressure and 185 lb. condensing pressure, having a rated capacity over 5 tons of refrigeration per 24 hr., require about 1.5 h.p. per ton of refrigeration; compressors having from 5-ton to 1-ton capacity, operated under like conditions, require from 1.5 h.p. to 2 h.p. per ton. Increasing the above pressures to 25 lb. suction, and 200 lb. condensing pressure, would increase the power necessary to operate the compressor about 16 per cent.

**309. Varying pressures and output requirements.** In the daily operations of a refrigerating plant, it is frequently necessary to operate a compressor at increased pressures. In some localities during warm weather the temperature of the condensing water will exceed 70 deg. Fahr. (21 deg. Cent.), and during extremely warm weather it may be necessary to force the compressor beyond its rated capacity in order to meet unusual requirements, all of which require increased power. For compressors of 50-ton rated capacity and smaller, about 25 per cent. additional motor capacity should be provided for these possible excessive operating conditions; for larger compressors, from 15 to 25 per cent. additional motor capacity should be provided, depending upon the local and probable operating conditions of the plant.

**310. Classification of ice-making plants.** Ice-making plants may be divided into two classes: those making ice from **distilled water**, and those making ice from **raw, or natural water.** The former method uses the **can system**, while the latter may use either the can system, or the **plate system.** The compressor-room equipment for an ice plant of equivalent capacity is the same for all of these methods, except for the plate system, where about 15 to 20 per cent. more compressor capacity is required.

**311. Operating data on 90-ton can-system ice plant using distilled water**

| Month | Maximum input (kw.) | Input (kw-hr.) | Tons of ice made |
|---|---|---|---|
| January | 115 | 92,530 | 2,033 |
| February | 102 | 65,080 | 1,493 |
| March | 97 | 71,870 | 1,737 |
| April | 192 | 133,550 | 3,055 |
| May | 209 | 139,550 | 3,742 |
| June | 230 | 145,686 | 3,291 |
| July | 218 | 157,640 | 3,657 |
| August | 230 | 156,700 | 3,579 |
| September | 219 | 160,250 | 3,408 |
| October | 205 | 154,090 | 2,989 |
| November | 112 | 76,460 | 1,792 |
| December | 122 | 91,210 | 2,226 |
| Total | ..... | 1,444,616 | 33,002 |

**312. Equipment of plant using can system.** The compressor-room equipment in this plant (Par. 311) consisted of two vertical 16-in.×24-in. double-cylinder single-acting ammonia compressors of 70 rev. per min., at full-speed. Each of these compressors had a rated capacity of 45 tons of ice per 24 hr., when operated at 15 lb. suction pressure and 185 lb. condensing pressure, with condensing water at 70 deg. Fahr. (21 deg. Cent.). Each was belt-driven by a 175-h.p., 500-rev. per min., 3-phase, 25-cycle, 2,200-volt, variable-speed, slip-ring induction motor. The speed control consisted of a 13-step drum controller, and iron-grid resistance of sufficient capacity to permit the continuous operation of the motor at any speed from full speed to one-half speed continuously.

Digitized by Google

There was also installed in the compressor room a 6-in. × 6-in. ammo compressor having a capacity of about 4 tons of refrigeration, which operated by a 10-h.p., 750-rev. per min., 3-phase, 25-cycle, 440-volt, variab speed induction motor. This compressor was used for pumping out ammonia system, and also was used, in connection with repairs, for testi thus avoiding the necessity for operating the large compressors for th purposes.

The auxiliary and tank room equipment was all operated by 3-phase, cycle, 440-volt induction motors consisting of the following: 1 conden water pump, 25-h.p., 750-rev. per min., variable-speed, belted motor; 4 br agitators, 5-h.p., 750-rev. per min., constant-speed, direct-connected moto 1 distilled water pump, 5-h.p., 750-rev. per min., variable-speed, belted mot 1 soft-water pump, 5-h.p., 750-rev. per min., variable-speed, geared mot 1 boiler feed pump, 5-h.p., 750-rev. per min., variable-speed, geared mot 1 water-softener mixer, 1-h.p., 750-rev. per min., constant-speed, bel motor; 2 cranes, 3-h.p., 750-rev. per min., variable-speed, geared motor

**313. Operating costs of plant using can system.** The average c sumption of power in this plant (Par. 311) was 44 kw-hr. per ton of ice, wh the other items of expense were: engine and boiler room labor per t 15.51 cents; fuel per ton, 10.68 cents; tank-room labor per ton, 12.55 cen

**314. Equipment of plant using plate system.** While the compress room equipment in both distilled-water plants and raw-water plants practically the same, the auxiliary equipment differs, depending upon type of plant, and the system used. The auxiliary and tank-room equipm of a raw-water plate plant electrically operated, and having a rated capac of 100 tons of ice per 24 hr., may be taken as an example. In this plant the motors are of the 3-phase, 25-cycle, 220-volt, induction type. A centri gal condenser-water pump, direct-connected to a 6-h.p., 1,500-rev. per m constant-speed motor is used to supply excess water to the condenser in weather, when the natural flow of city water supply is insufficient. A br pump, belted to a 2-h.p. 750-rev. per min., constant-speed motor is used circulate warm brine around the plates in order to loosen the ice. A rot blower, belted to a 7.5-h.p., 750-rev. per min., constant-speed motor is u to agitate the water in the tanks. The rest of the equipment consists cranes, each equipped with one 5-h.p. and one 3-h.p., 750-rev. per m variable-speed motors; 2 tilting tables, each geared to a 2-h.p., 1,500-r per min., constant-speed motor; 1 30-in. circular ice saw, operated by ch drive from a 3-h.p., 1,500-rev. per min. motor; 1 ice elevator, operated and geared to a 3-h.p., 1,500-rev. per min. motor.

**315. Extracting the lifting rods, in the plate system.** After plates of ice have been placed upon the tipping table, the ends of the lift rods (which extend about halfway through the plate) are connected to secondary terminals of a 1-kw. transformer, having a 220-volt primary a 4-volt, 250-amp. secondary. In about 4 min. after the current has b turned on, the rods will be melted loose, and can be readily withdrawn.

**316. Centre-freeze system.** The can-system raw-water plant, quently referred to as the "centre-freeze" or "core" system, undoubte presents the ideal of an electrically operated ice-making plant, as it has the advantages of the can system, together with the productive econo obtained through the use of raw water. In brief, this type of plant cons of stationary cans, fed from the bottom, with raw water supplied throug cooling tank. During the period of freezing, the water in the cans is c stantly agitated by a jet of air under a pressure of about 3 lb. per sq. in. water freezes in the cans from the sides toward the centre, so that the sp containing free water and all the impurities is gradually diminished. W this space has reached a very small area, all the water remaining, with impurities contained therein, is drawn off, and the core is filled with distil water; this, when frozen solid, gives a cake of very clean pure ice.

**317. Auxiliary equipment of a 60-ton plant using the cent freeze system.** A 15-h.p. motor is belted to the line shaft, which in t drives the following: 1 fan having a capacity of 500 cu. ft. per min., whic used for agitating the water in the freezing cans; 1 centrifugal pump hav a capacity of 200 gal. per min., which is used in pumping the brine thro the cooling or supply tank; 1 air compressor having a capacity of 40 cu. per min., used to operate overhead cranes which are employed in remov

Digitized by Google

the ice from the cans; 1 7.5-h.p. motor direct-connected to brine agitator. The distilled water used is furnished from a 10-h.p. boiler operated at from 10 to 15 lb. steam pressure.

**318. Operating data on plant using centre-freese system.** The first complete month's operation of the above plant showed a total maximum demand of 125.8 kw., with an energy consumption of 91,056 kw-hr., and a production of 1,599 tons of ice. This is equivalent to a resultant maximum demand of 2.42 kw., or 3.24 h.p. per ton of ice, and 57 kw-hr. per ton of ice.

**319. The Audiffren-Singrun refrigerating machine** in its completed form, as placed on the market, is in reality a self-contained refrigerating plant, and is especially adapted for use in restaurants, butcher shops, clubs, apartment houses, and large residences, or where the average requirements may run from 10 to 100 lb. of ice per hr., or the refrigeration effect equivalent to the melting of from 15 to 100 lb. of ice per hr. The ideal method of drive is the electric motor, which can be of any type.

This machine operates on the compression system, using sulphur dioxide which condenses at a very low pressure, as the refrigerating medium. The principal element of this machine consists of a shaft on which two drums are mounted, and the driving pulley. One of these drums, located at about the mid-point of the shaft, contains the condenser, and revolves in a tank of running water which serves to carry off the heat absorbed. The other drum, in which expansion of the sulphur dioxide takes place, is connected to the condenser drum by a bronze pipe (which forms part of the shaft), and revolves in a tank containing either the brine or the water to be cooled.

The air is entirely exhausted from these drums, and, after having received the proper charge of sulphur dioxide and necessary lubricating oil, they are hermetically sealed, thus absolutely protecting all of the vital working parts from any outside element which might cause their wear or depreciation, and further making it impossible for any unskilled operator to tamper with the mechanism of the machine.

**320. Rating and operating characteristics of the Audiffren-Singrun refrigerating machine,** when operated under average conditions of brine at 27 deg. Fahr. (−2.8 deg. Cent.) and condensing water (at outlet) at 77 deg. Fahr. (25 deg. Cent.).

| | Machine number | | | |
|---|---|---|---|---|
| | 2 | 3 | 4 | 6 |
| Capacity in B.t.u. absorbed per hr.... | 2,260 | 5,640 | 11,280 | 22,560 |
| Capacity in pounds of ice per hr..... | 10.5 | 26.0 | 52.0 | 105.0 |
| Hours necessary to produce refrigeration equivalent to melting 100 lb. of ice. | 6.38 | 2.55 | 1.28 | 0.64 |
| Horse power required..... | 0.55 | 1.26 | 2.15 | 4.3 |
| Horse power of motor recommended.. | 0.75 | 1.50 | 3.0 | 5.0 |
| Kw-hr. required to produce refrigeration equivalent to melting 100 lb. of ice. | 2.63 | 2.39 | 2.09 | 1.57 |
| Kw-hr. required to produce 100 lb. of ice. | 3.92 | 3.62 | 3.15 | 2.34 |
| Water at 68 deg. Fahr. (20 deg. Cent.) required, in gal. per hr. | 40.0 | 100.0 | 200.0 | 400.0 |

To obtain actual power and energy consumption of motor, divide the above power values by the efficiency of the motor.

## TEXTILE MILLS

### BY WILLIAM W. CROSBY

*Consulting Engineer, Member, American Society of Mechanical Engineers*

**321. Mechanical drive from steam plant.** If the power plant can be centrally located, the mechanical drive with a belt or rope tower, is most efficient. By this arrangement energy is imparted to the shafting on each floor directly. The steam plant usually proves the most flexible of the

Digitized by Google

several methods of power development, and can often be placed at the ce of the mill; the proper location of the sidetrack and coal pocket mus considered.

**323. Mechanical drive from a water-power plant** is likely to p inflexible. In a development of any size, the location and constructio foundations become difficult if the water wheels are at or near the centr the plant. If they are located at one end of the mill, the shafting wil large, and the friction losses great. In some cases a canal may extend par with the river and the mills can be located between the canal and the ri Such construction allows several water wheels to be placed on the cen line of the mill. While this last plan obviates the use of shafting of l diameters, it necessitates several control points, but this is not serious, water wheels need but little attention after they have been started.

**323. Steam auxiliary plant.** There are not, however, many ri whose minimum flow is sufficient to drive the mills dependent on t and as textile mills, owing to their high capital costs, require a high rat production, they should be provided with auxiliary steam plants capabl carrying the whole load, even though the water power has a good record dependability.

**324. Use of steam in textile processes.** Nearly all textile mills n use steam at some point in the manufacturing process, and for heating buildings in winter. A boiler plant is therefore essential and it gener follows that one or more engines are employed to deliver their power to water-wheel shaft, the engine governor caring for the variations of load. such cases a portion of the steam power may be developed by simple eng operating against small back pressure, the exhaust instead of live st being used for certain processes; or steam may be taken from the receive a compound engine is used. If turbines are the prime movers, the blee type may be used to furnish the necessary amount of low-pressure ste In cotton mills the most common use for steam (aside from heating buildi is in the slashers, which require a small amount steadily through the d Woolen and worsted mills use steam for scouring, drying, back washing combing. Finishing mills, which may form a part of either cotton or wo mills, use steam for numerous purposes such as heating water, rolls, pla etc.

**325. Application of electric drive.** Existing water wheels and st engines can be made to drive generators, and even though the units scattered, the control may be from a central point. In general the lo in textile mills are steady, and there should be close speed regulation. E tric drive is in general superior from the standpoint of speed regulati aside from the advantages of flexibility and cleanliness.

**326. Group and individual drives.** In all kinds of textile mills anyth that scatters dirt, lint, flecks, etc., becomes more of a nuisance as the go produced become finer, for the finer textures reveal the foreign substa more plainly, and, being imperfect, are less valuable. In determini therefore, whether to use individual drives or group drives, the presence belt becomes a deciding factor.

**327. Type of motor adapted to textile mills.** While for many reas the direct-current motor meets the demands of the textile mill, the presenc more or less lint in the air makes the induction motor preferable. At the of a day's run individual machines are disconnected from the drive, so t their motors will have but small starting loads; usually the totally enclo squirrel-cage type is well adapted to the work. To eliminate a possible va tion of speed dependent upon variable slip, a group arrangement may employed where the constituent machines are either little affected by sm changes in speed, or have constant loads. It is well to use only enclosed switches. Inasmuch as starting conditions are favorable there is often opp tunity to use synchronous motors, if the power-factor is low, either on same line-shaft with squirrel-cage motors, or in separate units.

**328. Cotton-mill cards** may be run in groups, belted from above below.

**329. Cotton-mill fly frames** are driven from one end and may be arranged that by means of extended shafts and two pulleys on each end of motor, four frames may be driven by one motor. As these machines can

Digitized by Google

topped individually, doffing and empty bobbin replacing may be accomplished without stopping more than one frame at a time. Ring spinning and twisting may well be treated similarly to fly frames, although here again individual motors may be used.

**330. Looms** are perhaps the most susceptible to power variations of any textile machinery. The power to drive a loom varies with the speed of the loom, usually expressed as so many picks per min., a pick being one strand of filling left in the warp by a traverse of the shuttle. While there are so-called positive shuttle looms, most shuttles are thrown across the lay of the loom by a blow of the picking stick. As the shuttle enters the box at the end of its traverse, it pushes out one side of the box, called the swell, which operates a stop motion; when the shuttle does not properly enter the box, the swell is not displaced and this is called "banging off." The speed of the shuttle must therefore be sufficient to accomplish this, yet not so much as to cause rebound. The adjustments vary with the speed. The power to drive a loom also varies with the weight of goods, the start-up, the number of harnesses and boxes in use.

**331. Advantage of motor drive for looms.** Overhead shafting and belts are objectionable on account of the damage likely to occur from flying lugs, oil, etc. As looms must be stopped and started continually, and as they start under full-load immediately, belts in weaving rooms require much attention if high efficiency is to be maintained. The shafting can be put below the floor, and long lines reduced by group drives, but the belt from shaft to loom remains. The individual motor obviates practically all of these troubles. It may be arranged to drive through a clutch or be geared directly to the loom. In the first case the motor is kept running all the time, while in the second case it is started and stopped with the loom. The shipper handle of the loom is connected with the control switch of the motor, so that the operative has nothing new to learn. A direct-connected motor must start instantly with full-load torque. The induction motor with small slip has, then, an advantage over belted drives in cleanliness and in constant speed. **Variations in angular velocity** are undoubtedly less in the case of direct electric drives than with belted drives, as shown by tachometer readings.

**333. Automatic loom economies.** It should be remarked that with the increase of automatic looms the necessity for frequent stopping and starting decreases. Automatic looms have increased production from, say 80 per cent. to 95 per cent., or even 98 per cent., but as yet they are not generally used except by plain-goods mills. However, their use in fancy-goods mills is increasing.

**334. Woolen and worsted mill drives.** Scouring bowls, which extend to considerable length, are satisfactorily driven by several overhead motors. These rooms are damp and the air is vapor laden. Pickers and cards may be driven in groups. Mules are usually set in pairs, and one motor may drive each pair. Combs, gill boxes and roving machinery, whether for Bradford or French systems, may be driven in groups. Cap, ring or flyer spinning frames may be arranged as for cotton ring frames, that is, four frames may be driven by one motor.

**335. Manufacture of woolen and worsted yarns.** Both woolen and worsted yarns are supposedly made of wool, but other fibres are often mixed with the wool. In general woolen yarn is made of short fibre and worsted of long fiber. Furthermore, in woolen yarn the fibres are made to lie in a variety of angles with reference to the axis of the yarn, for ultimately the fabric is fulled or felted. The finisher card doffs narrow strips of the carded fibre, passing them between rub rolls or aprons (or tape condenser), which, while carrying the roping along, rub it into cylindrical shape. Forty or more of these ends are wound on jack spools and are made into yarn by the mule. The tendency of the mule is to throw one end of each fibre to the outside of the yarn, while holding the other end in the centre, that is, the shape of the fibre is helical.

With worsted, the fibre is combed after carding, to remove the short fibres or noil. Then follow the processes of gilling and drawing, each of which makes the fibres more and more parallel, just the reverse of the woolen process. The Bradford worsted system converts the roving into yarn by means of the spinning frame, either cap, ring or flyer. The French worsted system starts with the "top," essentially the sliver, carded, combed and gilled, wound into about 8-lb. balls. There is no twist in the sliver, and by the French process no twist is put in until the final or spinning process. In this case a mule is used which is much like the cotton mule, which keeps the fibres smooth and parallel.

# PAPER AND PULP MILLS

**BY JOSEPH H. WALLACE**

*Industrial Engineer, Member, American Society of Mechanical Engineers*

**338. General application.** Motors are generally well adapted for driving pulp- and paper-making machinery where the source of power is steady and reliable and will insure continuous operation of the plant. The choice of the grouping method (group drive), or the assembling of several machines to be driven by one motor through shafting and belting, and the unit method (individual drive), or the driving of each machine by its individual motor, will be determined by local conditions of layout and the probability of one or more machines in a group requiring operation while others in that group are shut down. Where machines can be assembled in groups that are easily served by short lines of shafting, the grouping method is more often to be preferred. The motor units then become larger, and being fewer in number, installation and maintenance costs are reduced, and speed reductions are more easily secured without the use of countershafts or gears. The unit method is preferable in case of large machines or where direct-connected apparatus can be used, and in places where points of power demand are scattered and would involve long lines of shaft to group the machines together. It affords convenience in locating machines in places desirable from the operator's standpoint, and is preferable where individual control of machines is frequently required.

**339. Equipment adaptable to motor drive.** In the equipment of paper and pulp mills specially suited to motor-drive can be included the following: flat and centrifugal screens, stuff pumps, suction-box pumps, white-water and effluent pumps, water-supply pumps, winders, rewinders, cutters, refining engines, elevators, exhaust fans, kollergangs, agitators, mixers, slushers, concentrators, savealls, wet machines, rotary digesters, rotary boilers, conveyors, shredders, chippers, supercalenders and beaters.

**340. Jordan engines.** The application of motors for driving Jordan engines is very successfully accomplished by direct connection. The motor is mounted on an extension of the Jordan base, and mechanical arrangements provided for the movement of the Jordan plug either by a coincident movement of the motor, or by a special form of coupling connecting the motor with the Jordan shaft. In the refinement of paper stock much depends upon the pressure put upon the Jordan plug as it rotates within its shell or casing. The power required is influenced by the pressure applied, and a good indication of what the refiner is doing is presented by the readings of a wattmeter placed in the feeder circuit to the motor. When power-factor correction is necessary or desirable, the direct-connected Jordan engine presents an excellent opportunity for attaching a synchronous motor large enough to provide for the required condensing effect. Jordan engines are started without the working load applied, and the friction load is usually within the capacity of self-starting synchronous motors.

**341. Beaters.** The question of driving beaters and other large units electrically will be largely affected by the elements entering into the generation of energy. Beaters are usually grouped, and driving can be economically accomplished through main line shafting. Considerable quantities of power are required within comparatively narrow limits, and conditions are often in favor of steam engine drive instead of motor drive, where the power can be developed in efficient slow-speed compound condensing steam engines located in close proximity to the beater room. This method is especially favorable where electric power is generated with steam-driven equipment. Mills deriving electric power from hydroelectric plants can usually adopt the motor drive for beaters with success.

**342. Fourdrinier and cylinder paper machines** that require variable speed, and steam for drying purposes, are driven best by variable-speed steam engines, using the exhaust steam for drying the paper. Pulp grinders are seldom driven by electric motors; the power requirements are so great that the method almost invariably accepted as the best is to attach the grinders direct to a water-wheel shaft.

**343. Types of motor suitable.** In general polyphase alternating-current (induction) motors give the best satisfaction in pulp and paper mill service where constant speed is desired. In cases where variable speeds are

Digitized by Google

required from the same motor, or where smooth and even accelerati desired in starting, as in the operation of supercalenders, direct-cu motors can be employed to advantage. In other cases the alterna current motors will be lower in first cost, more reliable for contin operation, and lower in cost of maintenance. It is possible to use moto higher voltage with alternating current than with direct, resulting reduction in cost of transmission and distribution circuits. Indu motors wound for 2,200 volts are frequently used in units of 75 h.p. and For smaller size motors, 440 volts is usual and for lighting 110 volts i generally accepted standard; 550 volts is quite as common and is consid more desirable than 440 by the author. Step-down transformers are con ient for lowering the voltage, and require a minimum amount of atten Three-phase alternating-current has been found to be most adaptable to eral uses in paper-mill work. With unity power-factor, the amount of co required for distribution of energy will be about 25 per cent. less than required by direct-current of equal voltage. The absence of commut on induction motors is a decided advantage from an operating standp and where slip-ring induction motors are provided with brush-lifting short-circuiting devices, the element of fire hazard due to arcing disapp A frequency of 60 cycles per sec. has been generally adopted as stan in the United States and Canada for paper- and pulp-mill practice, altho 25 cycles is sometimes used where considerations outside the influence of pulp- or paper-mill proper demand attention; 50 cycles is the accepted st ard in Great Britain, and in some of the European countries.

**344. Motor characteristics.** Induction motors with short-circu rotors of the squirrel-cage type can be well recommended for most appl tions to paper-mill machinery where the units require a small amoun power, ordinarily under 50 h.p., or in larger sizes when the motor ca started and brought up to full speed under a light load. The startin large squirrel-cage motors draws heavily on the supply lines, and the selec of large units of this type of motor should be influenced by the size of power-plant supplying energy to such motors. Unless the generating p has large capacity compared with the size of the motor units to be star the heavy draft of energy will lower the voltage sufficiently to affect o motors that may be in operation. In order to overcome the limitation squirrel-cage motors in the larger sizes, motors of the wound-rotor or ring type may be used. These are desirable when motors require star under full-load, when the units are large, or when automatic or remote con of motors is necessary. Synchronous motors are desirable in cases where required starting torque is low, for the beneficial effect that they h on the power-factor; when of larger capacity than the actual requ ments for power, they can be used to raise a low power-factor. They suitable for direct-connection to Jordan engines, and for motor-generat but full consideration must be given to the available generator capa supplying them, as their starting characteristics are similar to those of squirrel-cage induction motors.

**345. Switching equipment** should be selected with great care, motors should be provided with some form of automatic protection aga overload. Fuses are often found to be unsatisfactory, and in large s are expensive for renewals. Oil-immersed switches fitted with overload low-voltage release are much preferred for pulp- and paper-mill installati

**346. Specifications** for motors to be used in pulp and paper mills sho call for heavy-duty machines. Form windings are to be preferred and squirrel-cage motors special attention should be given to the method attaching the rotor bars to the short-circuiting rings. Moisture-pr insulation in windings is important. Motors should be rated for a tempe ture rise not exceeding 40 deg. Cent. (104 deg. Fahr.) for continuous op tion and be capable of carrying 25 per cent. overload continuously with injurious heating.

**347. Standardization of sizes,** speeds and types is to be recommen when a considerable number of motors are required in the same mill. Sta ardization will result in reduced number of repair parts and will often fa tate the interchange of motors in case of repairs.

**348. Power required by paper- and pulp-mill machinery will v** through wide limits, oftentimes on the same machine. This is especi

Digitized by Google

true in the case of beaters and Jordans, when a variety of product is made in the same mill. Loads will frequently vary 100 per cent. in the treatment of different stocks, and the most careful judgment is required in the selection of motors that will meet the maximum demand, as this condition may exist for much longer periods than the overload capacity of a motor for the average load would allow.

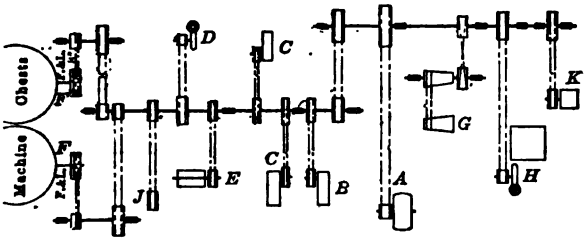

FIG. 36.

| Table of load variations | | | | |
|---|---|---|---|---|
| Kw. input | Amp. per phase | Volts | Power-factor | B.h.p. (motor efficiency, 90 per cent.) |
| 18.0 | 43.0 | 440 | 0.55 | 21.7 h.p. |
| 27.0 | 45.0 | 440 | 0.79 | 32.5 h.p. |
| 29.0 | 46.5 | 440 | 0.82 | 35.0 h.p. |
| 33.5 | 51.2 | 440 | 0.86 | 40.4 h.p. |
| 36.0 | 53.8 | 440 | 0.88 | 43.4 h.p. |

**351. Test on Jordan engine (Imperial size)** direct-connected to 100-h.p. induction motor. Full-load speed 330 rev. per min.

| Kw. input | Amp. per phase | Volts | Power-factor | B.h.p. (motor efficiency, 87 per cent.) |
|---|---|---|---|---|
| 103.42 | 159.25 | 470 | 0.8 | 120.5 h.p. |

Test was made on this machine for friction load, which showed an input of 10.6 kw. As the motor efficiency was low at this load, the friction load can be taken from 10 to 12 b.h.p.

**352. Test on Jordan engine (Majestic size)** direct-connected to 150-h.p. induction motor. Full-load speed 330 rev. per min.

| Kw. input | Amp. per phase | Volts | Power-factor | B.h.p. (motor efficiency, 91 per cent.) |
|---|---|---|---|---|
| 114.4 | 191 | 440 | 0.79 | 139.5 h.p. |

A test on this motor at another time showed an input of 135 kw. or approximately 163 b.h.p. *The power consumed in Jordan engines will vary greatly in different mills and under various treatment of stock.* A test was made by the author on a Jordan engine of exactly the same size (Majestic) as that of the above test, which was direct-connected to a 200-h.p. induction motor, with the following results:

Full-load speed 350 rev. per. min.

| Kw. input | Amp. per phase | Volts | Power-factor | B.h.p. (motor efficiency, 89 per cent.) |
|---|---|---|---|---|
| 240 | 70 | 2,250 | 0.88 | 286.3 h.p. |
| 235 | 68 | 2,260 | 0.88 | 280.4 h.p. |
| 220 | 64 | 2,280 | 0.87 | 262.5 h.p. |
| 200 | 60 | 2,240 | 0.86 | 238.6 h.p. |
| 180 | 54 | 2,270 | 0.85 | 214.8 h.p. |
| *12 | 18 | 2,240 | .... | 11.25 h.p. |

**353. Test on induction motor driving slitter and winder for 186-in. Fourdrinier paper machine.** Friction load, 3 h.p.; winding load, 14.5 to 31 h.p.

**354. Test on beaters, etc.** Wattmeter observations made at a mill where four 1,500-lb. Horne beaters, agitator in stuff chest, and 10-in.×12-in. triplex stuff pumps were driven through a short line of shafting from one motor, showed that 300 h.p. was required when beating strong sulphate pulp.

* Test on friction load, engine running full speed with plug drawn out and no stock passing through.

Digitized by Google

**355. Summary of approximate power required by paper-making machinery**

| | | | |
|---|---|---|---|
| Constant speed line or pump line on paper machine | 40–125 h.p. | Stuff pumps | 5– 10 h.p. |
| Fourdrinier paper machines (variable speed parts) | 50–400 h.p. | Chippers | 75–100 h.p. |
| Beaters | 30– 75 h.p. | Crushers | 25 h.p. |
| Jordan engines | 50–300 h.p. | Barkers | 10– 12 h.p. |
| Screens, flat plate screens | 4– 6 h.p. | Grinders | 250–350 h.p. |
| Wet machines | 8– 12 h.p. | Centrifugal screens | 10– 15 h.p. |
| | | Supercalenders | 50–100 h.p. |

## PRINTING, BINDING AND LINOTYPE MACHINERY

BY CHARLES E. CARPENTER

*Engineer, Cutler-Hammer Manufacturing Co., Associate American Institute of Electrical Engineers*

**350. Control.** There is a rapidly growing tendency among the manufacturers of printing machinery to equip their motor-driven machinery with self-starters and self-starting, predetermined-speed-adjusting controllers, operated either directly from the line (service) switch or by the operation of one or more push-button or hand-control stations.

**357. Job or platen presses,** from the smallest to the largest size, on account of their large inertia, require a motor much larger to start than to operate them. In the following table the motor sizes are ample, although under normal printing conditions the machines require about half the rated motor horse power, or even less. The best practice is to obtain about 40 per cent. speed reduction below normal by armature resistance and about 25 per cent. increase above normal by field control. This is accomplished by the use of a predetermined-speed-adjusting self-starting controller, usually supplied with a self-contained line switch for starting and stopping (Fig. 38).

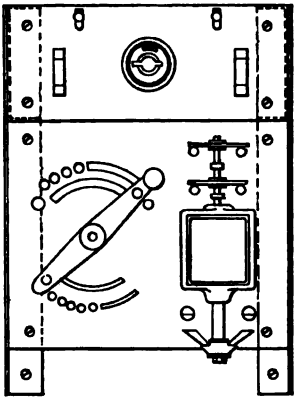

FIG. 38.—Starter-controller with self-contained line switch.

**358. Power required by job or platen presses**

| Size: inside chase | Maximum impressions per hr. | H.p. |
|---|---|---|
| 8 in. × 12 in. | 2,800 | 0.25 |
| 10 in. × 15 in. | 2,500 | 0.25 |
| 12 in. × 18 in. | 2,250 | 0.33 |
| 13 in. × 19 in. | 2,100 | 0.33 |
| 14 in. × 20 in. | 2,000 | 0.50 |
| 14½ in. × 22 in. | 2,000 | 0.75 |
| 17 in. × 22 in. | 1,700 | 1.00 |
| Automatic feed, high speed | | |
| 13 in. × 19 in. | 3,500 | 1.5 |

Digitized by Google

**359. Flat-bed cylinder presses,** on account of the reciprocating motion which results in unsteady load conditions, should be belt driven with a compound-wound motor. A self-starting predetermined-speed-adjusting controller is recommended, with a dynamic brake, giving at least 35 per cent. speed variation by field control and about 50 per cent. speed variation by armature control (Fig. 39); this can be operated from the feed board by one push-button station, from which operator can "stop," "inch" and "run" to predetermined speed. In the case of single-color presses one push-button station for the delivery end of the press is arranged for "stop" and "safe." In the case of two-color presses a push-button station at each end of the press should be employed for "stop" and "safe." Where reversal is required, a station combining push-button control with interlock spring-returned reversing lever is recommended.

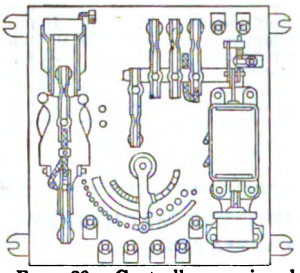

FIG. 39.—Controller equipped with time-acceleration starter and dynamic brake.

**360. Power required by flat bed presses**

| Size of bed | Maximum impressions per hr. | H.p. |
|---|---|---|
| **Single color—one cylinder** | | |
| 26 in. × 34 in. | 2,700 | 1.5 |
| 27 in. × 35 in. | 2,600 | 2.0 |
| 28 in. × 41 in. | 2,400 | 2.5 |
| 31 in. × 42 in. | 2,400 | 2.5 |
| 32 in. × 44 in. | 2,400 | 2.5 |
| 34 in. × 48 in. | 2,300 | 3.0 |
| 35 in. × 50 in. | 2,200 | 3.5 |
| 39 in. × 53 in. | 2,200 | 4.0 |
| 43 in. × 56 in. | 2,000 | 4.5 |
| 46 in. × 62 in. | 1,700 | 5.0 |
| 46 in. × 68 in. | 1,700 | 6.0 |
| 51 in. × 74 in. | 1,600 | 7.5 |
| **Two color—two cylinder** | | |
| 43 in. × 56 in. | 1,700 | 9 |
| 46 in. × 62 in. | 1,600 | 10 |
| 52 in. × 65 in. | 1,500 | 12 |
| 52 in. × 67 in. | 1,550 | 15 |

**361. Rotary lithographic presses** require variable-speed shunt-wound or interpole motors, preferably with belt drive, having at least 50 per cent. speed variation by field control and 40 per cent. by armature control, and should be used in connection with a self-starting, predetermined-speed-adjusting controller equipped with a dynamic brake (Fig. 39). One push-button station should be located near the control levers of the automatic-feed press for "stop," "inch" and "run," and in case of the hand-fed press this station should be located at a point convenient to the feeder on the side of the press; also one push-button station for "stop" and "inch" located near the rollers, to be used when washing up and making ready; and one "stop" and "inch" station on the side of the

Digitized by Google

near the floor, convenient for operation from a point beneath the press. Where automatic feeders are used, a "Feeder clutch switch" should be attached to the clutch rod for automatically slowing down the press when the feeder clutch trips, and for automatically accelerating the press back to its predetermined speed when the feeder clutch rod is again thrown in, thus eliminating the necessity for operating push buttons or other starting devices. Reversal is only an occasional performance, and a double-pole two-way knife-blade switch for reversing the armature connections can be placed under the running board.

**362. Power required by rotary lithographic presses**

| Size of sheet | Normal impressions per hr. | H.p. |
|---|---|---|
| **Zinc or aluminum** | | |
| 32 in. × 45 in. | 2,000 | 4 |
| 42 in. × 53 in. | 1,800 | 5 |
| 45 in. × 65 in. | 1,500 | 5 |
| 50 in. × 65 in. | 1,400 | 5 |
| **Offset** | | |
| 22 in. × 28 in. | 4,000 | 2 |
| 26 in. × 34 in. | 3,000 | 3 |
| 30 in. × 42 in. | 2,800 | 4 |
| 34 in. × 46 in. | 2,500 | 5 |
| 38 in. × 52 in. | 2,400 | 6 |
| 44 in. × 64 in. | 2,000 | 10 |

**363. Rotary typographical presses** (not newspaper presses) are divided into two classes, sheet-feed rotaries and magazine rotaries. The sheet-feed rotaries range in power requirements from 5 h.p. to 10 h.p., and require non-reversing self-starting, predetermined-speed-adjusting push-button controllers, similar to those for rotary lithograph presses. On account of the high speed at which these presses are operated, it is essential that they be equipped with a very efficient quick-acting dynamic brake to prevent damage to the plates, etc., in case the feeder trips out for any cause. Magazine rotaries require from 7.5 h.p. to 25 h.p. motors, used in conjunction with push-button controllers. The smaller size may be used with a predetermined-speed-adjusting controller, Fig. 39, but a better equipment, especially for larger presses, would be a controller where the press may be accelerated or retarded from several interlocking (safety) push-button stations.

**364. Embossing presses** of various sizes require moderate-speed compound-wound motors from 1 h.p. to 15 h.p., arranged with from 25 to 50 per cent. field (speed) control, and should be used in connection with a self-starting predetermined-speed-adjusting controller without dynamic brake, controlled from one or two push-button stations for "run, stop and inch."

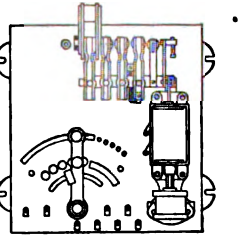

FIG. 40.—Controller for large folders.

**365. Folders** of the type generally used in printing offices require moderate-speed shunt-wound motors from 0.5 h.p. to 3 h.p., with combined armature and field control; 20 per cent. field (speed) control and 50 per cent. armature control may be considered good practice for ordinary requirements, without dynamic brake. For 0.5 h.p., 0.75 h.p. and 1 h.p. sizes the controller shown in Fig. 38 should be used; this may be controlled from the line switch. For larger sizes the controller shown in

Digitized by Google

Fig. 40 may be used; this should be provided with one or two push-butto stations for "run," "stop," and "lock-open" for "safe" while working in th machinery.

**366. Paper cutters** require compound-wound motors of moderat constant speed, from 0.5 h.p. to 7.5 h.p. capacity, in connection with a sel starter with self-contained line switch and fuses located directly on th machine. The motor is started and stopped by closing and opening the lin (service) switch. On account of the heavy fly-wheel, the self-starter shoul be adjusted for about 15 sec. acceleration.

**367. Linotype and monotype machines,** have a 14-in. × 2-in. drivin pulley and require a motor of 0.25 h.p. suitable for 15 per cent. speed increas above normal. The controller should be a single-step self-starter wit field (speed) regulation, operated by a double-pole rotary snap switch situate within reach of the operator. Linotype machines require slow-speed or back geared motors, operating at 400 rev. per min., either belted or geared t the main drive shaft, which operates at about 64 to 72 rev. per min., wit field control. Monotype machines have a driving shaft speed of 140 to 16 rev. per min., while the motor speed may be about 850 to 1,000 rev. per min A flat-face pulley is used for shifting the belt, permitting of automatically shutting off the power in case of an exhausted template or a misplaced cast etc. Compressed air at 15 lb. per sq. in. is also required, either from a mai source of supply, or from an individual compressor requiring not over 0.5 h.p Owing to the presence of flying particles of type metal, motors should b protected by fine gauze screening.

## FLOUR MILLS

### By JOHN F. HARRISON

*Manager, Milling Machinery Dept., Allis-Chalmers Manufacturing Co.*

**368. Drive.** While a flour mill contains many separate machines, these machines must run as a unit, and it is not profitable from a commercial standpoint to drive each machine with a separate motor.

**369. Machines included.** A flour mill may be considered divisible as follows: (a) The roller mills or grinders; (b) bolting and purifying machinery, lofting elevators, conveyors and all the machinery in the mill proper above the roller floor; (c) the wheat cleaning department, and in the larger mills the wheat receiving machinery; (d) on navigable water, the marine leg. All the car pullers, passenger and freight elevators are operated from separate motors.

**370. Types of motors.** For the main driving motor in a flour mill, where as much as 700 h.p. is concentrated in a single motor, a wound-rotor slip-ring induction motor with a secondary resistance starter is recommended. The equipment should also include a primary panel containing an oil switch with overload and no-voltage trips, in order to protect the motor from excessive overloads or from failure of voltage on the supply line.

The smaller motors throughout the mill may be of the squirrel-cage type of induction motor, equipped with a potential starter or compensator.

**371. Power requirements.** The total power required to operate a mill having a capacity of 3,500 bbl. in 24 hr. will be approximately 0.4 h.p. per bbl. or 1,400 h.p. for the complete plant. This can be increased 10 per cent. in mills making only 100 bbl. or less per day. The power required for a flour mill varies considerably, depending on the condition of the wheat and the fineness of the flour to be produced, as damp or tough wheat or close milling require increased horse power. The hard varieties of spring wheat require more power than the soft varieties of winter wheat.

For an entire mill requiring 1,400 h.p., the wheat-cleaning department would consume one-fourth of this amount, or 350 h.p.; the roller mills one-half, or 700 h.p.; and the bolting machinery, which includes the sifters, purifiers, bran and shorts dusters, suction fans, elevators and conveyors, would require one-fourth, or 350 h.p.

## BEET-SUGAR MILLS

**BY WIRT S. SCOTT, M.E. IN E.E.,**

*General Engineer, Westinghouse Elect. and Manufacturing Co., Member, American Institute of Electrical Engineers*

**373. Power requirements.** With electric motors properly applied, the total power consumption should not be over one-half of that required for steam-engine-driven factories. The machines of the types mentioned in Par. **374** to **392** inclusive, vary in size according to the individual requirements, but the examples cited will serve as a guide as to the average practice.

**374. Beet lift.** Sixteen feet diameter by 2 ft. wide, with 33 buckets 12 in. deep, making 4 rev. per min., driven by pinion meshing with 8 ft. gear on lift; 10 h.p. required, at constant speed, with high starting torque.

**375. Beet washer.** Six feet diameter by 18 ft. long, with thirty-two 24-in. arms or paddles. Shaft makes 14 rev. per min.; 7.5 h.p. required, at constant-speed and with a moderate starting torque.

Digitized by Google

**376. Beet elevator.** Thirty-four buckets, 22 in. wide by 17 in. deep, V-shaped; 70 to 120 ft. per min.; 10 to 20 h.p. required, at constant speed, with moderate starting torque.

**377. Beet slicer.** Capacity 50 tons per hr., 55 rev. per min.; 25 h.p. required, at constant speed, with high starting torque.

**378. Cossette conveyor.** Capacity 60 tons per hr., belt 12 in. wide by 125 ft. long; belt speed, 250 ft. per min.; 5 h.p. required, at constant speed, with light starting torque.

**379. Sugar mixers.** Shaft 50 ft. long, 12-in. paddles, speed 1.5 rev. per min.; 10 h.p. required, at constant speed, with moderate starting torque.

**380. Tube mill or granulator;** 6 ft. diameter by 30 ft. long, 10 rev. per min.; 10 h.p. required, at constant speed, with high starting torque.

**381. Bagging machinery.** Bag-sewing machine, requires 2 h.p.; bag stacker, requires 3 h.p.

**382. Pumps.** Hydraulic gasket pump, for operating doors on bottom of diffusion batteries, requires 5 h.p. Carbonation pump, 450 gal. per min., 50 lb. pressure, requires 25 h.p. Thick juice pumps, 450 gal. per min., 30 lb. pressure, requires 10 h.p.

**383. Crystallizers.** Ten feet diameter by 16 ft. long; paddles 4.5 ft. long secured to driving shaft which makes one revolution in 5 min. The power required varies considerably during the cycle of operation, the amount required at the completion of the operation being almost double that required at the start. For this reason the machines are best driven in groups of from four to eight, by one motor. For driving an individual machine, from 2.5 to 3 h.p. is required at the beginning of the cycle, and 5 h.p. at the end. Since the complete operation may require 60 hr., a motor must have sufficient capacity to operate at maximum capacity continuously, with individual drive. Where crystallizers are driven in groups of from four to eight machines, 3 h.p. per crystallizer will be sufficient.

**384. Centrifugals.** The sugar centrifugal is one of the most important machines in sugar making, the operating conditions of which are very severe due to the inertia of the load and the cycle of operation. The time required for the complete spinning process varies with the grade of sugar. Ordinarily one man can operate two centrifugals on granulated sugar and up to four centrifugals on white sugar. When these machines are to be individually driven the cycle of operation must be known, as the rating of the motors will depend upon the root-mean-square value of the power requirements, and the torque required for accelerating in a given time.

**385. Average cycle of operation of group-driven centrifugals with fine granulated sugar.** The average time required is as follows: filling, one-fourth speed, 30 sec.; accelerating, one-fourth to full speed, 10 sec.; full speed, 120 sec.; power off, retarding by braking, 20 sec.; revolving at about 25 rev. per min., 30 sec.; total time, 3 min., 30 sec.

**386. Average cycle of operations of individually driven centrifugals with fine granulated sugar.** Filling basket, revolving by hand, 10 sec.; accelerating, 100 sec.; full speed, 30 sec.; power off, retarding by braking, 20 sec.; stop, unloading by hand, 60 sec.; total time, 3 min. 40 sec.

**387. Average cycle of operations of individually driven centrifugals with coarse granulated sugar.** Filling basket, revolving by hand, 10 sec.; accelerating, 60 sec.; power off, retarding by braking, 20 sec.; stop, unloading by hand, 60 sec.; total time, 2 min. 30 sec.

**388. Average cycle of operations of individually driven centrifugals with coarse white sugar.** Filling basket, 25 sec.; accelerating, 100 sec.; full speed, 15 min.; power off, braking, 30 sec.; stop, unloading by hand, 145 sec.; total time, 20 min.

**389. Group-driven centrifugal machines** furnish a very satisfactory arrangement, whereas individual drive, although successful, has been used to a much lesser extent. The character of the load is very similar to that of a fly-wheel, so that with these machines arranged in a group and driven by one motor, the centrifugals in operation will help to bring the idle machines up to speed and maintain a uniform load on the motor. This can best be

Digitized by Google

shown by the following data. A group of ten 40-in. centrifugal machines, driven by a 100-h.p. motor, with 1 machine starting, requires 20.5 h.p.; with 2 machines starting, and 1 at full speed, 40 h.p.; with 3 machines starting, and 3 at full speed, 52.5 h.p.; with 4 machines starting, and 4 at full speed, 60 h.p.; with 1 machine at full speed 5.5 h.p.

**390. When centrifugals are individually driven,** the peak load is about eight times the normal running load; for a 40-in. machine the peak is approximately 40 kw. input, corresponding to about 40 h.p. output. Since at the very start the speed is zero, the horse power is zero, therefore the power required at start should be stated in terms of pounds torque at 1 ft. radius. The starting torque, together with the root-mean-square horse power for the cycle, furnishes sufficient data for determining the motor required.

**391. The speed of a direct-connected centrifugal machine** increases very rapidly at the start and at a much lower rate as the motor approaches synchronous speed. The motors are usually of the squirrel-cage type with high-resistance end rings designed to give approximately 15 per cent. slip at full-load; but, since full-load is never attained except at starting, the maximum speed which can be attained by the centrifugal is almost synchronous speed, and in nearly every case the operation is completed before the machine has attained its highest possible speed.

**392. The torque necessary for starting a loaded centrifugal machine,** and accelerating it to a given speed in a certain length of time can be determined by the following formula:

$$T = 2\frac{Wr^2}{g} \times \frac{2\pi N}{60 \times S} \qquad \text{(ft-lb.)} \qquad (8)$$

$T$ = pounds torque at 1 ft. radius, $W$ = weight in lb. to be accelerated, $R$ = radius of gyration of entire mass in ft., $N$ = rev. per min. machine will attain in $S$ seconds, $S$ = seconds required for accelerating.

The above expression does not take into consideration friction and windage, and it will be necessary to increase the result thus obtained by 10 per cent. in order to obtain the required starting torque.

## LAUNDRY MACHINERY

**BY FRITZ BALZER**

*Mechanical Engineer, Troy Laundry Mach'y Co. Ltd.; Member, American Society of Mechanical Engineers; Member, Verein Deutscher Ingenieure*

**393. Advantage of electric drive.** The power laundry with its large number of different machines can employ electric drive to great advantage. The elimination of belts reduces the friction load of the plant, permits the convenient location of the different machines to reduce handling expenses, assures cleanliness and light, reduces danger of accidents and finally decreases the operating cost. From a number of tests all over the country this saving in operating cost appears to be from 25 to 30 per cent. Alternating-current polyphase induction motors are recommended wherever possible.

**394. Use of steam in processes.** When introducing electric drive in any laundry it must be kept in mind that a laundry requires a large amount of steam for drying and for the heating and boiling of water. This question is important in the controversy regarding the generation of electrical energy versus its purchase from a central station. In the latter event, steam must be produced independently of the source of power. A careful study of conditions must be made in order to determine which method is the more economical.

**395. Classification.** Laundries may be divided into three groups: (a) those doing family work only; (b) institution laundries (hotels and hospitals); (c) laundries doing railroad or steamship work only. Each of these groups has a different requirement for steam in amounts which can be expressed in terms of the horse-power requirements. Thus, for group (a) the number of pounds of steam used per hr. could be expressed as 1.2 times the horse power for that group; for group (b) 1.4 times the horse power; and for group (c) 1.8 times the horse power.

Digitized by Google

**396. Method of drive.** Group-drive of laundry machines is, generally speaking, not desirable, for the reason that the groups must contain machines which are not in constant use, and therefore the operating expense could not be reduced as satisfactorily. The table below gives the machine groups in their proper sequence for the three classes of work done in the laundry.

| Flat-work group | Starched-work group | Rough-dry group |
|---|---|---|
| Washers.<br>Extractors.<br>Tumblers.<br>Flat-work ironers. | Washers.<br>Extractors.<br>Starchers.<br>Dryrooms.<br>Dampeners.<br>Ironers and finishing machines. | Washers.<br>Extractors.<br>Dryroom-tumblers. |

All machines enumerated above should be placed on one motor, unless a laundry makes a specialty of one particular class, and does work in the other classes only a part of the time. In the latter case it is advisable to place all machines, which are frequently used, on one motor, and to group the others as outlined above. The load factor is between 40 and 45 per cent. Individual drive is recommended wherever possible, and the data in the following paragraphs refer to this class, unless otherwise stated.

**397. Washers** consist of a stationary outside shell, inside of which revolves a cylinder. The goods are placed therein and subjected to the action of the wash solution. To prevent tangling of the wash it is necessary that the cylinder alternate its direction of rotation. This reversing action is obtained in various ways, which are described in Par. **398** to **402**. The load characteristic is different with each application and each case will therefore be treated separately. The cylinder should make from seven to twelve reversals per min., and in order to get the best results the surface speed of the cylinder should always be near 280 ft. per min. From a number of tests which have been made it appears that for every cubic foot of cylinder space the following power is required:

32 in., 0.04 h.p.; 36 in., 0.05 h.p.; 42 in., 0.06 h.p.

**398. The power required by washers** of standard size can be expressed as follows: 32 in.×46 in., or smaller, 1.5 h.p.; 36 in.×54 in., or smaller, 2 h.p., 36 in.×70 in., or 42 in.×54 in., or smaller, 3 h.p., 42 in.×70 in., or smaller, 5 h.p. These figures check quite well with the empirical data given in Par. **397**.

The cylinders may have either of two kinds of perforations, the plain round embossed hole or the turbine slots; of these the latter require about 20 per cent. more power than the former, but are frequently used on account of the attendant saving in time and supplies.

**399. Washers with belt reverse** require either enclosed direct-current motors, having a 25 per cent. compound winding, or alternating-current polyphase motors with high-resistance rotors. The motors are mounted on a bracket on top of the washer, and the usual speed is 1,800 rev. per min. The use of a fly-wheel will add materially to the efficiency of the drive. The load factor is 65 per cent. A disadvantage arises through the necessity of using very short belts, with a consequent large loss of power. The washers also are topheavy, and since the motor is fully enclosed, it must be larger than would otherwise be necessary.

**400. Washers with reversing motors.** Reversing motors applied to washers are probably the best for the purpose, but their success depends upon the method of control used. In these installations the motor is usually mounted on a bracket attached to the machine, for gear drive.

**401. Timers for reversing washer motors.** An auxiliary motor for timing is sometimes used to drive one or more controllers, which are constantly rotating and making the proper connections with the individual motors. Individual and mechanically operated timers are also used, the timer being actuated by the revolutions of the cylinder axle; this timer operates a

Digitized by Google

suitable double-throw switch, which makes and breaks connections with two relays of a contactor panel. The switch is so arranged, as to disconnect the relay between reversals, in order to allow the contactors to open the main circuit and permit the motor to slow down. The load factor of this group varies between 55 and 60 per cent.

**402. Mechanical reversing devices for washers** are best suited for group drive from one shaft by gear or chain. The reversals are obtained by clutches attached to two bevel gears which are driven by a third gear. The washer is so arranged that connection is shifted from one clutch to the other clutch. Three 36-in.×70-in. washers require one 7.5-h.p. motor of 900 rev. per min. Other sizes may be calculated from the data given above. The load factor is 75 per cent.

**403. Extractors** are machines employed to remove the water from the goods after washing. This is done by placing the pieces in a perforated basket and revolving the basket at a very high speed, whereupon the water is thrown out by centrifugal force.

**404. Extractor speeds** (Troy Laundry Machinery Co. Ltd.)

| Basket diameter (in.) | Speed (rev. per min.) | | |
|---|---|---|---|
| | Copper | Steel | Monel metal |
| 20 | 1,400 | 1,600 | 1,800 |
| 24 | 1,200 | 1,400 | 1,600 |
| 26 | 1,100 | 1,350 | 1,500 |
| 28 | 1,000 | 1,250 | 1,300 |
| 30 | 900 | 1,150 | 1,200 |
| 32 | 800 | 1,000 | 1,100 |
| 40 | 700 | 900 | 1,000 |
| 48 | 600 | 800 | 900 |

**405. The power required to start an extractor** is from two to three times the normal motor rating, but after the basket reaches its proper speed the power consumption drops very rapidly to only a fraction of the motor rating. The table below gives the necessary data for Troy machines with copper baskets, if run at the above speeds (Par. 404). The power required to start the machine varies exactly as the square of the rated full speed.

| Basket diameter (in.) | Rating of motor (h.p. intermittent) | Horse power at starting | Horse power running | Acceleration period (min.) |
|---|---|---|---|---|
| 20 | 1.0 | 2.5 | 0.33 | 0.75 |
| 24 | 2.0 | 4.2 | 0.5 | 0.85 |
| 26 | 2.0 | 4.7 | 0.65 | 1.0 |
| 28 | 3.0 | 5.5 | 0.85 | 1.1 |
| 30 | 3.0 | 6.0 | 1.0 | 1.2 |
| 32 | 5.0 | 8.0 | 1.5 | 1.5 |
| 40 | 5.0 | 9.0 | 2.0 | 1.5 |
| 48 | 7.5 | 10.0 | 3.0 | 1.5 |

The above data were compiled from the results of a large number of tests; different loading, maintenance and speed conditions will, however, change these figures. The average load factor is 35 per cent.

**406. Starchers** are built for both collar and cuff work as well as shirt work. A great many types are on the market, the commonest machines being enumerated below. All direct-current motors should be enclosed on the pulley end to prevent the entrance of spray starch. For direct-current as well as for alternating-current they should be of the constant-speed, non-reversing type. The load factor is about 50 per cent.

Digitized by Google

| (a) Collar and cuff starchers | |
|---|---|
| American (Hagen type) 0.25 h.p.<br>Troy No. 3.....0.75 h.p.<br>Troy dip wheel No. 1...0.5 h.p. | Troy No. 6.....0.25 h.p.<br>Troy dip wheel No. 2.....0.5 h.p. |
| **(b) Shirt starchers** | |
| Troy No. 1.....0.25 h.p. | Troy No. 3.....0.25 h.p. |

**407. Dryrooms.** There are two types, one in which the goods are hung on racks, trucks, etc., and another in which the goods are carried through the room continuously on an endless chain conveyer. The first group requires a motor to drive a ceiling fan, for which purpose a 0.167-h.p. motor is used, with a load factor of 100 per cent. Conveyer dryrooms are built in various sizes and depths, the standard depth being 9 ft. Besides driving the chain, the motor operates one or more fans. The motor should never be mounted in the dryroom proper, as the temperature is very high. It is best practice to set the motor on a wall-bracket or to hang it on the ceiling and drive the regular countershaft of the cabinet by belt. The sizes are given by the number of loops (one-half the number of chains inside). Assuming, that the 2-loop room requires 1 h.p., it has been found by tests that each additional loop requires 0.5 h.p. Each additional fan requires 0.25 h.p., and for every foot added to the standard depth, additional power must be supplied amounting to one-sixth of the power required by a standard room of the same size. For example, the horse power rating of a 4-loop conveyer dryroom 11 ft. deep, supplied with two fans may be calculated as follows: standard 4-loop room with one fan, 2 h.p.; additional 2 ft. depth, 0.33 h.p.; additional fan, 0.25 h.p.; total, 2.58 h.p.

The load factor of these machines is 65 per cent. The motors are of the constant speed, non-reversing type, and should be equipped with a rail base, for tightening the belt.

**408. The dryroom tumbler** is used for rough dry work. This machine consists of a revolving and reversing cylinder, enclosed in a suitable housing. One or more fans, usually directly attached to the machine, either blow or draw heated air over and through the goods to be dried. The motor is generally placed on the side of the machine, and drives a countershaft through a silent chain; the pulleys of the cylinder and fan shaft are driven from this countershaft. The machines are built in two sizes, 36 in., which requires a 3-h.p. motor, and 42 in., which should be driven by a 5-h.p. motor. All direct-current motors should be compound-wound, with about 20 to 25 per cent. compounding. On alternating-current circuits plain squirrel-cage motors give good results. The load factor of motors driving tumblers is 60 per cent.

**409. Dampeners** are machines used to moisten all starched goods after drying and prior to the ironing process. A large number of machines are on the market, the table below (Par. 410) giving some of the more prominent ones. No special features are required of the motors, and the load factor varies between 45 and 55 per cent.

**410. Power requirements of dampeners**

| (a) Collar and cuff dampeners | | |
|---|---|---|
| Hagen.....0.25 h.p.<br>Troy No. 1...0.3 h.p. | B. & E.....0.75 h.p.<br>Troy No. 2...0.75 h.p. | Wilson....0.125 h.p. |
| **(b) Shirt dampeners** | | |
| B. & E.....0.375 h.p. | Bishop conveyor 0.5 h.p. | Troy.....0.5 h.p. |

**411. Collar and cuff finishing machines.** A number of machines comprise this class, of which only the ironers themselves are individually

Digitized by Google

driven, while the small finishing machines are belted from a line shaft attached to the finishing table.

**Collar and cuff ironers,** for the most part, require no special motors. However, in the case of steam-heated ironers, it may be sometimes desirable to use variable-speed motors, in order to choose the speed best adapted to the steam pressure, should the latter be changeable. The load factor is 55 per cent.

**412. Power requirements of collar and cuff finishing machines**

| | | |
|---|---|---|
| Troy No. 5 | Gas-heated, 3 rolls, 24 in. | 1.0 h.p. |
| Troy No. 5 | Gas-heated, 3 rolls, 40 in. | 1.5 h.p. |
| Troy No. 5 | Gas-heated, 5 rolls, 24 in. | 1.75 h.p. |
| Troy No. 5 | Gas-heated, 5 rolls, 40 in. | 2.0 h.p. |
| Troy No. 14 | Gas-heated | 1.0 h.p. |
| Troy | Steam-heated, all sizes | 0.75 h.p. |
| B. & E. No. 22 | Steam-heated | 0.75 h.p. |

**Finishing table.** The motor, which is of 0.5 h.p. capacity, is of the non-reversing constant-speed type, and geared directly to the line shaft, from which the small finishing machines are belted. The load factor does not exceed 45 per cent.

**413. Shirt finishing machines.** These machines are used to iron or press the neckband, bosom, sleeves and bodies of shirts. For each of these operations a special machine is used, in some cases there are several types of machine for each operation. See Par. **414** and **415**.

**414. Bosom ironers.** Three distinct types of bosom ironers are in use; first, the reciprocating type, where the bosom passes back and forth under a revolving drum; second, the one-way type, where the bosom travels in one direction only under one or more heated rolls; and third, the presses.

**Reciprocating ironers** require a motor of 0.5 h.p. Reversals may be obtained by means of reversing switches, in which case direct-current motors must be compound-wound and alternating-current motors must have high-resistance rotors. Reversals may also be accomplished by means of mechanical-reverse devices, in which case non-reversing, constant-speed motors should be used. The reverse switch, as well as the mechanical device, is actuated by a foot treadle and lever connections. The load factor for reversing motors is 75 per cent., and for the mechanical reversing type 55 per cent.

**One-way machines** require motors of 1 h.p. capacity, without any special features. The load factor is 55 per cent.

**Presses** are built in two types. In one case a reversing motor operates a screw, and through it a toggle. This motor has a capacity of 0.5 h.p. Should it be a direct-current motor, it ought to be compound-wound; should it be an alternating-current motor, it ought to be equipped with a high-resistance rotor. Single-phase motors cannot be used unless some kind of mechanical reversing device is employed. The load factor is 75 per cent.

The other type of press is operated by a fluid (usually oil) under pressure. A constant-speed, non-reversing motor of 0.5 h.p. capacity operates the pump. The load factor is 55 per cent.

**415. Neckband ironers.** For this service, small motors of from 0.125 to 0.25 h.p. capacity are required. There are no special features, and the load factor is 55 per cent.

**Sleeve and body ironers.** These machines are almost identical, their only difference being in respective size. All modern machines are reversing and, like bosom ironers, are reversed either electrically or mechanically. The sleeve ironers require a motor of 0.25 h.p. capacity; the body ironers, 0.5 h.p. If the reverse switch is used the motors must be built for reversing duty (compound-wound if for direct current, or having high-resistance rotors if for alternating current). Single-phase motors cannot be used for this service. If the mechanical reversing device is employed, standard motors without special features should be used. The load factor of reversing motors is 75 per cent., of the others 55 per cent.

**416. Flatwork ironers or mangles** are used to dry and iron flatwork by passing the goods under pressure over heated rolls or chests. With rolls, one or more aprons may be used to insure perfect contact of the goods over the

Digitized by Google

heated surfaces, and while not essential, this may also be done where chests are used. Nearly all machines of this class must be arranged to deliver goods at varying speeds, and the problem of motor selection must be carefully worked out in detail.

The data given below represent the average results of a large number of tests.

**417. Power requirements of flatwork ironers**

| (a) Flatwork ironers, chest-type without aprons | |
|---|---|
| Troy gas ironer | 0.5 h.p., constant speed. |
| Troy handkerchief ironer | 0.5 h.p., constant speed. |
| Troy addition 2, 3, 4 chest | 0.75 h.p., armature control. |
| Troy addition 5, 6 chest | 1.5 h.p., armature control. |
| Troy triplex No. 1 | 1 h.p., armature and field control. |
| Troy triplex No. 2 | 1.5 h.p., armature and field control. |
| Troy triplex No. 3 | 2 h.p., armature and field control. |
| Troy five roll (8-in. rolls) | 1 h.p., armature control. |
| Troy five roll (12-in. rolls) | 2 h.p., armature or 3 to 1 field control. |
| **(b) Flatwork ironers, chest type with aprons** | |
| Troy four roll | 2 h.p., field control, 3 to 1 speed range. |
| Troy six roll | 3 h.p., field control, 4 to 1 speed range. |
| **(c) Flatwork ironers, cylinder type** | |
| Troy Trojan, 1 cylinder 48 in. | 2 h.p., field control, 3 to 1 speed range. |
| Troy big two, 2 cylinder 24 in. | 2 h.p., mechanical regulation. |
| Troy duplex, 1 cylinder 24 in. | 1 h.p., armature control. |
| Troy addition, cylinder only 36 in. | 1 h.p., armature control. |
| **(d) Flatwork ironers, chest and cylinder type (aprons)** | |
| Troy addition, 1 cyl., 36 in. and 2, 3, 4 chests. | 2 h.p., field control, 3 to 1 speed range. |

**418. Dry cleaning plants.** The underwriters do not allow the installation of electric motors in the cleaning room proper; therefore it is necessary to mount the same outside and operate the plant by group drive. The power required may be calculated from the above data for the various machines. The load factor, as in group drive, is 45 per cent.

## SMALL MOTOR APPLICATIONS

**BY BERNARD LESTER**

*Engineer, Westinghouse Electric and Manufacturing Co., Member, American Institute of Electrical Engineers*

**419. Motor characteristics and types.** The large majority of alternating-current motors in sizes of 1 h.p. and below are split-phase induction motors, since they are simple in construction, reliable in operation, and possess speed-torque characteristics which are suited to the majority of driven machines. The principal limiting features in connection with the application of this type of motor are starting torque and "pull-out" (maximum) torque.

Shunt, compound or series-wound direct-current motors are applied by following the same principles involved in the application of larger motors.

The term "universal" is applied to those motors which will operate either upon alternating-current or direct-current, either without any change whatever in the adjustment of the motor or with the addition of external

Digitized by Google

resistance, or with one or both of these features. Such motors are necessarily series wound and possess a speed torque characteristic in general similar to a series-wound direct-current motor. Consequently, their application is limited to disc types of fans, blowers, electric tools, etc.

**420. Service rating of motors.** Obviously a motor which is required to operate under load for short intervals will not attain the temperature reached when operating at a similar load continuously. Consequently, for intermittent service, smaller motors may be employed than for continuous service. However, where the motor is frequently started and stopped, though the aggregate running time is small compared to the idle time, the heating may become excessive due to the frequent inrush of current incident to starting. The simplest method of arriving at the proper motor capacity is by actual trial of a sample motor, subjecting it to a cycle of operations which will be equivalent to the most severe service conditions.

**421. Split-phase motor characteristics.** In analysing the speed-torque* characteristics and other features of split-phase motors for purposes of application, Fig. 41, will prove of use in the calculation of approximate value.

**422. Calculation of full-load torque,** knowing the horse power and the speed, may be illustrated by the following example: find the full-load torque of a 0.75 h.p. motor running at 1,700 rev. per min. at full-load (1,800 rev. per min. synchronous speed). Find in Fig. 41 the intersection of the vertical line through 1,700 rev. per min. with the curve marked 0.75 h.p. (560 watts), and horisontally opposite this intersection at the left is the torque 36.5 ounce-feet.

**423. Starting torque.** Since the starting torque and the pull-out or maximum torque of a small split-phase induction motor are limiting features, care should be taken that the motor selected will start the driven machine under the severest conditions of torque. The starting torque varies approximately as the square of the applied voltage, and any reduction in voltage caused by the inrush of current incident to starting, and possibly emphasized by insufficient wiring or transformer capacity in commercial circuits, reduces very materially the starting torque delivered by the motor. It is customary to select a motor which will start the driven machine at a voltage of approximately 80 per cent. of the normal circuit voltage.

The starting torque and the maximum running torque can be found by multiplying the full-load torque by the proper constants. For example, if the starting torque of the particular motor considered in Par. **422** is 1.5 times the full-load torque, its value will be $1.5 \times 36.5 = 55$ oz-ft. Likewise if the maximum running torque of the motor is 2.5 times the full-load torque, its value will be $2.5 \times 36.5 = 91$ oz-ft. These constants must be determined from the characteristic curves of the individual motor, Fig. 41.

**424. The horse power at maximum torque** can also be determined from the curve if the speed is known. For approximate results the slip of small split-phase induction motors at maximum torque can be assumed to be 25 per cent. In the case of the motor discussed in Par. **423**, the speed at maximum torque will therefore be approximately 1,350 rev. per min. Find in Fig. 41 the intersection of the vertical line through 1,350 rev. per min. with the horisontal line through 91 oz-ft. torque; this is near the line representing 1.5 h.p., which is the approximate power developed by the motor just before pulling out, or stalling.

**425. Input.** The problem is to find input in watts, when given the horse power and the efficiency. Assume for example that the efficiency of a 0.75-h.p. motor is 75 per cent. Find in Fig. 41 the intersection of the vertical line through 75 with the 0.75 h.p. curve, and horisontally across from this intersection is the value 746 watts.

**426. Current per phase.** Knowing the watts input, the power-factor and the voltage, the problem is to find the current per phase (or per terminal); for example, assume that the power-factor of the foregoing motor is 70 per cent. and the voltage is 220 volts. Locate in Fig. 41 the intersection of the 70 per cent. vertical power-factor line with the diagonal representing 746 watts. The horisontal line passing approximately through this point, repre-

* Torque measured with brake-arm and scales at 1 ft. radius.

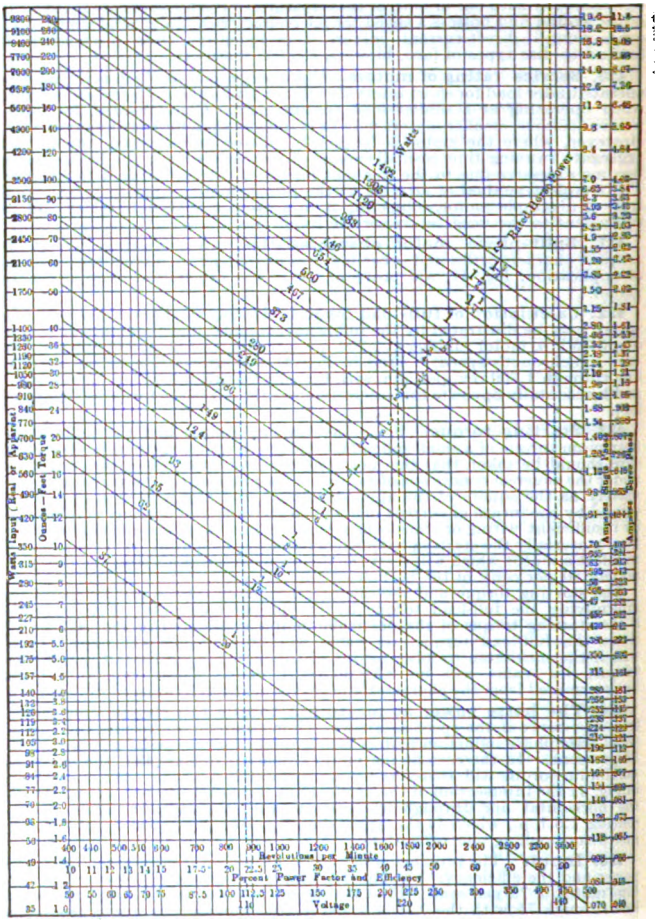

FIG. 41.—Characteristics of split-phase motors.

sents 1,050 apparent watts. Then from the intersection of the vertical line representing 220 volts with the diagonal representing 1,050 watts, the horisontal line representing amperes may be determined, namely, 4.8 amp. single-phase, or 2.8 amp. three-phase. The current per terminal in a two-phase motor is one-half that for a single-phase motor, and in this case would be 2.4 amp.

## MOTOR CONTROL

**BY CLARK T. HENDERSON**

*Engineer, The Cutler-Hammer Manufacturing Co., Fellow, American Institute of Electrical Engineers*

### STARTERS

**429. Necessity for starters.** Standard direct-current motors of small capacity and of any winding may be thrown directly on the line without requiring an undue rush of current and without being injured. Specially designed motors as large as 10 h.p. can be started in the same manner, but larger machines—whether shunt wound, compound wound, or series wound—require some form of starting device not only for restricting the current inrush at starting but also for the protection of the motors themselves. Also see Sec. 5.

Standard alternating-current, squirrel-cage motors of moderate potential and of any capacity, may be thrown directly on the line without injury. High-voltage motors are made only in large capacities, and it is inadvisable to throw such motors directly on the line because of the line surges which are the invariable result of such procedure.* Even in the case of machines of moderate potential the current inrush is so great as to cause serious line disturbances if any except small machines are started in this manner, and most power companies prohibit this practice with motors of capacity exceeding 5 h.p. Generally speaking, the starting current required by standard squirrel-cage motors when thrown directly on the line is from five to eight times that required under full-load conditions.

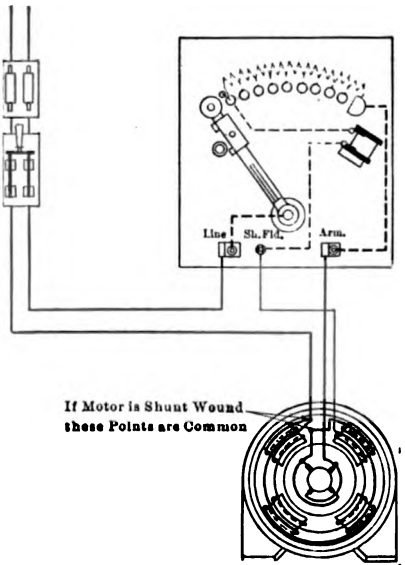

FIG. 42.—Direct-current motor starter.

**430. Direct-current starters** in their simplest form consist of a resistance of such value that only a proper current inrush is allowed, together with a switching device for removing this resistance in one or more steps. In small and moderate capacities the switching device generally employed for short-circuiting the starting resistance, consists of a lever movable across a series of contacts which are connected to the starting

* No. 20 (Par. 468).

Digitized by Google

resistance. A typical starter* of this class is illustrated diagrammatically in Fig. 42.

The **no-voltage release** which is usually a part of the direct-current starter consists of the resistance-controlling lever (Fig. 42) normally held at the extreme left or in the open-circuit position by means of a spring, and an electromagnet in series with the shunt field of the motor, adapted to hold

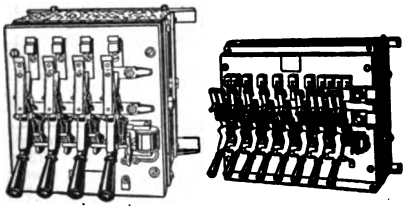

FIG. 43.—Direct-current starter for large motors.

the starting lever in the full-speed position as long as there is voltage on the line. In case of voltage failure this magnet will be de-energized, and the starting lever will return to its open-circuit position. This no-voltage release magnet is sometimes placed in the shunt-field circuit, and is sometimes connected across the line. The former arrangement is preferable because the motor circuit will be opened in case of failure of the shunt-field circuit.

In large capacities the use of a series of successively closed manually operated switches seems to be preferred by most controller manufacturers. Interlocks are usually provided which prevent the closure of such starting switches in any other than their regular order. Fig. 43 shows typical starters of this class.

**431. Apportionment of resistance in direct-current starters.** Fig. 44 shows the starting current required by a direct-current motor, it being assumed that a step of resistance is cut out each time the current falls to a predetermined value. For equal starting peaks the resistance must be divided unequally, the proper ratio between successive steps being a geometrical progression. The resistances of the steps, as well as the current peaks which will obtain, may be determined graphically from Fig. 44, where $I_1$ = initial inrush; $I_3$ = current at which a step of starting resistance is removed; $I_3$ = running current; $r_0$ = resistance of motor and its connections; $R$ = external starting resistance. The ratios of progression with various numbers of starting steps, $n$, and for various values of $\alpha$ (which equals $r_0/R$) are given in the following tabulation:

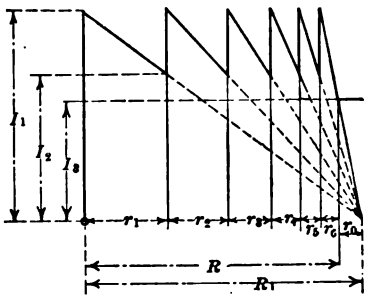

FIG. 44.—Direct-current motor starting current.

$I_1$ = Current peak.
$I_2$ = Current just before a step of resistance is cut out.
$I_3$ = Running current.
$R_1$ = Total resistance.
$R$ = External or starting resistance.
$r_0$ = Resistance of motor and its connections.
$r_1, r_2, \ldots, r_n$ = Resistance of starting steps.

* No. 27. Par. 468.

Digitized by Google

| n | Values of $\alpha$ | | | | | |
|---|---|---|---|---|---|---|
| | 0.03 | 0.04 | 0.05 | 0.06 | 0.08 | 0.10 |
| 2 | 5.97 | 5.02 | 4.47 | 4.09 | 3.54 | 3.16 |
| 3 | 3.22 | 2.92 | 2.71 | 2.56 | 2.32 | 2.16 |
| 4 | 2.40 | 2.23 | 2.11 | 2.02 | 1.88 | 1.78 |
| 5 | 2.02 | 1.91 | 1.82 | 1.76 | 1.65 | 1.59 |
| 6 | 1.79 | 1.71 | 1.65 | 1.60 | 1.53 | 1.47 |
| 7 | 1.61 | 1.58 | 1.54 | 1.49 | 1.44 | 1.39 |
| 8 | 1.55 | 1.49 | 1.45 | 1.42 | 1.37 | 1.33 |
| 9 | 1.48 | 1.43 | 1.39 | 1.37 | 1.32 | 1.26 |
| 10 | 1.42 | 1.38 | 1.35 | 1.32 | 1.29 | 1.25 |

The above takes no account of motor impedance or armature acceleration and, for this reason, practical results may be quite different from those calculated. The current-carrying capacities of starter resistances are proportioned for short-time duty; this determination of carrying capacity is more a matter of experience than calculation.

**432. Star-delta switches for starting alternating-current motors,** are used in connection with specially designed, three-phase, squirrel-cage motors whose windings are adapted for connection in star during acceleration and in delta for running. This form of starter is not often used in capacities exceeding 15 h.p. nor with potentials exceeding 550 volts. Fig. 45 shows the connections for this form of starter. Although not shown by the diagram (Fig. 45), star-delta switches are almost invariably arranged either to short-circuit the fuses entirely during starting or to transfer starting current through a second set of fuses which are of higher capacity than the running fuses. Some arrangement of this sort is almost essential, for if the starting current passes through the running fuses, they must be made so large as to afford practically no protection against overloads in normal operation. Star-delta switches are often equipped with no-voltage release, the magnet in such instances being connected directly across the line.

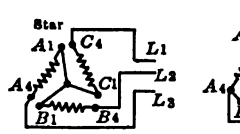

FIG. 45.—Connections of delta-star starter.

**433. Primary-resistance alternating-current starters** are employed to a limited extent in connection with two-phase and three-phase squirrel-cage motors, and, to a considerable extent, in connection with single-phase motors which start as repulsion machines. They are of the same general form as those employed with direct-current motors, except, of course, that where they are used in connection with two-phase or three-phase motors, they must provide for the inclusion and removal of resistance from two lines instead of one. Since polyphase motors require greater starting currents when started by the primary-resistance method than when induction starters are employed, primary resistance is not often resorted to in any except the small capacities. Its one advantage over the induction type of starter lies in its lower first cost and its greater simplicity. Fig. 46 shows a typical three-phase primary-resistance starter. These starters are often equipped with no-voltage release, the no-voltage coil being connected across the line.

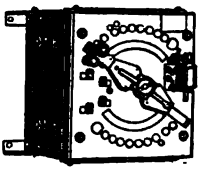

FIG. 46.—Three-phase primary-resistance starter.

**434. Induction starters for alternating-current motors** are more widely employed than any other form of alternating-current starting device. They consist of an auto-transformer together with a switching device for

Digitized by Google

connecting the stator winding, first across reduced potential obtained from the starting transformer, then directly to the line. In large capacities these induction starters are often arranged to operate in three or more steps, thus reducing the current surges. For moderate-capacity machines they are generally designed to connect the stator first across transformer taps which deliver from 40 per cent. to 75 per cent. of line potential, and then to the line. Induction starters are almost invariably arranged to disconnect the starting-transformer windings from the line in all positions except the starting position.

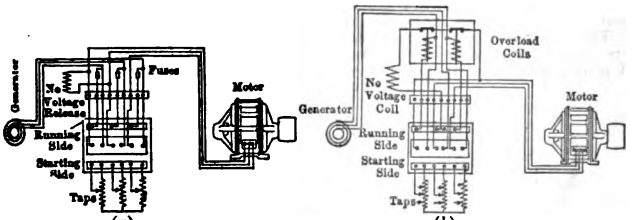

FIG. 47.—Induction starters for alternating-current motors.

Induction starters are also arranged to short-circuit the individual running fuses during starting. Sometimes the starting current is taken through auxiliary starting fuses of heavy capacity, but in most instances the motors are unprotected during starting. This class of starter is now almost invariably equipped with no-voltage release, and often with overload release which replaces the fuses. The overload release generally takes the form of overload relays which are adapted to open the circuit containing the no-voltage release magnet; this allows the switching mechanism to open the motor circuit. Where overload release is employed, the overload relays are individually short-circuited during starting. Fig. 47a is a connection diagram for a typical induction starter with no-voltage release and protected with fuses, while Fig. 47b shows the same device supplied with overload release.

In large plants one bank of starting transformers is sometimes employed for starting all motors, and a five-wire system is installed. Where this arrangement is employed the motors are first connected to a common line and two starting lines, and then directly to the distributing mains. Fig. 48 shows the arrangement described.

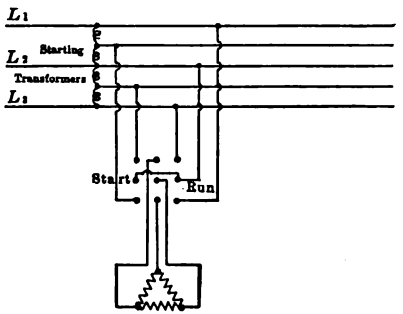

FIG. 48.—Five-wire system of starting alternating-current motors.

**436. Secondary-resistance starters for alternating-current motors** are used in connection with alternating-current slip-ring motors for the purpose of increasing the secondary impedance during starting, and are of the same general type as primary-resistance starters. Since slip-ring motors almost invariably have their secondaries wound polyphase, it is quite important that the starters used with such motors be designed to keep the secondary circuit as nearly in electrical balance as possible, for any unbalancing of this circuit reduces the starting torque which it is possible to obtain with a given line current. Generally speaking, unbalancing the secondary circuit 10 per cent. will reduce the possible torque by approximately 15 per cent.

Digitized by Google

Secondary-resistance starters are sometimes entirely separate from the switching apparatus used to open and close the primary circuit. In other instances the primary switch is interlocked with the device for controlling the secondary resistance in such a manner as to prevent the closure of the former unless the latter is in a position where all secondary resistance is in circuit. Where a slip-ring motor is started and stopped at frequent intervals, the primary switch and the secondary resistance commutating device are often connected to a single control lever, so that, as the latter is moved from the "off" position toward the full-speed position, the primary circuit is first closed and then the secondary resistance is removed step by step.

The characteristics of motors with which secondary-resistance starters are employed have so much influence upon the design of the resistance that it is impossible to lay down any rules governing the determination of the ohmic value of the various steps; see Sec. 7. Non-inductive resistances should be used exclusively in the secondary circuit of slip-ring motors.

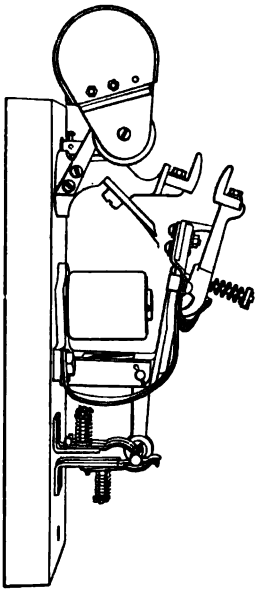

FIG. 49.—Direct-current magnetic switch.

**436. Automatic or self-starters** are used in connection with both alternating-current and direct-current motors when it is desired to have them start and stop automatically in response to variations in pressure, water level, etc.; or when it is desired to start the motor with greater convenience and with less demand upon the intelligence of the operator than is required where hand-operated starting apparatus is installed; or when the motor is so large that its control-equipment becomes cumbersome and difficult for the operator to handle; or when the motor is frequently reversed and is likely to be injured by taking an excessive current when "plugged."*

Self-starters and automatic control would be an utter impossibility without **magnetic switches** (sometimes termed contactors) and consequently a brief description of such devices and their characteristics appears necessary before entering into a discussion of the various types of self starters (Par. **437** to **445**).

**437. Direct-current magnetic switches** are generally of the single-pole type. The most common form is operated by an electro-magnet of the clapper form (Fig. 49). The movable element or clapper carries a contact member adapted to engage a corresponding stationary contact, and a flexible connection carries current to the contact mounted on this moving clapper. Because an electro-magnet adapted to long-pull work is inherently inefficient and slow in operation, the modern contactor is almost invariably arranged for a short break and in large capacities must be provided with a magnetic blow-out for disrupting the arc. In small capacities the arcing contacts are often used for carrying the current as well, but in larger capacities the main or current-carrying contacts generally consist of laminated brushes which engage contact plates. This laminated contact is protected against arcing and burning, by auxiliary contacts located in the magnetic blow-out field; these are adapted to engage sooner than the laminated contacts, and to open later. Fig. 49 shows a typical direct-current contactor with the blow-out pole pieces swung upward so as to render the contacts easily accessible for repairs.

* Par. **468**, No. 8, 9, 13, 25.

Digitized by Google

In order to be quick acting and positive in operation, direct-current contactors should have coils which are capable of closing the switch with potential equal to 75 per cent. of normal impressed at the coil terminals, when the coils are at the operating temperature.

**438. Alternating-current contactors** are almost invariably called upon to handle two circuits simultaneously and are, therefore, almost invariably of the double-pole type. They are generally of the clapper form, but the magnetic circuit is necessarily laminated. Particular care should be taken to insure the holding of the laminations with sufficient rigidity to secure a permanent structure. The pull exerted by an alternating-current magnet is proportional to the square of the voltage impressed at its terminals, consequently it is not practicable to make alternating-current contactors which have the same operating range as direct-current contactors.

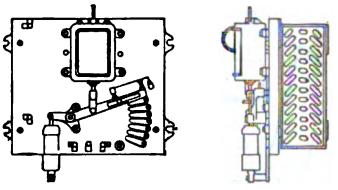

FIG. 50.—Direct-current time-acceleration starter.

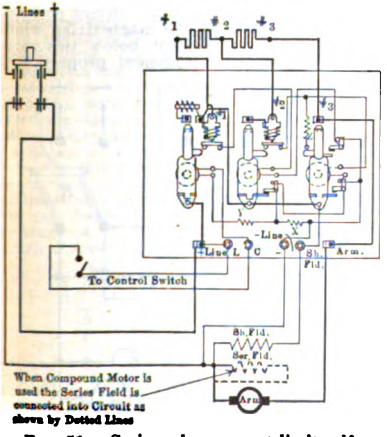
It is practically impossible to obtain sufficient sealing pressure with alternating-current magnets to allow the use of laminated contacts, and, as a result, most alternating-current contactors depend upon butt contacts of copper for opening the circuit and for carrying the current when closed. Alternating-current contactors designed for voltages up to 550, are almost invariably equipped with magnetic blow-outs, and those built for higher potentials are generally arranged to open the circuit under oil. Air-break contactors have been made, however, for potentials up to 2,200 volts. These high-potential contactors are equipped with horn-type arc gaps, which permit the arc to increase in length until it reaches the point of disruption.



Lines
To Control Switch
Sh. Fld.
Ser. Fld.
When Compound Motor is used the Series Field is connected into Circuit as shown by Dotted Lines

FIG. 51.—Series-relay current-limit self starter.

**439. Time-acceleration self-starters** are designed to accomplish the necessary starting operations in a predetermined and adjustable period. The timing may be accomplished in many ways, but a solenoid whose action is retarded by an adjustable dash-pot, is perhaps the most widely used device. A typical direct-current time-acceleration starter is shown diagrammatically in Fig. 50.

**440. Current-limit self-starters** are devised to halt the starting operation whenever the required starting current exceeds an adjustable predetermined value, the starting operation being resumed when the current falls below this limit. There are several forms of current-limit acceleration self-starters, and only those which are most widely used will be described.

**441. A series-relay current-limit self-starter** is shown in Fig. 51. It will be noted that the starting resistance is removed from the motor circuit by a series of successively energised magnetic switches or contactors. The motor circuit is initially closed by operating a control switch, thus

Digitized by Google

causing the line contactor to close. The current passes through starting resistance 1–3, also through the series relay which controls accelerating contactor No. 1. If the initial current inrush is sufficiently great, it will cause this relay to lift its plunger and thus prevent the closure of any of the accelerating switches. When the starting current has fallen to the dropping point of this series relay, the first accelerating switch will close, remove one step of starting resistance, include the second series relay and complete the circuit to the winding of the second accelerating switch through contacts controlled by the second series relay. It is obvious that with such a structure the removal of starting resistance will be halted whenever the current exceeds a predetermined value and will be resumed when it has fallen below this value.

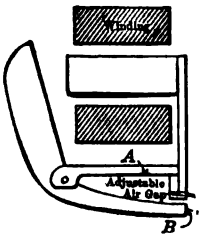


FIG. 52.—Series switch-operating magnet.

**442. A series switch operating magnet** is shown in Fig. 52; this piece of apparatus is designed to accomplish the current-limit acceleration of direct-current motors. The series switch is operated by an electromagnet, which, as the name of the device indicates, may be connected in series with the motor. The magnetic circuit enclosing this winding may be of the solenoid or clapper form, but invariably includes a section of restricted area, "*A*," bridged by a movable element, "*B*," which gives a maximum shunting effect when the switch is open, and a minimum shunting effect when it is closed. An adjustable air gap is included in the magnetic bridging circuit. Whenever the current passing through the winding is in excess of a certain value, that section of the magnetic circuit ("*A*") which is of restricted area will be saturated, and the excess flux lines set up by the winding will, therefore, seek the other path and tend to hold the switch in an open-circuit position. The switch remains open as long as the current in the magnetising winding is above the value for which the switch is adjusted; below this value the restricted area becomes capable of carrying a sufficient proportion of

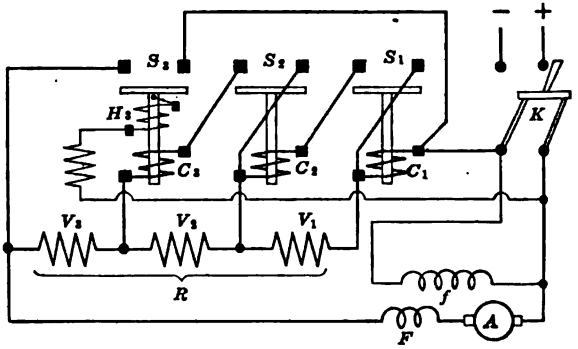

FIG. 53.—Starting device using the series switch of Fig. 52.

the flux to set up a counter force capable of overcoming the restraining pull, and close the switch.* The solenoid-type series switch is quite fully illustrated and described in the *Transactions*, of A. I. E. E., Vol. XXX, page 1563, in a contribution by A. C. Eastwood.

Fig. 53 is a typical connection diagram for a self-starting device made up of these switches. When the line switch "*K*" is closed, current passes

*Par., 443, No. 29.

Digitized by Google

from the positive line through the shunt-field windings, "$f$," to the negative line; also from the positive line through the armature, "$A$," the series field, "$F$," the resistance sections, "$V_2$" "$V_3$," "$V_1$," and the operating coil, "$C_1$" of the first series accelerating switch, to the negative line. If the initial current inrush is in excess of the value at which "$C_1$" locks open, no resistance will be cut out until the accelerating current has fallen to the point which will permit "$C_1$" to lift its plunger. When "$C_1$" lifts its plunger, switch "$S_1$" is closed, thereby short-circuiting resistance section "$V_1$" and including the winding "$C_2$." The operation of these series switches is progressive. When "$C_3$," the last of the accelerating windings, closes its switch "$S_3$," windings, "$C_1$," "$C_2$" and "$C_3$," are short-circuited and the shunt winding, "$H_3$," is connected in circuit directly across the lines. Winding "$H_3$" serves to hold "$S_3$" closed during running, thus guarding against the dropping out of the accelerating switches should the motor operate under light load.

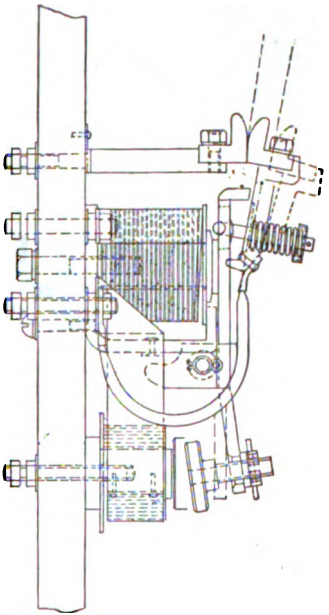

FIG. 54.—Magnetic lock-out switch.

**443. The magnetic lock-out switch,** illustrated in Fig. 54. is applicable to direct-current motors. It is a clapper-type switch of conventional form, operated by a series winding instead of shunt, and having a second series winding, separately mounted, adapted to act on a downwardly projecting extension of the switch clapper, and to hold the switch open as long as the force exerted by this secondary winding exceeds that of the closing coil. An adjustment is provided by which the air gap between the secondary or locking-out coil and its armature can be varied; thus the current above which the switch will be locked in an open position can be adjusted through a wide range.

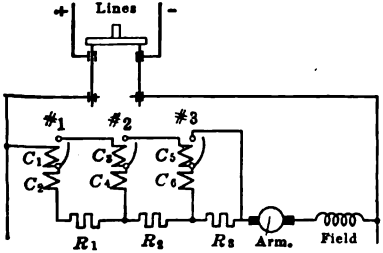

FIG. 55.—Starter comprising three magnetic lock-out switches.

Referring to the diagram, Fig. 55, which covers a simple starter consisting of three magnetic lock-out switches, it will be noted that when the line circuit is closed, the motor current passes from the positive line through the two windings of the first magnetic lock-out switch, thence through three sections of starting resistance to the armature of the motor to be started. As long as the current passing through these windings is in excess of a predetermined and adjustable value, the restraining force exerted by the lower or locking-out magnet will exceed the attractive force exerted by the upper or closing magnet, and the switch will maintain an

Digitized by Google

open-circuit position. When the current has fallen below this predetermined value, the upper or closing magnet will develop sufficient pull to overcome the lock-out winding. As soon as the contacts of the switch engage, one section of the starting resistance is removed, and, with this section, the lock-out coil, so that any tendency which this coil might have to hold the switch in an open-circuit position is entirely removed. No. 1 accelerating switch, in closing, not only short-circuits a section of the resistance and its lock-out coil, but also automatically includes both windings of the second accelerating switch, which in turn locks open until the starting current has

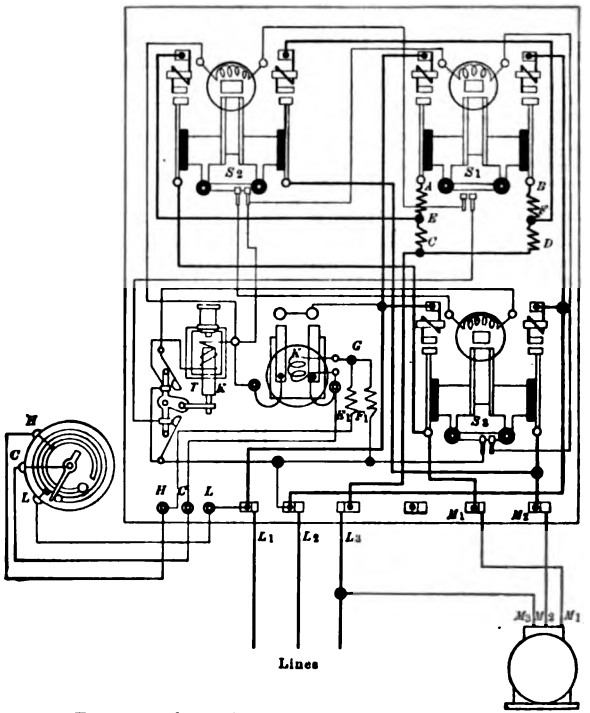

FIG. 56.—Alternating-current time-limit self starter.

fallen below the value at which it is adjusted to operate. These switches will remain closed with 5 per cent. of their normal current; consequently no shunt winding is ordinarily required for the last switch.

**444. The counter-e.m.f. starter for direct-current motors** is in reality a current-limit starter. In this device the starting resistance is removed by a series of magnetic switches whose operating windings are connected across the motor armature; these switches close successively as the counter e.m.f. of the motor increases with the speed.

**445. Alternating-current induction self starters** may also be of either the time-limit or current-limit type. In the former the primary windings are connected to the starting transformer for a predetermined length of time, and are then thrown directly on the line. Fig. 56 shows a typical starter of

Digitized by Google

this class. A very similar starter is employed for the control of secondary starting resistance, the removal of the starting resistance being accomplished after a predetermined time interval. Both induction and primary-resistance self starters of the current-limit type are manufactured, but have not proven as satisfactory as the time-acceleration type on account of the low starting torque of squirrel-cage motors, and the possibility of their being so loaded that they will not accelerate sufficiently to enable a current-limit type of starter to change from starting to running position. Fig. 57 shows a current-limit acceleration controller for use in connection with an alternating-current slip-ring motor. This controller consists of a primary contactor and two

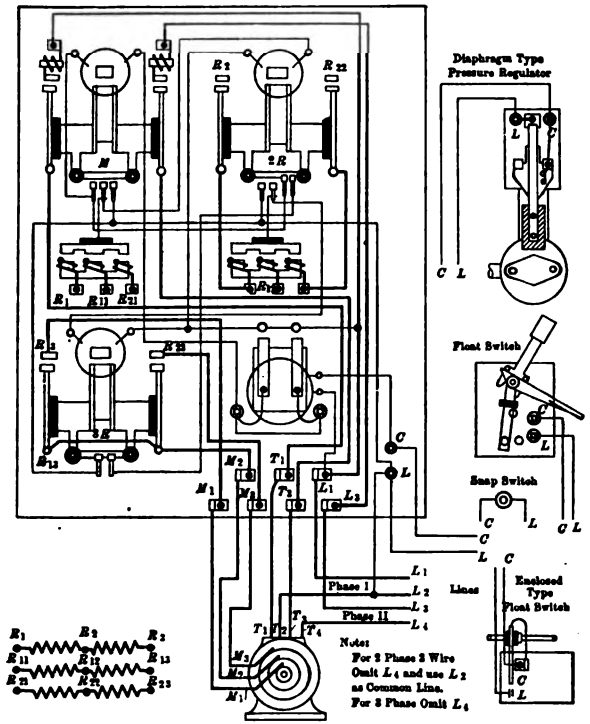

FIG. 57.—Alternating-current current-limit self starter.

secondary resistance contactors, all of which are double-pole type. The operation of the primary contactor may be controlled by a pressure regulator, a float switch, or a simple snap switch. The secondary resistance switches are arranged for successive operation, and are governed by two 3-phase, secondary series relays, which are arranged to halt acceleration whenever the motor current exceeds the value for which they are adjusted.

## SPEED REGULATORS

**446. Direct-current speed regulators.** The speed of direct-current motors may be varied in two ways: first, by varying the potential impressed at the armature terminals, the field strength remaining constant (the speed

Digitized by Google

of a direct-current motor operating at constant field will be directly proportional to the voltage impressed on its armature terminals); second, by varying the field strength, the voltage at the armature remaining constant. The speed of a motor whose armature potential remains unchanged, will be inversely proportional to the field strength. Speed control can also be obtained by a combination of the two methods just mentioned.

There are many ways in which the armature potential may be varied, the most common being to insert a resistance in the armature circuit; the *IR* drop, across this resistance serves to reduce the voltage impressed upon the armature. This method is open to the objections that it is inefficient and that the *IR* drop varies with the motor load; consequently the regulation is not good and only a limited range of regulation can be obtained. Assuming a motor to be operating under full-load torque, about 125 per cent. of full-load current will be required to start it, and the amount of resistance which will permit such a current inrush will give 75 per cent. reduction in armature e.m.f. and speed with full-load torque and current. It may therefore be said that 4 to 1 is the maximum speed range which it is possible to obtain satisfactorily by the armature-resistance method, and that in many cases 3 to 1 will be the maximum range obtainable. The regulation with this method at reduced speed, under variable loads, is so poor as to make armature-resistance speed regulation impracticable for any but constant-load work.

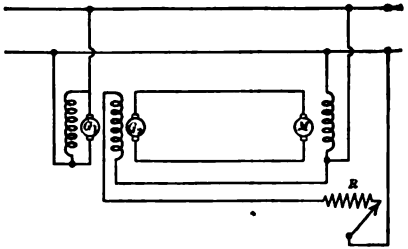

FIG. 58.—Ward-Leonard system of direct-current control.

**447. The Ward-Leonard system of direct-current control** is well adapted for wide range, and has good regulation. Fig. 58 is a connection diagram for a typical system of this class. "G-1" and "G-2" are two generators, one of which is self-exciting, and furnishes current for the fields of "G-2" and the motor "M." By means of rheostat, "R," the voltage of "G-2" can be varied, and the speed of "M" will be correspondingly varied. The regulation of such a system is very good, through a wide range of control, and becomes unsatisfactory only when the comparatively small *IR* drop in the armatures "G-2" and "M" and the connections between them, becomes a large percentage of the total potential generated by "G-2" (Par. **443**, No. 4).

By reversing the fields of "G-2," the direction of rotation of the motor, "M," can be changed (Par. **443**, No. 19, 21 and 24). This system is extensively employed for reversing mill and mine hoist duty.

**448. The multiple-voltage method of direct-current speed control** is generally used in connection with a certain amount of field control. The older multiple voltage systems are almost invariably four-wire, as per Fig. 57. A balancer set having three armatures is connected across a 250-volt system and gives 60, 80 and 110 volts between the three sets of mains. The motor whose speed it is desired to control, may obviously be so connected that it will have 60, 80, 110, 140, 190 or 250 volts impressed on its armature. Field control is used to smooth out the steps; the motor field strength is reduced while the armature is connected to each potential, before stepping to the next higher potential, and is increased to normal strength as the change is made.

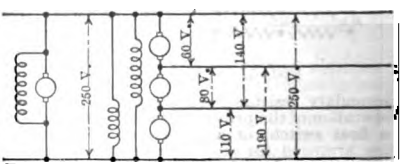

FIG. 59.—Multiple voltage system of direct-current control.

Later systems employ but three wires (Par. **443**, No. 5) and provide for

Digitized by Google

110 and 220, or 125 and 250 volts at the motor armature. To obtain reasonably small speed increments throughout the entire speed range, these three-wire systems require a motor whose speed may be varied by field control through a wider range than is required where a motor is operated on the four-wire system.

**449. The field strength of a motor may be varied** by electrical or mechanical means. When this is accomplished electrically, the field strength is generally varied by a field-regulating rheostat. Field regulation is effected mechanically by changing the air gap and consequently the reluctance of the field circuit. Either method produces the same results, the former having the advantage that the regulating rheostat can be conveniently located at some distance from a motor, also that the field strength can easily be increased to normal during starting.

The extent to which the speed of a motor can be varied by field control depends upon its design. Generally speaking, a standard machine will seldom commutate well if its speed is increased in this manner more than 20 per cent., while specially designed inter-pole motors have been built for speed ranges as great as 10 to 1. On account of their good inherent regulation and their high efficiency at all speeds, field-control motors are almost universally employed where speed control of direct-current motors is required.

**450. A combination of armature-resistance and field control** may be used to advantage where reduced speeds are required for comparatively short periods, and the expense of installation can be materially reduced by such procedure. It will also be found where a wide range of speed is required in connection with the Ward-Leonard system (Par. **468**, No. 18), Fig. 56, that it will be advisable to regulate the field strength of the motor as well as that of the generator.

**451. Self-starting speed regulators.** In machine-tool practice, self-starters are used to start and stop machines whose speeds are adjustable by a regulator controlling the motor fields. Such self starters may be equipped with a vibratory field-regulating relay, the winding of which is connected in series with the motor armature. When the armature current reaches a predetermined value this relay will short-circuit the field rheostat, thus increasing the motor field strength to normal. The field strength is continued at normal until the armature current decreases sufficiently to allow the relay to drop, thus inserting the field resistance and increasing the armature current because of the reduced counter e.m.f. Increase in armature current causes the relay again to short-circuit the field rheostat, and the relay continues to vibrate, alternately short-circuiting and cutting in the field resistance, until the motor has accelerated to such an extent that the field resistance may be left in circuit without causing the armature to take a current in excess of the relay setting.

**452. Series-parallel control of two motors** is a convenient and efficient means of obtaining two speeds, one speed being one-half the other. Such a control system has the added advantage of reducing the current required to produce a given starting torque. This system of control is most widely used in railway work (also see Par. **468**, No. 10).

**453. Speed control of squirrel-cage** motors may be accomplished in two ways: first, by changing number of poles; second, by varying the combined voltage and frequency impressed on the primary. The number of poles may be changed by the use of separate windings and selective energisation, or by regrouping the windings to change the number of poles. The former method is employed where more than two speeds are required. To obtain a 1 to 2 ratio the windings are generally connected as shown in Fig. 60. It should be particularly noted that in changing from the star, or half-speed connection, to the double star, or full-speed connection, it is necessary to reverse two of the incoming lines in order to prevent the motor from running in a reverse direction.

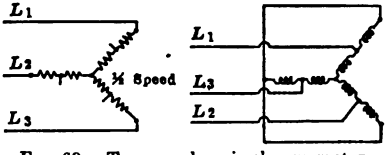

FIG. 60.—Two-speed squirrel-cage motor.

Digitized by Google

Where voltage and frequency are changed they must be varied in the same ratio, i.e., for half speed, half voltage and half frequency. The speed of the squirrel-cage motor *cannot* be varied by the use of primary resistances.

**454. A combination of variable frequency and change of poles** is sometimes found effective. For example, a system employing a 10-pole/20-pole, 440-volt, 60-cycle motor at 720 rev. per min. (maximum synchronous speed), may be used in connection with two frequency-changing sets, and the following speed range obtained:

| | | | |
|---|---|---|---|
| 60 cycles | 440 volts | 10 poles | 720 rev. per min. |
| 45 cycles | 330 volts | 10 poles | 540 rev. per min. |
| 60 cycles | 440 volts | 20 poles | 360 rev. per min. |
| 45 cycles | 330 volts | 20 poles | 270 rev. per min. |
| 30 cycles | 220 volts | 20 poles | 180 rev. per min. |

The horse-power output of motors used with such a control system is directly proportional to the speed at which they operate.

**455. Slip-ring motors can be varied in speed** by the use of secondary resistance. This method of speed regulation is open to several objections. It is not efficient, and the speed regulation at reduced speeds is not good, because the amount of speed reduction obtained with a given amount of secondary resistance in circuit varies directly with the load which the motor is carrying. Under the most favorable conditions it is not commercially possible to obtain a greater reduction in speed than 75 per cent., and in most cases 50 per cent. reduction in speed will be found to be the practical limit.

Slip-ring motors are sometimes constructed with means for varying the number of poles, either by the use of multiple windings, or by regrouping the windings. Since both the primary and the secondary windings must be controlled, such systems are commercially impracticable for most small installations, but are used to some extent in rolling-mill work.

**456. Concatenation control of induction motors.** The speed of two alternating-current induction motors mounted on the same shaft may be varied by connecting them in cascade, or, in other words, by operating in

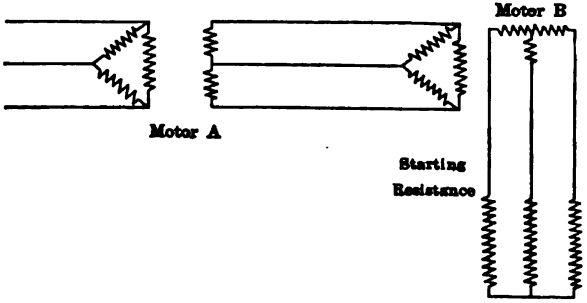

FIG. 61.—Cascade connection of two motors.

concatenation (Sec. 7). The first motor of such a system must be of the slip-ring type, and the second may be of the squirrel-cage type, although the use of a slip-ring machine is preferable on account of the possibility it affords of obtaining higher starting torques and reduced speeds. With two concatenated motors, a total of four economical running speeds can be obtained, as follows: one with motor "A," connected to the line; the second with motor "B" directly on the line; the third with "A" and "B" in direct concatenation, and the fourth with "A" and "B" in differential concatenation. Motors are said to be in direct concatenation when they tend to revolve in the same direction and in differential concatenation when the second ("B")

Digitized by Google

tends to oppose the first ("A"). See also Par. 468, No. 6. The synchronous speed for each of the concatenated connections can be determined as follows:

$$S = \frac{\text{cycles} \times 120}{P_1 \pm P_2} \qquad \text{(rev. per min.)} \qquad (9)$$

where $S$ is the synchronous speed in rev. per min.; $P_1$ is the number of poles of motor "A"; $P_2$ is the number of poles of motor "B." The plus sign should be used when the motors are in direct concatenation, and the minus sign when in differential concatenation. The diagram in Fig. 61 shows the connections for a cascade system.

There are so many methods by which the speed of one or more slip-ring motors can be varied (see Par. 468, No. 6, 7, 15 and 26), that it is impossible to cover them all in the limited space available.

**457. Single-phase motors of the repulsion type** may have their speed varied either by the use of primary resistance, or by shifting the brushes. The results obtained by various motor manufacturers are so widely diverse as to make it almost impossible even to outline the limitations of such systems.

**458. Synchronous motors** are not susceptible of speed control; see Par. 468, No. 22.

## ELECTRICALLY OPERATED BRAKES

**459. Classification.** In the control of electric motors it often becomes desirable to provide a brake which is electrically released and applied by a spring or weight. Such brakes are made in three types—the multiple-disc, the band and the shoe type.

**460. Band brake.** In one type of band brake, a wheel is attached to the shaft to be braked, and this wheel is encircled by a band lined with a suitable friction material. Normally the band is brought into frictional engagement with the wheel by means of a spring; a solenoid is provided for the purpose of compressing these springs and relieving the brake band. The band brakes are manufactured for either alternating-current or direct-current service.

**461. A multiple-disc brake** is illustrated in Fig. 62. This typical form of brake is manufactured only for direct-current service. It consists of

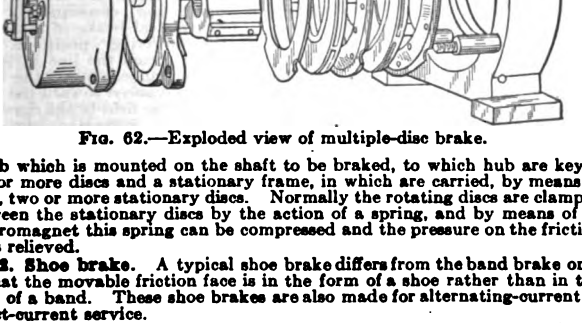

FIG. 62.—Exploded view of multiple-disc brake.

a hub which is mounted on the shaft to be braked, to which hub are keyed one or more discs and a stationary frame, in which are carried, by means of keys, two or more stationary discs. Normally the rotating discs are clamped between the stationary discs by the action of a spring, and by means of an electromagnet this spring can be compressed and the pressure on the friction discs relieved.

**462. Shoe brake.** A typical shoe brake differs from the band brake only in that the movable friction face is in the form of a shoe rather than in the form of a band. These shoe brakes are also made for alternating-current or direct-current service.

**463. Advantages of the various types.** The disc brake has the advantage, over either other type, of imposing no side strains on the shaft to which

Digitized by Google

it is applied. Naturally, it also provides equal braking for either direction of rotation, whereas some forms of band and shoe brakes do not possess this feature. The band-type brake, generally speaking, is superior to the shoe-type, because of the larger proportion of the brake wheel which is in actual service, and the consequent reduction in unit pressure on braking surfaces. Moreover the band-type brake possesses the tendency to wrap itself around the wheel; consequently it can be operated by means of a smaller solenoid than is required for a shoe brake of corresponding rating.

## DYNAMIC BRAKING

**464. Classification.** Dynamic braking may be defined as the retardation of a machine by a motor acting as a generator, which takes no current from the line other than for excitation. The subject of dynamic braking may be divided into two parts as follows: first, for the purpose of effecting a quick stop; second, for the retardation of a descending load.

**465. For the purpose of retarding the descending load** on cranes and ore-handling machinery, it is common practice to employ dynamic braking. The motors used for this service are almost invariably series-wound, and in starting down it is necessary to take current from the line by a separate circuit in order to energize the series field. The systems employed are almost innumerable, and it is impossible to describe them all here. The connection diagrams, Fig. 63, illustrate the theory of a control system of this character. It will be noted that in hoisting, the motor armature and field are first connected across the line in series with a resistance. This resistance is removed step by step as the control lever is advanced toward the full-speed position. A mechanical brake set by a weight or spring serves to hold the load in any position, and a series-wound solenoid, "B," is adapted to release this mechanical brake when hoisting or lowering is taking place. In the "off" position, the circuits to both motor and brake solenoid are open, and consequently the mechanical brake is set. In the lowering positions the motor field and the brake solenoid are connected across the line in series with a variable resistance; the motor armature is bridged across the field and the brake solenoid. As the control lever is advanced toward the full-speed lowering position, the resistance included in the field-brake circuit is increased until all the resistance is inserted. Further movement increases the resistance included between the armature and the series field until the armature is finally connected directly to the line. The higher the resistance included in the armature circuit, the greater will be the speed at which a given load will descend; and the lower the value of resistance included, the lower will be the descending speed. Should the descending load be insufficient to overhaul the motor, the latter will run as a shunt-wound machine, and actually drive the hoist drums in a reverse direction, paying out line to the descending hook. For sending a light hook down at high speed, the series field is weakened by shunting.

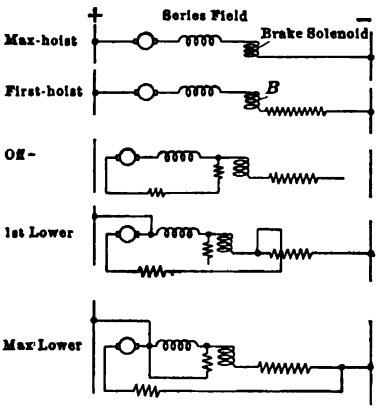

FIG. 63.—Retarding a descending load by dynamic breaking.

**466. Dynamic braking of direct-current motors for the purpose of effecting a quick stop** is employed quite extensively in connection with elevators, printing presses and machine tools, centrifugal extractors, etc. The arrangement generally provided consists of a switching appliance for

Digitized by Google

connecting a fixed step of resistance across the terminals of the motor armature after the line circuit is interrupted. As a result of this procedure the motor acts as a generator and serves to retard and stop the machine which it drives. While it is possible to effect a quicker stop by this method than if it were not employed, it does not provide for the quickest stopping that can be obtained; it is obvious at once that as the motor speed decreases, the potential generated by its armature correspondingly decreases, and the reduction in current which the armature will send through the fixed step of resistance results in a gradual diminution of the braking force, until it reaches zero when the armature stops.

Inductive resistance is often employed in the braking circuit for the purpose of prolonging the period during which the braking current remains at high value, and quicker stoppage can be effected by its use. Where the quickest possible stop is desired, a variable resistance should be connected across the motor armature; this resistance should be reduced by a series of magnetic switches, the successive closure of which will be halted whenever the braking current exceeds a predetermined value. With such an equipment, the braking current can be maintained at a high value throughout the entire stopping period, and much faster results obtained than are possible by any other method. In the interest of economy the starting resistance and the accelerating switches are generally employed for graduated dynamic braking. Thus the same apparatus which is used to limit the current of acceleration, serves also to limit the current of retardation.

**467. Alternating-current motors can be used for dynamic braking** only when direct-current is available for their excitation; the method is seldom used, for this reason. For quick stopping, the reversal of the primary and the inclusion of a high resistance in the secondary is equally effective and does not require direct current. For the retardation of descending loads it has not been very popular, largely on account of the general unpopularity of alternating-current motors for this class of service, direct-current machines being better adapted on account of their inherent characteristics (Par. 468, No. 11).

## ELECTRIC TRACTION

BY

**ALBERT H. ARMSTRONG**

*Asst. Engineer, General Electric Company Member, American Institute Electrical Engineers*

REVISED WITH THE ASSISTANCE OF

**NORMAN W. STORER**

*General Engineer, Westinghouse Electric and Manufacturing Co., Fellow, American Institute of Electrical Engineers*

### INTRODUCTION

**1. Considerations affecting general design.** All railway estimates are based upon the performance of the rolling stock, as this determines the type of equipment to be used, its capacity, the possibilities of schedule speed, and the power input to the train, both maximum and average. This last-named factor in turn determines the characteristics of the low-potential distribution system, whether trolley or third-rail, and its capacity. These considerations lead up to the determination of substation capacity and, finally, the capacity and cost of the generating station. It is important, therefore, that the characteristics of the different types of motive power be thoroughly understood, as a false assumption of error in the preliminary calculation of motive-power capacity and train energy consumption may lead to very serious errors in laying out the entire generating and distributing systems.

**2. Classification of systems now employed.** There are four **types of motors** available for railway service, giving rise to three systems of distribution: (a) the direct-current series-wound motor of from 600 to 1,200 volts, fed from a synchronous-converter or motor-generator substation, tied into a high-potential three-phase alternating-current transmission system; (b) the alternating-current series-wound motor fed directly from an alternating-current high-potential transmission system through intermediary step-down transformers; (c) the alternating-current three-phase induction motor fed directly from an alternating-current three-phase transmission system through step-down transformers; (d) the alternating-current polyphase induction motor, fed from a single-phase circuit through an intermediate phase converter ("split-phase system").

All four systems enjoy the advantage of alternating-current generation and transmission of power at high potential, the direct-current and induction motor system demanding multiphase generation, while single-phase generation and distribution best serves the needs of the single-phase alternating-current motor and split-phase systems.

**3. Method of studying traction problems.** The various steps to be followed in the determination of the proper relation of motive power equipment, distribution and generating systems, are as follows: (a) a knowledge of train-resistance values; (b) calculation of possible schedule with the frequency of stops, train weight and other fixed factors entering into the problem; (c) determination of train input as obtained from train resistance and energy consumption values; (d) determination of motor capacity; (e) calculations of train diagrams; (f) determination of capacity of low-potential distribution system and substations; (g) determination of generating-station capacity; (h) estimate of cost of the various parts of the electric railway system as determined by the capacity found above; (i) approximate cost of operation; (j) approximate gross income as determined by comparative statistics; (k) dividend earning power of road.

## TRAIN RESISTANCE

**4. Tests.** Careful experimental tests, carried out during the past few years with electric locomotives and motor-cars, have thrown new light on the much discussed question of train resistance at the higher speeds. Without, in any way, disparaging the care taken in tests made with steam locomotives, it was not until electrical methods of measuring power introduced greater accuracy than was possible by use of the steam indicator, that consistent results became obtainable with light trains operating at very high speeds.

The electric motor was the means of introducing the single-car train operating at speeds up to 70 miles per hr. At that time no data were extant concerning the operation of single-car trains. It was soon found that such a car operating alone required an input out of all proportion to the power required to propel a train composed of several such cars operating at the same speed, consequently new adjustments had to be made in train-resistance formulas then existing.

During the spring of 1900, a series of tests were made by Mr. W. J. Davis, Jr., on the Buffalo & Lockport Railway, which consisted in running a 40-ton electric locomotive alone and with trailers at speeds approaching 60 miles per hr., as a maximum. These tests probably constitute the first consistent attempt to utilize the benefits of greater accuracy which electrical methods of recording afford. Since then other tests, taken under better conditions and with various classes of equipment, afford data from which it is possible to predict, with a considerable degree of accuracy, the total resistance (wind, bearing and rolling) opposing the movement of cars or light trains up to speeds of 100 miles per hr.

**5. Train resistance may be expressed in pounds tractive effort** exerted at the rim of the driving wheels of the prime mover of a train. It includes all losses in bearings, losses due to rolling friction, bending rails, flange friction, etc., and the wind-resistance loss. The last item is made up of head-on resistance, skin or side resistance and eddy currents caused by the suction at the rear of the car or train. All these variables depend upon the condition of bearings, design of trucks, condition of the road-bed, shape and cross-section of cars, direction of wind, etc., so that any tests, to furnish authoritative data, must be sufficiently comprehensive to eliminate the errors of purely local conditions. As no such elaborate series of tests have yet been made, any formulas predicated on the data available must at best be approximate.

Data are available on the performance of locomotives and cars of modern construction as follows: Buffalo and Lockport experiments in 1900; Zossen high-speed tests in 1902–3; tests on New York Central type locomotive at Schenectady, 1905–6; tests on car No. 5 at Schenectady, 1906; tests made by the Electric Railway Test Commission, on the test car "Louisiana," 1904–5; New York Subway tests, 1905; Dynamometer car tests by Prof. Edward C. Schmidt, University of Illinois, 1910.

Many isolated tests have been made from time to time other than those mentioned above, but either the data was not sufficiently complete or the conditions were too unfavorable to justify using the results obtained as applying to other than local conditions. The data comprised in the tests given above are sufficiently general, as they include the operation of trains varying from a single 35-ton car, to a train of 532 tons, and at speeds up to 130 miles per hr. in the Zossen tests.

**6. Frictional resistance.** The laws governing the **friction of journal bearings** are fairly well understood, and such bearing friction opposing the motion of a train, need introduce no undetermined factors in a calculation of train resistance. Such friction losses decrease with the pressure on the bearings and are a function of the speed. Hence, the expression, $f' = A' + B'S$, where $f'$ is bearing friction expressed as lb. per ton, $A'$ and $B'$ are constants determined by experiment (see Par. **8**) and $S$ is the speed expressed conveniently in miles per hr. **Rolling friction** (see Par. **22**) is due to the friction of metal rolling on metal where the surfaces are not perfect; the bending of rails due to insufficient support, or meager cross-section of rail; and flange friction between rail and wheel flange. All these factors are proportional to speed, and hence may be represented by a straight line function of speed. As bearing and rolling friction are both approximately proportional to the speed they may constitute the first two terms of a train resistance formula,

$$f_1 = A + BS \quad \text{(lb. per ton)} \qquad (1)$$

Digitized by Google

**7. The friction constant, A,** has been determined by experiment to vary from 3.5 to as high as 12 lb. per ton, depending upon the weight concentrated on the journal bearings. Both the Zossen cars and the New York Central locomotive have indicated in test a value of $A = 3.5$ to 5, both the cars and locomotive having a weight of approximately 200,000 lb. concentrated on twelve journal bearings. Tests on Car No. 5 at Schenectady on the other hand, gave a value of approximately 8.5 for $A$, this car having 68,800 lb. on eight bearings. Hence, the impossibility of giving a single value to $A$ that will obtain over wide variation in type of equipment.

The factor, $A'$, can be expressed in terms of the train weight and the following purely empirical term is suggested as agreeing remarkably close with experimental results.

$$A = \frac{50}{\sqrt{W}} \qquad (2)$$

where $W$ = tons weight of train.

In using such a term it is necessary to limit $A$ to a minimum value of 3.5

**8. Values of A (Par. 7)**

| | | | |
|---|---|---|---|
| 20-ton car | 11.2 | 60-ton car | 6.45 |
| 30-ton car | 9.12 | 80-ton car | 5.58 |
| 40-ton car | 7.9 | 100-ton car | 5.00 |
| 50-ton car | 7.07 | 200-ton car | 3.54 |

**9. The friction constant B.** The coefficient of $S$ in the second term of a train resistance formula (Par. 6), takes cognisance of the increase of rolling and bearing friction with speed. This coefficient can be determined experimentally by operating a train with and also against a wind of known velocity. Given a wind of say 10 miles per hr. in the direction of the test track, if a series of runs be made at 40 miles per hr. against, and 60 miles per hr. with the wind, the effect of wind resistance would be the same in both cases. On the other hand, any difference in the total train resistance found would measure the (journal and rolling) frictional difference occurring for a speed change of 20 miles per hr. Unfortunately the published data of the Zossen test are incomplete in this respect, and offer no material upon which to place a value for the second term coefficient. Other tests, made for the purpose, give values of $B$ for speeds up to 80 miles per hr. with trains of any composition. As the effect of $B$ is small with heavy trains and almost negligible with single cars operated at high speed, any errors introduced by reason of insufficient data, do not seriously affect the accuracy of the train resistance formula as applied to the classes of equipment commonly met.

Values of $B$ obtained experimentally vary from 0.03 to 0.07, depending upon the type of equipment and condition of track. For practically all operating conditions a value of $B = 0.03$ will give sufficiently accurate results, using higher values of $B$ for very light equipments (under 30-ton cars) and poor track conditions, such as scanty rail, accumulations on rail, etc.

**10. Wind resistance.** By far the most important term of a train resistance formula (Eq. 4) for light trains is the term expressing the relation between effect of wind and speed of train. It is in this term that the many elaborate tests made with steam locomotives have failed in affording accurate data, especially for very light trains operating at high speeds. Such tests have usually been made either with steam indicator or dynamometer car as the means of determining the effect of wind pressure. The indicator card included in its readings all the intermediate internal friction losses of the locomotives, thus making results obtained by its use of small value when applied to other types of motive power having much smaller internal losses. The dynamometer car, while giving accurate readings of the draw-bar pull required to haul the succeeding trailers, failed to indicate the amount of head-on wind pressure, which constitutes by far the larger proportion of the total resistance opposing the progress of a light train at high speed. Hence, the tendency to discard in a large part, the experimental data obtained from steam locomotive tests and place reliance upon the data obtained from such tests as the series listed in Par. 5.

Tests made upon small models (Goss in 1897) and by means of whirling surfaces, seem to indicate that wind pressure increases as the square of velocity.

The Zossen experiments also indicated that the wind effect upon the car increased as the square of the speed, thus following along the line of labora-

Digitized by Google

tory experiment and previous experimental train tests by Davis in 1900. Hence, that portion of train resistance which results from the effect of wind may be given by the relation

$$f_2 = \frac{CaS^2}{w} \quad \text{(lb. per ton)} \qquad (3)$$

where $f_2$ is the wind resistance in lb. per ton, $C$ is a constant, $a$ is the projected area, and $W$ is the train weight in tons. This equation leads to the third term of Eq. 4.

**Values of C** (*Kernot*, 1894)

$C = 0.004$ for flat surfaces, $C = 0.0020$ for cylinder,
$C = 0.0024$ for octagonal prism, $C = 0.0014$ for sphere.

**11. Method of making wind resistance experiments.** The simplest and most accurate is the coasting method, where a moving train is allowed to drift until it reaches standstill, the rate of speed decrease and elapsed time being accurately noted. The efforts of most experimenters have been directed toward securing such data during periods of no wind in order to eliminate this troublesome feature. However, a series of runs taken with and against a wind of known velocity offers much data not otherwise available, and affords a ready means of solving directly for the coefficient of the second and third term of the train resistance formula (Eq. 4).

For example, given a wind of 20 miles per hr. velocity, a series of runs made with and against such a wind will, at say 50 miles per hr. train speed, correspond to a wind pressure at 30 miles per hr. with the wind and 70 miles per hr. against the wind, the rolling friction being constant at the value obtaining at the train speed of 50 miles per hr. As the wind pressure varies as the square of the speed, such a series of tests affords a means of determining the coefficient of $S^2$ for the particular type of equipment used.

**12. The shape of the car** end has a large influence upon the coefficient of $S^2$, such a result being reasonably expected from the results of experiments by Goss, Kernot and others: in fact, Davis checked up the values of 0.004 found by Kernot for flat surfaces. As a matter of fact, no cars or locomotives used for high-speed service have perfectly flat ends, and hence, all experimental values of $C$ have been found to be less than 0.004.

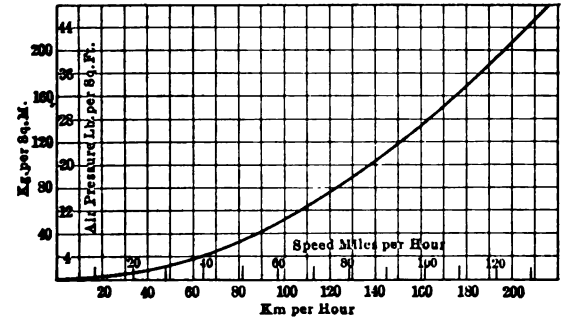

FIG. 1.—Wind-resistance test (Berlin-Zoesen).

Little attempt has been made to construct cars for least wind effect, owing largely to a lack of full understanding of the benefits to be secured thereby. The cars used for high-speed suburban service and all electric locomotives, with few exceptions, are provided with partially rounded ends, with the result that the effective wind pressure is considerably reduced. A notable example of the extreme type of pointed nose design is the steel gasolene motor-car No. 7, of the Union Pacific Company, and such construction is a step in the right direction.

**Values of C** vary from 0.004 with perfectly flat ends to 0.0015 with noses

Digitized by Google

of the extreme type, while the average rounded end suburban car and electric locomotive with sloping front give rise to values of $C$ from 0.002 to 0.0025 (see Par. 10).

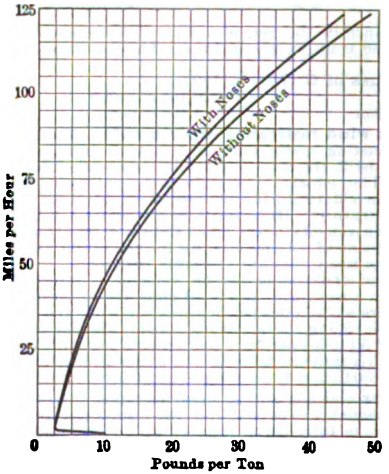

FIG. 2.—Train resistance (Berlin-Zossen tests 1903; Allgemine car weight 206,400 lb., area 130 sq. ft.).

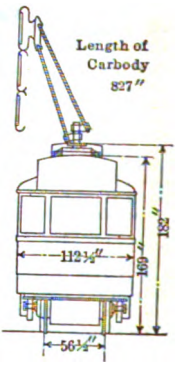

FIG. 3.—End elevation Allgemine car (Berlin-Zossen tests).

**13. The complete train-resistance formula for single-car operation becomes**

$$f = A + BS + \frac{CaS^2}{W} = \frac{50}{\sqrt{W}} + 0.03S + \frac{0.002aS^2}{W} \qquad (4)$$

wherein $S$ is the speed in miles per hr.; $a$ the cross-section in square feet, and $W$ the car weight in tons.

It was found by Davis that somewhat larger coefficients for $B$ and $C$ obtained from the limited data of the Buffalo and Lockport tests, but much subsequent data seem to indicate values of $B = 0.03$ and $C = 0.002$ for cars weighing not less than 40 tons and having partially rounded ends.

**14. Comparison of calculated car-resistance with the actual test values**

(Zossen experiments)*

| Speed miles per hr. | 10 | 20 | 40 | 60 | 80 | 100 | 120 |
|---|---|---|---|---|---|---|---|
| $A = 4.92$ | 4.92 | 4.92 | 4.92 | 4.92 | 4.92 | 4.92 | 4.92 |
| $BS = 0.03V$ | 0.30 | 0.60 | 1.20 | 1.80 | 2.40 | 3.00 | 3.60 |
| $\frac{CaS^2}{W} = \frac{0.002S^2 \times 128}{103.2}$ | 0.25 | 1.00 | 3.96 | 8.93 | 15.90 | 24.80 | 35.70 |
| $F$ (calculated) = | 5.47 | 6.52 | 10.08 | 15.65 | 23.22 | 32.72 | 44.22 |
| $F$ (observed) = | 3.5 | 5.5 | 9.10 | 14.9 | 22.8 | 33.3 | 46.00 |

* Here $a = 128$ sq. ft. and $W = 103.2$ tons (2,000 lb.).

Digitized by Google

It is very possible that the higher values obtained at the maximum speeds were influenced by reason of the track being not rigid enough for speeds of 120 miles per hr., and hence increasing the value of $B$.

**15. A consideration of trains of several cars** makes it necessary to introduce an additional factor in the third term of the proposed train-resistance formula that shall express the effect of the wind resistance upon the sides of the succeeding cars. The head-on wind resistance is borne by the leading car, and hence additional cars only introduce the additional skin friction offered by a train of greater length.

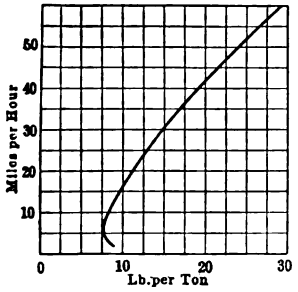

FIG. 4.—Train resistance (General Electric tests); weight 63,000 lb.

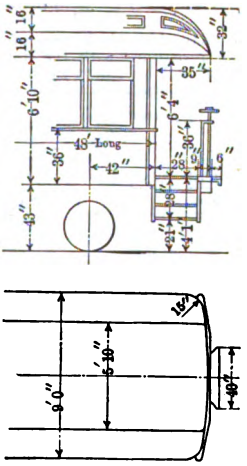

FIG. 5.—Elevation and plan, car No. 5 (General Electric tests).

**16. The most reliable and exhaustive series of tests made with trains composed of a different number of cars** is offered in the experimental runs of the New York Central locomotive No. 6,000, during its 50,000-mile endurance run, hauling trailers up to a nine-car train. Over 140 runs under different climatic conditions are condensed in the series of curves shown in Fig. 6, where the train resistance is expressed in pounds per ton weight of total train including locomotive. This set of curves indicates very plainly the reduction in train resistance per ton of train with the increase of train weight, such a reduction being largely due to the fact that the head-on wind resistance remains constant for any composition of train, being influenced only by the shape and cross-section of the locomotive.

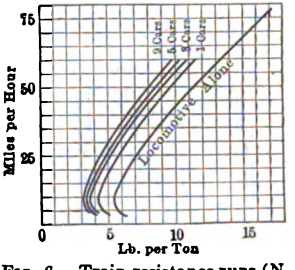

FIG. 6.—Train-resistance runs (N. Y. C. locomotive and train).

**17. The increase in skin friction along the surface of succeeding cars** corresponds closely to 10 per cent. of the value of wind resistance as expressed by Eq. 3, and for a train of several cars the expression for wind resistance becomes,

$$f_3 = \frac{CS^2a}{W}\left(1+\frac{n-1}{10}\right) \qquad \text{(lb. per ton)} \qquad (5)$$

where $n$ represents the number of cars in the train. This may be substituted for the third term of Eq. 4.

Digitized by Google

**18. The complete formula for any weight and composition of train** (see Par. 23) now becomes,

$$f = \frac{50}{\sqrt{W}} + 0.03S + \frac{0.002aS^2}{W}\left(1 + \frac{n-1}{10}\right) \quad \text{(lb. per ton)} \quad (6)$$

The above formula is presented as being an expression of the knowledge of train resistance with the data extant, but any such formula is largely empirical, and is subject to change from time to time as the results of additional tests become available.

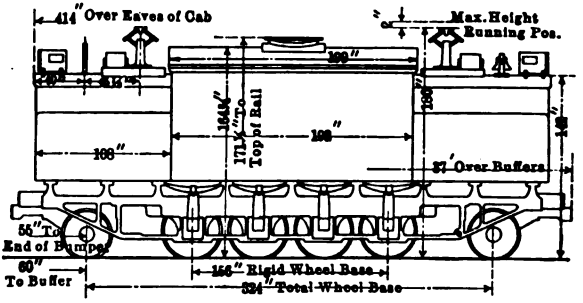

FIG. 7.—N. Y. C. locomotive, side elevation.

Figs. 9 to 13 show curves based upon this train resistance formula, and express the resistance encountered with cars of from 20 to 60 tons weight operating singly and in trains. Also, for high-speed locomotive service, a series of curves is plotted for train values up to nine-car train operation. All these results assume a perfectly level tangent track, free from any foreign matter, such as street accumulations, sand, snow, etc. The effect of such matter is to increase seriously the value of $B$, hence the curve values should be increased if conditions are unfavorable.

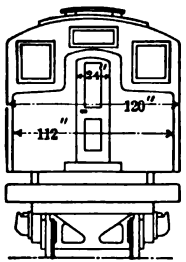

FIG. 8.—End elevation.

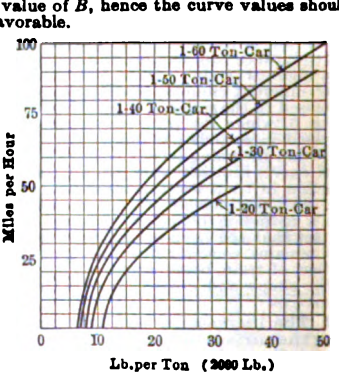

FIG. 9.—Train resistance, single-car train.

**19. Freight train resistance** is but little affected by wind resistance owing both to the low speeds of such trains and due also to the small cross-section of the car compared to the length of the train. What wind resistance is offered is therefore largely skin friction.

The results of a series of dynamometer car tests conducted by neering Experiment Station of the University of Illinois, are given Edward C. Schmidt in a paper read before the A. S. M. E., May These tests covered a wide range of car weights and train speed gives the results thereof.

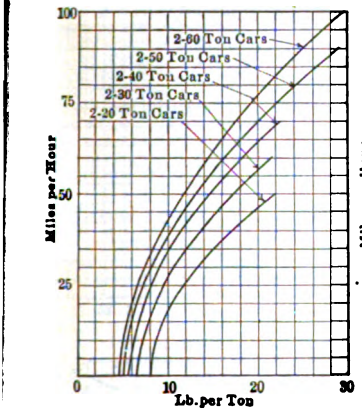

FIG. 10.—Train resistance, two-car train.

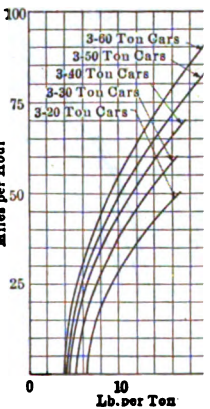

FIG. 11.—Train resist three-car train.

**20. Track curves** are usually expressed in degrees; a 1-deg. taken arbitrarily as one in which a 100-ft. chord will subtend a deg. or, which is the same thing, will subtend a 1-deg. angle at t Hence the radius of a 1-deg. curve is approximately $(100 \times 360)/(2\pi) = 5{,}730$ ft. Similarly the radius of any curve in feet is approximately 5,730/No. of deg.

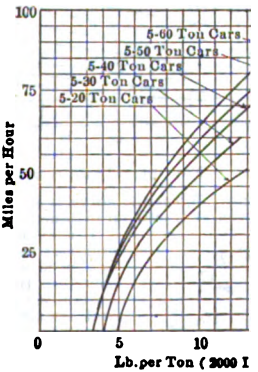

FIG. 12.—Train resistance, 5-

**21. Curve location.** This custom of rating curves by degrees instead of by radius has undoubtedly arisen from the facility offered for laying out a curve in the field with a transit. For instance, a transit is set up at the point of curve, *PC* (Fig. 15), and several angles, *EAB*, *BAC*, etc., each equal to one-half the degree of the curve are laid off. In the first of these directions 100 ft. is measured off and a stake driven. From this stake another 100 ft. is measured off and lined in by the transit in its second position. One-hundred-foot chords are thus laid off until point of tangent *PT* is reached. As indicated in Fig. 15, this point is seldom at an even station, but is always indicated by a stake marked as shown, *PT*. Sta. 102+80. Likewise with the point of curve case the *PC* is not at an even station, the first stake of the curve at an even station so that the remaining stakes of the curve wil

Digitized by Google

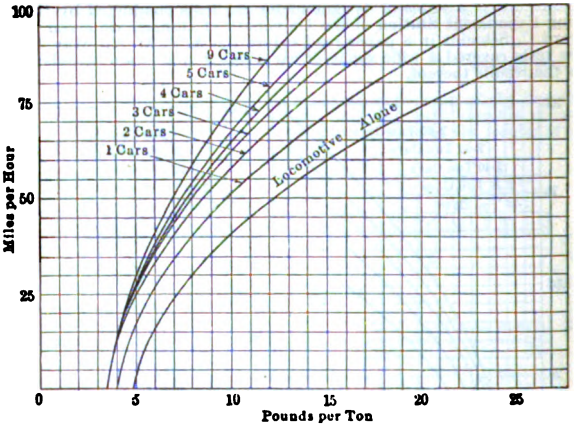

FIG. 13.—Train resistance, locomotive train.

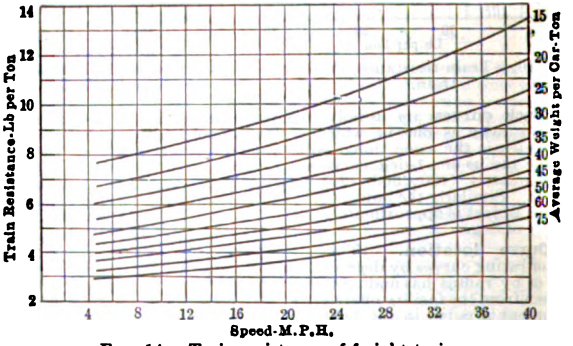

FIG. 14.—Train resistance of freight trains.

even stations. When the curve is sharp, intermediate stakes are necessary and are driven at fractional distances.

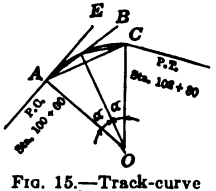

FIG. 15.—Track-curve lay-out.

It is evident that as the degree of curvature increases, this method of laying out a curve becomes less accurate and not particularly expeditious, therefore, the **sharp curves** met in city streets are generally rated as special work and are laid out and assembled in the works of the switch manufacturers before they are shipped, in which case the curves are generally rated by radius.

**22. Curve friction.** In rounding a curve, the rolling friction of a car is increased due to the increased flange friction, this increase being approximately at the rate of 1.0 lb. per ton for each degree of curvature. As curves are of necessity of limited length they do not become a serious factor in train

Digitized by Google

resistance calculations except in the calculation of locomotive constants assigned to mountain grade service, where both sharp curves and heavy grades occur.

**23. Grades** are expressed in percentages, being the ratio of the distance the train is raised to the distance travelled, in other words, the ratio of the ordinate of a right-angled triangle to the hypothenuse. A grade of plus 1 per cent. is one where the train is raised vertically 1 ft. for each 100 ft. travelled; a minus 1 per cent. grade is one where the train falls 1 ft. for every 100 ft. of distance travelled. It follows that a plus 1 per cent. grade calls for a tractive effort of 20 lb. per ton, while a minus 1 per cent. grade is equivalent to delivering a tractive effort of 20 lb. per ton to the train.

Where gradients are small it is not necessary to consider the reduction in train weight due to the angle of direction of travel to the true horizontal in calculations of friction (Par. 6) and adhesion (Par. 26). However, with the excessive grades, it is necessary to correct for effective train weight.

Grades are divided in railway parlance into virtual grades and ruling grades.

**24. Virtual grades** are of limited length and are so called as they express the equivalent grade, a value always something less than the true grade. A train running at constant speed can surmount a certain grade as determined by the maximum tractive effort available. The moving train however may be compared to a fly-wheel, and has stored in the moving mass a large amount of energy, which is usually expended in heating the brake shoes during the period of stopping. This stored energy may be used to furnish the extra tractive effort required to ascend a heavier grade than the available locomotive tractive effort alone would permit, but in such a case the grade must be of short length. Hence, the actual grade may be considerably in excess of the virtual grade, provided it is so short that the inertia of the moving train can supply the additional energy required to ascend it.

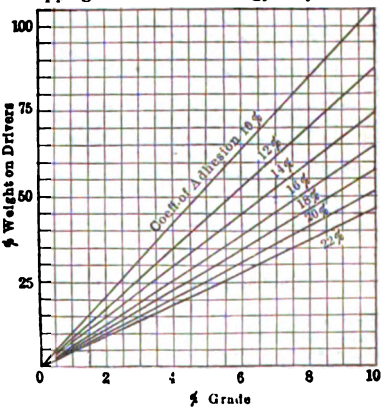

FIG. 16.—Relation between per cent. weight on drivers and per cent. grade.

**25. The ruling grade** means the maximum grade encountered on a given section of track and may be the actual grade, where such is of long extent, or the virtual grade, where the inertia of the train may be used to advantage in overcoming a heavier short grade. The ruling grade of freight hauling roads should be limited to 2 per cent. or less when the topography of the country will permit, in fact, on a modern freight road any grade exceeding 1 per cent. maximum would be considered excessive, and would demand the use of helper locomotives. While low grades are not so important on electric suburban railways where the income is largely derived from passenger receipts, the future possibilities of freight traffic over these lines makes a low gradient desirable whenever possible.

**26. Coefficient of adhesion** expresses the ratio between total tractive effort and weight on drivers. Coefficient $= F_e / W$ where $F_e$ is the maximum possible tractive effort in lb., and $W$ is the weight on the drivers in lb.

This is expressed in per cent. and is a variable depending upon the condition of track and composition of wheel. See Par. 27.

It is good practice to design the motive power of a car or locomotive so that it can slip the wheels on a dry rail, this practice not being strictly fol-

Digitized by Google

lowed in very high-speed motor-car equipment, owing to the enormous current input that this would demand of such an equipment, designed primarily for low tractive effort and high speed. In steam locomotive practice, however, it is customary to rate the locomotive at the tractive effort corresponding to a coefficient of 22 per cent. of the weight upon the drivers, that is, at practically the slipping point of the drivers. This practice is handed down from steam-locomotive practice, where the tractive effort is fluctuating during one revolution of the driver, hence on account of the perfectly uniform torque exerted by the electric motor, the electric locomotive could readily be rated about 15 per cent. higher in tractive effort for the same weight upon the drivers.

**27. Coefficients of adhesion with uniform torque** (approx.)

| | |
|---|---|
| Clean dry rail | 30 per cent. |
| Wet rail | 18 per cent. with sand 22 per cent. |
| Rail covered with sleet | 15 per cent. with sand 20 per cent. |
| Rail covered with dry snow | 10 per cent. with sand 15 per cent. |

**28. Maximum allowable grades.** The values for coefficients of adhesion given in Par. **27** are based upon the assumption that the motive power gives a perfectly uniform torque. Thus, while 30 per cent. is the maximum value given, tests with electric locomotives have recorded as high a coefficient as 35 to 40 per cent. under very favorable conditions. For single motor-car service where all axles are equipped with motors, the tractive effort available with a coefficient of adhesion of 22 per cent. is 22 per cent. of 2,000 = 440 lb. per ton, or sufficient to carry the car up a 22 per cent. grade, taking no account of train resistance or reduced effective weight of car on such an extreme grade, Par. **23**. A motor car, however, has to operate under all climatic conditions, and hence is liable to meet conditions where the coefficient of adhesion may drop to as low as 10 per cent., so that the maximum grade in practice should never exceed 12 to 13 per cent. Should such extreme grades be necessary, some form of track brake should be provided as an auxiliary to hand or air brakes in order to ensure safety in operation. Moreover, all curves encountered should be compensated where grades are heavy, especially if the rigid wheel base of the trucks is large and the radius of curvature small.

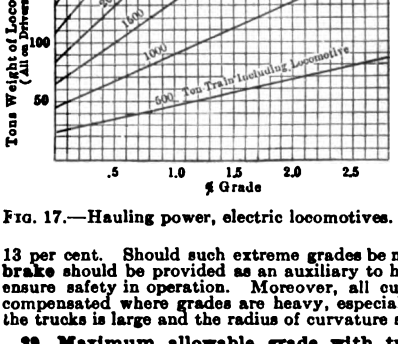

FIG. 17.—Hauling power, electric locomotives.

**29. Maximum allowable grade with trailers.** Where trailers are hauled, it becomes important to know what maximum grade can be surmounted with the tractive effort permitted by different coefficients of adhesion. In Fig. 16 is shown the relation between per cent. of total train weight on the driving wheels to the per cent. grade that can be surmounted when a flat allowance of 10 lb. per ton is made for train resistance.

*Example.* A motor car weighing 36 tons, all axles equipped with motors, hauls a trailer weighing 24 tons, what maximum grade can it ascend?

**Answer**: Total train weight 36 + 24 = 60 tons.
Weight on drivers = 36/60 = 60 per cent.

Hence, from Fig. 16, it is found that the train can ascend a 9.3 per cent. grade with 16 per cent. coefficient; or, with adverse rail conditions, a grade of 5.7 per cent. with a coefficient of 10 per cent.

**30. Starting on grade.** The values in Fig. 16 provide no leeway for starting on grade. A minimum of 10 lb. per ton is required for starting freight trains and an additional 4 lb. per ton for train resistance, hence,

Digitized by Google

total tractive effort on grade is expressed by the sum 4+10+(20×per cent. grade), in lb. per ton.

Based upon above formula, Fig. 17 is made up, giving the **weight of locomotive required** to operate trains from 500 to 3,000 tons gross weight on any grade. It is assumed that all the locomotive weight is on the drivers, an assumption that may hold true in slow-speed freight service if the alignment is good. Where pony or bogie guiding trucks are necessary for safety in rounding curves or to prevent "nosing," divide the values of locomotive weight as obtained from Fig. 17, by the percentage of weight on drivers to total locomotive weight obtaining in the design of locomotive required.

## SPEED-TIME CURVES AND MOTOR CHARACTERISTICS

**31. Acceleration.** The many problems connected with train acceleration can be treated either analytically or graphically. As will be shown later, there are so many variables entering into the consideration of train movements at variable speeds that the analytical method becomes somewhat complicated and difficult to follow. The graphical method is equally as accurate, much easier to work with, and the final results are given in such form that they are of general application without calling for the familiarity of terms and symbols made necessary by the analytical treatment.

There are several terms used in connection with train acceleration phenomena which are defined in Par. **32** to **38**.

**32. Tractive effort** is the torque in pounds developed at the rim of the wheels, divided by total train weight in tons. This term is usually expressed in pounds per ton of train weight and includes train resistance losses.

**33. Braking effort,** also expressed in pounds per ton is the opposite of tractive effort, expresses the force tending to retard the motion of the train and bring it to rest.

**34. Rate of acceleration** is the increment expressing the rate of increase in speed of train, and may be expressed in feet per sec. per sec., or miles per hr. per sec.—usually the latter.

**35. Rate of braking** is the increment expressing the rate of decrease in speed of train. Both rate of acceleration and rate of braking may vary considerably during successive periods of time, depending upon type of motive power and brake rigging used.

**36. Train resistance** a variable, expressed in pounds per ton and tending to retard the motion of the train (Par. **4** to **30**).

**37. Speed-time curves** express the relation of the above variables in curve form, generally with speed in miles per hr. as ordinates, and elapsed time in seconds as abscissas.

**38. Energy curves** show the energy consumption, generally expressed as watt-hours per ton mile, for different rates of acceleration, braking and train resistance, for various elapsed times over a given distance run.

**39. Curves of free acceleration.** A better understanding of the possible movements of a car or train operating at different speeds over different distances, is obtained by eliminating the type of motive power and brake rigging used, and assuming straight-line acceleration, coasting and braking curves. The results so obtained are fundamental, and may be applied to examples, considering any type of motive power using a correction factor, which will be treated later, known as the efficiency of acceleration.

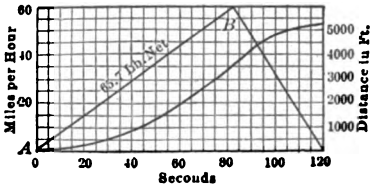

FIG. 18.—Typical speed-time-distance curve (no coasting).

**40. The problem of train acceleration** deals with the movement of a given weight over a given distance within a specified time. As it is impracticable to start and stop the train instantaneously, it is necessary to deal with some finite rate of acceleration and braking, thus giving rise to the simple form of speed-time curves shown in Fig. 18. The speed-time curve is here

Digitized by Google

shown in the simplest form, acceleration being carried on at constant rate up to the point of applying brakes, which are so applied as to also give a constant rate of braking. The area enclosed within the triangle, $A$, $B$, $C$, is proportional to the distance travelled, the distance covered up to any instant being represented by the distance-time curve shown. Thus, with the constants chosen in Fig. 18, a maximum speed of 60 miles per hr. is required to obtain an average speed of 30 miles per hr., that is, covering a distance of 5,280 ft. in 120 sec.

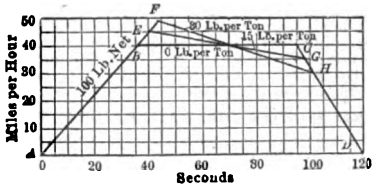

FIG. 19.—Typical speed-time curves (varying coasting resistance).

**41. The simple formulas required in the construction of fundamental speed-time curves** are given as follows:

Let $v$ represent velocity in ft. per sec.; $f$, the force producing acceleration expressed in lb. per ton; $t$, the time interval expressed in sec.; $m$, the mass, $m = w/g = w/32$; $w$, the weight in lb.

Then,

$$v = \frac{ft}{m} = \frac{ftg}{w} \qquad \text{(ft. per sec.)} \qquad (7)$$

On the basis of one ton,

$$v = \frac{32.2\,ft}{2{,}000} = 0.016\,ft \quad \text{(ft. per sec. per ton)} \quad (8)$$

It is more convenient to express velocity in miles per hr.

Hence $$v = 0.682v = 0.01098\,ft \quad \text{(miles per hr. per ton)} \quad (9)$$

The distance covered in any given time may be expressed

$$L = \frac{ft^2}{2m} \times \frac{ft^2 \times 32.2}{2 \times 2{,}000} = 0.00804\,ft^2 \quad \text{(ft. per ton)} \quad (10)$$

(See Par. 61)

**42. Actual speed-time curves.** In practical operation it is not possible to choose the rate of acceleration and braking with such niceness as shown in Fig. 18, a greater or less period of coasting being required. Introducing

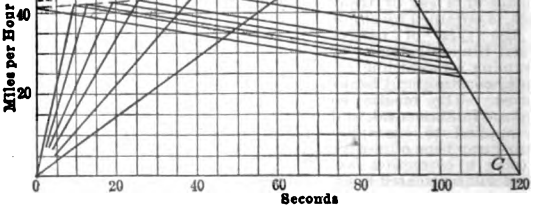

FIG. 20.—More extended set of speed-time curves.

coasting gives rise to the form of speed-time curve shown in Fig. 19, showing three friction rates—$f = 0$, 15 lb. per ton, and 30 lb. per ton respectively. With no friction the speed-time curve, $A$, $B$, $C$, $D$, is constructed, the speed being maintained constant at 40 miles per hr. during the coasting period. With 15 lb. per ton friction, the speed-time curve, $A$, $E$, $G$, $D$, is formed, and with 30 lb. per ton friction the speed-time curve, $A$, $F$, $H$, $D$. The intro-

Digitized by Google

duction of friction occasions a falling off of speed during the coasting period proportional to the friction value taken, which for the sake of simplicity is here assumed to be constant at all speeds.

The speed-time curves shown in Fig. 18 and 19 both indicate the completion of the run of 5,280 ft. in 120 sec., although in one case the rate of acceleration was that produced by 65.7 lb. per ton, and in the other case by 100 lb. per ton. These curves are of equal area, as the distance in each case is 5,280 ft. Thus, it becomes possible to produce any number of speed-time curves, for a given distance and elapsed time, by varying the rate of acceleration with consequent variation in time of coasting.

A more extended set of curves is given in Fig. 20, for the same distance of 1 mile covered in 120 sec., the rate of acceleration varying from 0.713 miles per hr. per sec. as a minimum to an infinite number of miles per hr. per sec. as a maximum.

A train resistance value of 15 lb. per ton is assumed constant at all speeds and the dotted curve, *A*, *B*, is described by the loci of the maximum speeds reached with the different rates of acceleration. The highest maximum speed required is obtained with no coasting, and the minimum speed is obtained with an infinite rate of acceleration. The pounds per ton corresponding to the different accelerating rates are given as including 15 lb. per ton train resistance, hence the net tractive effort values corresponding to the rates of acceleration indicated are 15 lb. per ton less than the figures given.

**43. Application of unit-distance speed-time curves.** Instead of plotting similar curves for distances other than 5,280 ft., advantage may be taken of the fact that the area enclosed by the speed-time curve is proportional to the distance travelled and the coordinates are proportional to the square root of the enclosed area. It is convenient, therefore, to plot a full series of curves for one distance, preferably one stop per mile, that is, a distance of 5,280 ft. run, and to apply the results so obtained for any other distance by using a factor expressing the relation of the square roots of the distance travelled. This is shown in Fig. 21, where *A*, *B*, *C*, *D*, represents an area of 1 mile, or one stop per mile, *A*, *F*, *I*, *L*, two stops per mile with a factor of $1/\sqrt{2}=0.707$; *A*, *E*, *H*, *K*, four stops per mile with a factor of $1/\sqrt{4}=0.5$, and *A*, *G*, *J*, *M*, one stop in 1½ miles with a factor of $\sqrt{1.5}=1.225$.

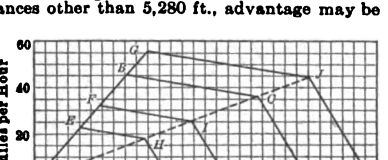

FIG. 21.—Similar speed-time curves (varying distances).

Referring to Fig. 19, it is obvious that a similar sheet could be prepared for any elapsed time other than 120 sec., using the same train resistance and braking values of 15 and 150 lb. per ton respectively.

**44. Imposed time limits.** In Fig. 22 is shown the time limits imposed by 15 lb. per ton train resistance, and 150 lb. per ton braking for any length of run and any rate of acceleration. The dotted curves indicate the loci of the several maximum speeds reached with different accelerating rates for a run made in a given elapsed time. Thus the dotted curve terminating at 80.7 lb. per ton is a reproduction of the similar dotted curve, *A*, *B*, given in Fig. 20, and gives the maximum speed reached with any rate of acceleration for a run of 5,280 ft. in 120 sec. with 15 lb. per ton train resistance and 150 lb. braking effort. Similarly, the dotted curve terminating at 100.4 lb. per ton gives the limiting maximum speeds reached, with any rate of acceleration, when a run of 5,280 ft. is accomplished in 110 sec., using the same values of train resistance, braking, etc.

**45. Time limits with and without coasting.** The full line *C*, *D*, gives the angle made by a coasting line when the rate train friction is 15 lb. per ton. Thus, in a run completed in 120 sec., the minimum accelerating rate corresponds to 80.7 lb. per ton (gross), with no coasting introduced, for here braking commences as soon as acceleration ceases.

Digitized by Google

If a higher rate of acceleration than 80.7 lb. per ton be used for a cycle completed in 120 sec., for example 132 lb. per ton (gross), coasting must be introduced between the accelerating and braking lines. This coasting line may be plotted, with 132 lb. per ton acceleration, by drawing a line parallel to full line *C,D* (Fig. 22). This line starts at the intersection of accelerating line, 132 lb. per ton, and the dotted line to 80.7; and terminates at the intersection with the braking line ending at 120 sec.

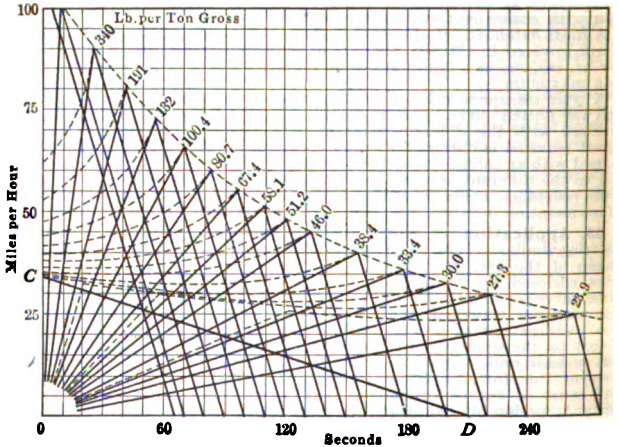

FIG. 22.—General speed-time curves (train-resistance 15 lb., braking 150 lb.).

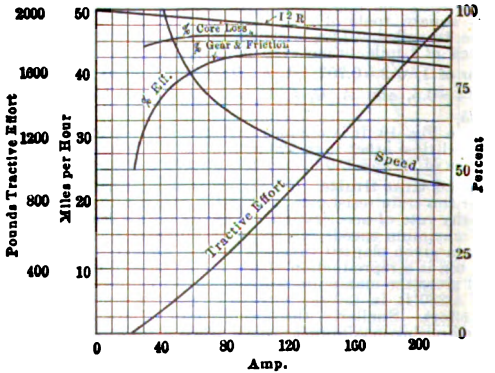

FIG. 23.—Typical direct-current motor performance (75 h.p., 500 volts).

**46. Application of general speed-time curves.** By the use of Fig. 22, it becomes possible to determine the time required to make a run over any distance with any rate of acceleration, provided the train resistance is 15 lb. per ton and braking corresponds to 150 lb. per ton retarding effort.

Digitized by Google

*Example:* Given a distance of 8,000 ft., train resistance 15 lb. per ton, braking effort 150 lb. per ton, tractive effort gross 67.4 lb. per ton (including 15 lb. per ton train resistance), what is the minimum time required to perform the run and what maximum speed is reached?

*Solution:* From Fig. 22, minimum elapsed time with 67.4 lb. tractive effort is 130 sec. with no coasting. Ratio of distances $= \sqrt{8{,}000/5{,}280} = 1.23$. Hence for 8,000 ft. time of run $= 130 \times 1.23 = 160$ sec.; maximum speed for 5,280 ft. = 55.6 miles per hr.; hence for 8,000 ft. speed $= 55.6 \times 1.23 = 68.5$ miles per hr.

**47. In actual practice, a certain amount of coasting is necessary;** hence, the run of 8,000 ft. (Par. 46), would be made in somewhat more than the minimum possible limit of 160 sec., or else the tractive effort should be increased to allow for a higher rate of acceleration that would permit of some coasting. Fig. 22 is of universal application as it is not limited to any particular type of motive power, having its own peculiar speed characteristics. Moreover, the values of 15 lb. and 150 lb. chosen for train resistance and braking effort respectively are conservative operating values obtaining in practice.

**48. The maximum speed reached during the performance of a service run** will be little influenced by the type of motive power and its curve characteristics (See Par. 42). The values indicated in Fig. 22 will hold approximately true in service operation with series motors of either the alternating-current or direct-current types, and hence, the curves given constitute a set of fundamental data by means of which it becomes possible to attack any acceleration problem and determine the data required.

**49. Electric motors used in railway service** are of the following types:

(1) Series-wound direct-current motors,
(2) Single-phase alternating-current motors,
(3) Polyphase alternating-current induction motors.

In addition to the above, there have been several attempts at operating shunt-wound direct-current motors, but as such motors have not come into even partial use, owing to the superior qualities of other types, the shunt-wound motor will not be discussed.

**50. Direct-current series-wound motor characteristics and applications.** The direct-current series motor has the general characteristics shown in Fig. 23. Applying this motor characteristic to the performance of a car, it becomes necessary to reduce the motor voltage during the starting or accelerating period of the car in order to limit the tractive effort to a value that will not slip the driving wheels. In other words, if full voltage were to be applied to the motor at standstill, the resulting current would be enormous, would produce a torque that would slip the wheels, and would far exceed the safe commutating capacity of the motor. Hence, the necessity of introducing external starting resistance in successive steps during acceleration, with the result that the starting current is maintained practically constant at the full-load rating of the motor.

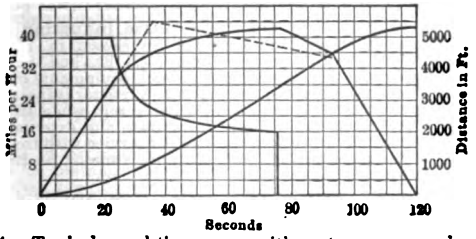

FIG. 24.—Typical speed-time curve with motor-curve acceleration.

**51. A speed-time curve with direct-current series-wound motor** is shown in Fig. 24, indicating a constant current input up to a speed of 28 miles per hr. At higher values of speed, the motor has full voltage applied

Digitized by Google

to its brushes, and hence operates with a constantly decreasing current until full speed is reached, when current and tractive effort both become constant.

**52. Advantage of straight-line functions.** As many acceleration problems involve curves of rather short radii and grades, requiring a step-by-step method of plotting the performance of a train operation, any general speed-time curves other than straight line functions (Fig. 22), would not be of universal application; especially as considerable variation exists in the characteristics of railway motors in general use. The straight-line functions give sufficiently close approximation as regards maximum speed, rate of acceleration and general constants required to perform a given schedule as indicated in Fig. 24, comparison of straight line and motor characteristics.

**53. The alternating-current series-wound motor** must operate at a lower flux density than its direct-current competitor and hence has a motor characteristic that is even more drooping than that of the direct-current series-wound motor. In consequence, there is less straight-line operation and more motor-curve operation during the accelerating period, resulting in a lesser peak-load demand upon the distributing system. Thus, while constant rate of acceleration with direct-current motors may be carried up to 60 per cent. of the free running speed, this ratio may be reduced to possibly 40 per cent. with the alternating-current motor.

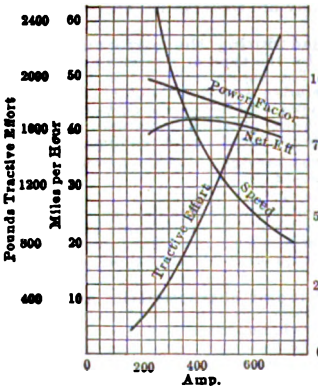

FIG. 25.—Typical alternating-current motor performance (75 h.p., 225 volts).

**54. Speed with series-wound motors.** The maximum speed attained during the performance of a service run, however, will be practically the same for either direct-current or alternating-current series-wound motors, and a preliminary speed-time run may be deduced from Fig. 22, straight line characteristics.

**55. The polyphase induction motor** is practically a constant-speed motor, its speed dropping only approximately 12 per cent. from no load to maximum tractive effort developed. During the accelerating period, therefore, this type of motive power labors under the disadvantage of demanding full rate of acceleration carried up to full free running speed, a condition calling for a very large peak load as compared with either direct-current or alternating-current series motor performance.

**56. The characteristics of the three-phase induction motors in use on the Great Northern locomotives** are shown in Fig. 26. This motor is rated 475 h.p. at 75 deg. cent. rise for 1 hr., and the speed curve indicates the almost constant speed at which such equipments must operate.

For starting and for fractional speed running, a resistor is inserted in series in the secondary circuit, the speed attained being zero when the full secondary e.m.f. is absorbed by the combined armature and external resistance.

Owing to its general unfitness for rapid-transit service with frequent stops, the induction motor is limited to long distance running as its legitimate field.

**57. The permissible rate of acceleration** is determined first by comfort of passengers and second by the tractive effort available. It has been found experimentally that the discomfort to passengers is occasioned largely by the change in rate of acceleration and not entirely upon its intensity. Thus, a very high rate, 2 miles per hr. per sec. may occasion no discomfort with cars having cross seats, provided the rate of acceleration is attained gradually with no abrupt change. The following accelerating rates obtain in practical operation.

Digitized by Google

### 58. Table of accelerating rates

LOCOMOTIVES

Steam locomotives, freight service..... 0.1 to 0.2 miles per hr. per sec.
Steam locomotives, passenger service..... 0.2 to 0.5 miles per hr. per sec.
Electric locomotives, passenger service.... 0.3 to 0.6 miles per hr. per sec.

MOTOR CARS

Electric motor cars interurban service....0.8 to 1.3 miles per hr. per sec.
Electric motor cars city service .....1.3 to 1.8 miles per hr. per sec.
Electric motor cars rapid transit service...1.5 to 2.00 miles per hr. per sec.
Highest practical rate.....2.00 to 2.5 miles per hr. per sec.

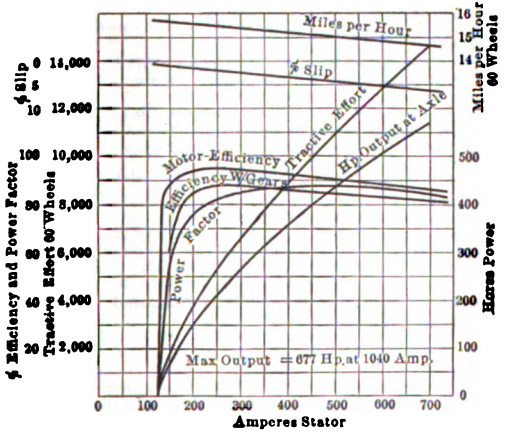

FIG. 26.—Typical polyphase induction motor performance.

**59. Limits of acceleration rate.** The rates given in Par. **58** apply only to that part of the accelerating period during which the current is maintained practically constant by means of cutting out successive sections of the external starting resistance. The higher rates from 1.0 to 2.5 miles per hr. per sec. demand a gradual increase to those values in order to avoid the discomfort to passengers that would surely result from a sudden application or cessation of such rates.

The coefficient of adhesion (Par. **26**) also determines the accelerating rate by limiting the available tractive effort, thus giving rise to the values given above for locomotive practice. As the practice is common to run locomotives very close to the limit of adhesion for full-speed operation, it leaves but a small excess of tractive effort available to accelerate the train. High acceleration demands that all axles shall be equipped with motors, and if trains are run, that all cars must be motor cars, that is, no trailers are permissible when extreme accelerating rates are required to make the schedule desired.

**60. Limits of braking rate.** The limits reached in acceleration hold equally true in braking. As a matter of fact, acceleration may be at a higher rate than braking, for two reasons: first, discomfort to passengers is greater during braking of cross-seat cars, as the inertia of the passenger tends to carry him away from his seat and he lacks the supporting back that prevents discomfort during rapid acceleration when his body is pressed backward; second, in braking a train to standstill, it is necessary for the operator to stop within a distance of a few feet of a fixed spot, and the skill shown in judging speed and distance will determine the braking rate. During acceleration no such limit exists; the motorman has absolute freedom; in fact, a

Digitized by Google

system of motor control is available that will bring about uniform or automatic acceleration, the rate being determined by the necessities of the service.

**61. The inertia effect of revolving parts** must be considered. This factor reduces the effective accelerating and braking rates. In other words it is necessary to expend from 4 to 12 per cent. more tractive effort during acceleration and braking in order to overcome the inertia of car wheels, gears and motor armatures, than is required to accelerate the car or train longitudinally on a level track. This inertia may be calculated as follows:

$$\text{The energy of a rotating body} = W + gV^2 = W + g\frac{r^2}{R^2}V^2 \quad \text{(ft-lb.)} \quad (11)$$

where $V$ = the speed of the centre of gravity of the body in ft. per sec.
$V$ = speed of train in ft. per sec.
$r$ = radius of gyration in ft.
$R$ = radius of rim in ft.

or the effective weight = $Wr^2/R^2$. The ratio $r^2/R^2$ has been found from a large number of tests to be approximately 0.6 for ordinary designs of car wheels, hence the effective weight of the wheels

$$= 0.6 \times \text{weight of wheels (lb.)} \quad (12)$$

The ratio, $r^2/R^2$, for armature is approximately 0.5. For geared motors it is important that allowance be made for the higher speed of the armature.

$$\text{Hence the effective weight of the armature} = 0.5\left(\frac{\text{dia. of arms}}{\text{dia. of wheel}} \times \text{gear ratio}\right)^2 \times \text{weight of armature (lb.)} \quad (13)$$

It is common practice to use 100 lb. per ton instead of 91.2 lb. per ton for 1 mile per hr. per sec. acceleration, and take dead weight of train only. This allows for approximately 10 per cent. equivalent weight due to the inertia of rotating parts. It is a very simple method and its results are very near the proper amount for street cars. For more accurate calculations, see Par. 62.

**62. Per cent. of total tractive effort consumed in rotating parts**

| | |
|---|---|
| Electric locomotive and heavy freight train | 5 per cent. |
| Electric locomotive and high-speed passenger trains | 7 per cent. |
| Electric high-speed motor cars | 7 per cent. |
| Low-speed motor cars | 10 per cent. |

The above percentages added to 91.2 and multiplied by the rate of acceleration will give the total pounds tractive effort per ton required for acceleration.

**63. Calculation of acceleration rate.** In figuring upon accelerating and braking problems for different classes of service, the percentages in Par. 62 should be added to the actual train weight to obtain the effective train weight. The net tractive effort as determined by the gross tractive effort minus the train resistance can then be used in connection with the effective train weight to arrive at the rate of acceleration as expressed in miles per hr. per sec.

**64. Schedule speed,** expressed in miles per hr., denotes the average speed of a train including all stops, slow downs, etc., being the distance run in miles divided by the elapsed time in hours, including time of stops enroute. See Par. 65.

**65. Duration of service stops**

| | |
|---|---|
| Through trains, steam | 5 min. |
| Local trains, steam | 2 min. |
| Interurban cars, electric | 10 to 30 sec. |
| City rapid transit trains, electric | 10 to 20 sec. |
| City surface cars, electric | 5 to 12 sec. |

The following frequency of stops are characteristic of the different classes of railway service:

**66. Frequency of stops in service**

| | |
|---|---|
| Steam locomotive through service | 1 stop in 100 miles. |
| Steam locomotive local service | 1 stop in 20 miles. |
| Steam locomotive suburban service | 1 stop per mile. |
| Electric interurban express | 1 stop in 10 miles. |
| Electric interurban local | 1 stop in 2 miles. |
| Electric suburban | 1 to 2 stops per mile. |
| City elevated or rapid transit | 2 to 3 stops per mile. |
| City surface lines | 5 to 10 stops per mile. |

Digitized by Google

**67. The relation between schedule and maximum speed with varying frequency of stops** is expressed in Fig. 27, which indicates the schedule speed possible to make with trains having a free running speed of 30, 45, 60 and 75 miles per hr. respectively.

Thus with a train geared for a free running speed of 60 miles per hr. it is possible to make a schedule of 45.5 miles per hr. with one stop in four miles, 37.5 miles per hr. with one stop in 2 miles, etc.

For frequent-stop service, a low free-running speed is desirable as it is easier on the equipment, calls for less motor capacity and less energy consumed in performing the service. Hence, it is advisable to use the lowest maximum speed that will give the schedule desired.

**68. Effect of acceleration on frequent-stop service.** When using Fig. 27, it should be recognized that where stops are more frequent than one per mile, the rate of acceleration becomes a controlling factor, and as shown in the curve, when the frequency of stops approaches three or more per mile,

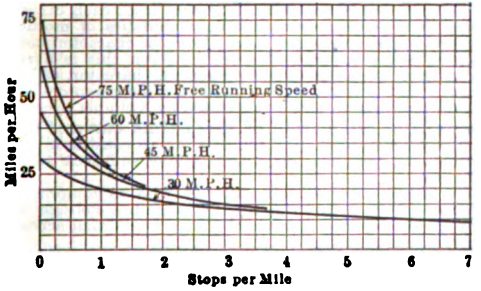

FIG. 27.—Relation between maximum and schedule speed and stops per mile.

the maximum free-running speed of the equipment does not have any appreciable effect upon the possible schedule speed. Hence, for frequent stop service where it is of great importance to attain the highest possible schedule speed, recourse should be had to Fig. 22, in order to determine the advantages of higher rates of acceleration than the 120 lb. gross which forms the basis of Fig. 29.

**69. Effect of track curves on rapid service.** In all classes of service, due recognition should be paid to the effect of curves of such short radii as to demand slowing down while rounding them. The safe speed at which a curve may be taken will depend upon the elevation of the outer rail, but a greater elevation than 8 in. is not common. Also curves having a spiral approach will ride much easier than those in which the tangent leads directly into the curve.

**70. Safe maximum speed on track curves**

| Radius of curve, ft..... | 10,000 | 5,000 | 2,000 | 1,000 | 500 | 200 | 100 | 50 |
|---|---|---|---|---|---|---|---|---|
| Speed, miles per hr..... | 100 | 75 | 50 | 35 | 25 | 15 | 10 | 6 |

The above values apply only when full elevation may be given outer rail. Speeds will be less when operating in city streets where such elevation is not possible, and where wheel flanges of three-quarters of an inch or less are the rule.

**71. Limitations of theoretical schedules.** On any road abounding in curves of short radius, it will not be possible to reach the schedules given in Fig. 27. No general rule can be given to fit all cases, as each problem must be treated according to local conditions. There is sufficient leeway in the schedules given in Fig. 27 to allow for irregularities of stops, as there is included a period of 10 sec. coasting that may be cut out when a stop has

Digitized by Google

exceeded the limit of 15 sec. assumed, but excessive duration of stops as time lost in meeting and passing trains on single-track systems, is n allowed for.

**72. The method of plotting speed-time relations** consists in takin successive small intervals of time or speed and assuming that the acceleratin force, train resistance and other factors remain constant during the interv It is, therefore, only necessary to take sufficiently small intervals in ord that the so-called step-by-step method may give results of great accurac Any speed-time calculations are at best an approximation, owing to the fa that in actual train operation there is a constant change taking place in t fundamental factors assumed as the basis of calculations. Hence a fa degree of accuracy is sufficient to afford as close an approximation as t problem warrants. This does not mean that errors made in calculatio are of no consequence, but that it is not required to assume extremel small speed intervals in order that the resulting speed-time values sha bear a proper relation.

**73. Speed-time curves following motor characteristics.** As the cha acteristics of different motors vary somewhat from each other, and there considerable divergence between the characteristics of motors of differen types, it is best to plot speed-time curves from the characteristics of the moto to be used in a given proposed service. Even this is a refinement no necessary in many problems of a more general character, as it will be foun that the speed and torque curves of modern railway motors are of the sam general shape and may in fact be expressed by a simple formula.

**74. Example of calculation of speed-time curves;* tractive force** The best step-by-step method of plotting curves consists in assuming smal speed increments, two-mile increments giving sufficient accuracy in prac tically all cases.

*Example:* Given a car weighing 32 tons, with an equipment of 4 motors Motor characteristics as per Fig. 23. Average line voltage 500. Find th relation of speed, amperes, distance and time for normal acceleration withi the capacity of the motors.

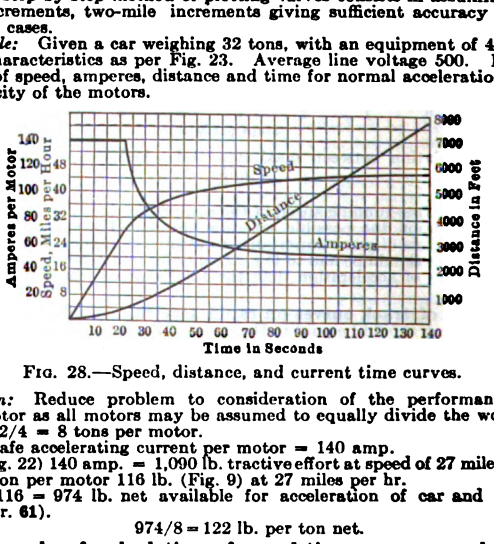

FIG. 28.—Speed, distance, and current time curves.

*Solution:* Reduce problem to consideration of the performance of a single motor as all motors may be assumed to equally divide the work.
Hence, 32/4 = 8 tons per motor.
Assume safe accelerating current per motor = 140 amp.
From (Fig. 22) 140 amp. = 1,090 lb. tractive effort at speed of 27 miles per hr.
Car friction per motor 116 lb. (Fig. 9) at 27 miles per hr.
1,090 − 116 = 974 lb. net available for acceleration of car and rotating parts (Par. 61).

$$974/8 = 122 \text{ lb. per ton net.}$$

**75. Example of calculation of speed-time curves, acceleration.** To find **acceleration** expressed in miles per hr. per sec. from a given force expressed in lb. per ton, proceed as follows.

* For another method of plotting speed-time curves see Mailloux, C. O. "Notes on the Plotting of Speed-time Curves," *Proc.* Am. Inst. of Elec. Eng., 1902, Vol. XIX, p. 901.

Digitized by Google

Acceleration, expressed in miles per hr. per sec. = [(32.2×0.682)/2,000]×lb. per ton = (lb. per ton)/91.2. The above value of (lb. per ton)/91.2 applies only to the net lb. per ton available for car acceleration only. In this particular problem assume 7 per cent. of the accelerating tractive force as being required to overcome the inertia of the rotating parts, then the factor of acceleration expressed in miles per hr. per sec. = (net lb. per ton)/(91.2×1.07) = (lb. per ton)/97.5. Hence—acceleration = 122/97.5 = 1.25 miles per hr. per sec.

Assume that car resistance remains constant at all speeds up to 27 miles per hr., as error introduced thereby is so small as to make it unnecessary to plot the curve step by step until motor-curve running is reached at 27 miles per hr.

The several relations may be calculated as given in Par. **76.**

**76. Relation of speed, distance, amperes and time (Par. 74); example of detailed calculations**

| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 |
|---|---|---|---|---|---|---|---|---|---|---|
| | 27 | 1,090 | 116 | 974 | 1.25 | 21.6 | 21.6 | 428 | 428 | 140 |
| 2 | 29 | 980 | 119 | 861 | 1.10 | 1.82 | 23.4 | 75 | 503 | 130 |
| 2 | 31 | 790 | 126 | 664 | 0.85 | 2.25 | 25.6 | 99 | 602 | 112 |
| 2 | 33 | 640 | 133 | 507 | 0.65 | 3.08 | 28.7 | 145 | 747 | 97 |
| 2 | 35 | 540 | 140 | 400 | 0.51 | 3.92 | 32.6 | 196 | 943 | 86 |

| 2 | 39 | 370 | 155 | 215 | 0.28 | 7.15 | 45.2 | 410 | 1,639 | 68 |
| 2 | 41 | 310 | 163 | 147 | 0.19 | 10.5 | 55.7 | 633 | 2,272 | 61 |
| 2 | 43 | 270 | 172 | 98 | 0.13 | 15.4 | 71.1 | 952 | 3,234 | 57 |
| 2 | 45 | 230 | 180 | 50 | 0.06 | 34.4 | 105.0 | 2,230 | 5,464 | 52 |

NOTE.—1. Speed increment of 2 miles per hr. 2. Sum of speed increments. 3. Gross tractive effort as obtained from motor characteristics (Fig. 22). 4. Car friction per motor (Fig. 9). 5. Net tractive effort available for gross acceleration after deducting car friction. 6. Acceleration as obtained by dividing net accelerating force (column 5 reduced to lb. per ton) by acceleration factor as determined (97.5). 7. Time increment as determined from 1 and 6. 8. Total elapsed time summation of 7. 9. Distance increment as determined from 2 and 7. 10. Total distance traveled, summation of 9. 11. Amperes as determined from motor characteristics. Values in 3, 5, 6 are average values obtaining during increase of speed increment in 1.

**77. Example of calculation of speed-time curves; effects of track curves, grades and coasting.** The above example is worked out on basis of level tangent track. The calculation of speed-time curves is generally based upon this assumption. Where it is necessary to predetermine the performance of a motor operating over grades and around curves, add or deduct tractive force so consumed from gross tractive effort and proceed as in Par. **76.** Also see Par. **22** and **23.**

Completing the speed-time cycle by introducing coasting and braking requires the same treatment as in Par. **76** except that both coasting and braking are equivalent to negative acceleration. Another method of plotting speed-time curves is given by Mailloux in Proceedings American Institute of Electrical Engineers, June, 1902.

## ENERGY AND POWER CONSUMPTION

**78. The energy consumed in moving a train** at constant speed is expended in overcoming train resistance (Figs. 9 to 14 inclusive) and internal motor losses. It is customary for manufacturers to give the net efficiency of railway motors after having carefully determined their internal losses from stand tests, and hence, the railway operator is concerned only with the

Digitized by Google

determination of the energy required to overcome train resistance when the speed of the train is constant at any fixed miles per hr.

Curves given in Figs. 9 to 14 inclusive express in pounds per ton the train resistance of different weights and combinations of cars. As a ready means of changing from pounds per ton to watt-hours per ton-mile, the following holds approximately true: Pounds per ton × 2 = watt-hours per ton-mile.

The above gives the watt-hours per ton-miles net output of the motive power, and to get train kilowatts input it is necessary to know the efficiency obtaining for different sizes of equipments as given by the manufacturers.

**79. Efficiency of direct-current railway motors**

| Capacity h.p. | 30 | 40 | 60 | 80 | 100 | 125 | 150 | 200 | 250 | *250 | *500 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Max. Efficiency, per cent. | 83 | 84 | 86 | 87 | 88 | 89 | 89 | 89 | 89 | 91 | 93 |
| Efficiency Car, full speed, per cent. | 65 | 68 | 70 | 72 | 73 | 74 | 74 | 75 | 75 | 90 | 92 |

**80. The maximum efficiency of railway motors of the geared type** occurs during maximum output, hence the values quoted should be used for calculation of the power required to accelerate a car or train. An exception to this rule may be taken in locomotive work, where it is customary to force the motors to nearly their maximum rated output even after the train has reached its normal maximum speed.

**81. The efficiency when the car is at full speed** is generally lower with motors of the geared type, owing largely to the losses in gears and also in the magnetic circuit of the motors themselves. This lower efficiency at higher speeds does not hold true of motors of the gearless type as indicated in Par. 79. The advantage of using gearless motors for high-speed passenger service is clearly indicated by the extremely high efficiency at light outputs. On the other hand, such motors do not compare favorably with the geared type for heavy freight haulage as the efficiency falls off rapidly at the overloads characteristic of this class of service.

**82. Power requirements at constant speed.** To determine power required to propel a car or train at any constant speed, proceed as follows:

$$P = \frac{F \times 2 \times W \times V}{\eta \times 1{,}000} \quad \text{(kw.)} \qquad (14)$$

wherein $F$ is the train resistance in lb. per ton (from Figs. 9 to 14 inclusive); $W$ the weight of the car or train in tons; $V$ the speed of the train in miles per hr., and $\eta$ the motor efficiency with the train at full speed.

**83. Calculation of power requirements of motor-car trains.** The tables show the kilowatts input required for motor-car trains, and also for high-speed passenger-train and low-speed freight-train operation. These tables are based directly upon the train-resistance values given in Figs. 9 to 14 inclusive, and represent the kilowatts input that would be expected with well-ballasted rail when trains are running at constant speed.

Constants assumed in these calculations are: efficiency at full speed, 75 per cent. based upon the use of direct-current geared motors; and train resistance as obtained from the formula

$$\text{Tractive effort} = \frac{50}{\sqrt{W}} + 0.03S + \frac{0.002aV^2}{W}\left(1 + \frac{n-1}{10}\right) \quad \text{(lb. per ton)} \qquad (15)$$

Cross-sectional area of cars is as follows: 20-ton car, cross-section 90, sq. ft.; 30-ton car, cross-section, 100 sq. ft.; 40-ton car, cross-section, 110 sq. ft.; 50-ton car, cross-section, 120 sq. ft.; 60-ton car cross-section, 120 sq. ft.

**84. Calculation of power requirements of passenger-service locomotives** involve the following assumed constants: efficiency at full speed, 90 per cent. for locomotive using series-wound direct-current motors of the gearless type; cross-section of cars, 110 sq. ft.; weight of car, 50 tons; weight of track rail, not less than 80 lb. per yd.

* Motors of gearless type.

**87. Power required on grades.** The values of power required to drive a car at any speed, apply only for constant speed on tangent level tracks. On up grades there is required an additional tractive effort of 20 lb. per ton for each 1 per cent. grade. Hence, to calculate power required on grades, proceed as follows:

The total train resistance is $F_g = F + F_g$, in lb. per ton; wherein $F$ is the train resistance in lb. per ton found from the curves, and $F_g$ the tractive effort due to the grade ($F_g$ = per cent. grade × 20). Then the power input is

$$P = \frac{2WF_gV}{1{,}000\eta} \qquad (16)$$

Digitized by Google

wherein $W$ is the weight in tons of the train; $F_0$ the total train resistance in lb. per ton; $V$ the speed in miles per hr., and $\eta$ the efficiency of the motors.

*Example:* Given a train of three 40-ton cars operating up a 2 per cent. grade at 40 miles per hr. what kilowatt input is demanded by the motors?

*Answer:* From Fig. 11, a three-car train requires a tractive effort of 9 lb. per ton at 40 miles per hr.

To this add for grade $2 \times 20 = 40$ lb. per ton (see **23**).
Tractive effort from Fig. 11 = 9 lb.

Total tractive effort 49 lb.
Train weight $= 3 \times 40 = 120$ tons.

Assuming that the excessive output demanded by the grade will almost completely load the motors, the maximum efficiency of the motor will be realized on the grade; with an 80-h.p. motor this would be 87 per cent.

$$\text{Hence input} = \frac{2 \times 120 \times 49 \times 40}{1{,}000 \times 0.87} = 540 \text{ kilowatts.}$$

**88. Energy of acceleration.** The above power values are based upon the assumption that the train has reached full speed and the power values are those required to maintain the train at constant speed. During the time that the train is attaining full speed, however, it is necessary to impart to it the energy required to accelerate the mass in the direction of travel and also to accelerate the rotating parts around their several axes.

$$\text{Energy of acceleration} = \frac{ms^2}{2} = \frac{ws^2}{2g} \quad \text{(ft-lb.)} \qquad (17)$$

where $w$ is the weight in lb.; $s$ the velocity in ft. per sec., and $g$ the gravity constant (32.3 ft. per sec. per sec.).

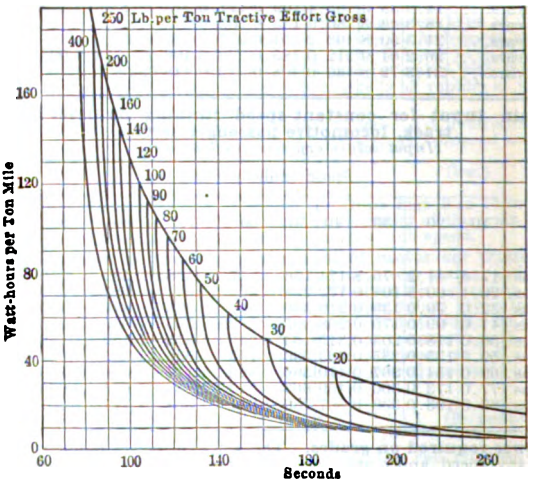

FIG. 29.—Energy stored in train ($ms^2/2$).

**89. Power required to overcome train resistance.** In addition to the energy of acceleration, it is necessary, during the accelerating period, to furnish power to the train in order to overcome train resistance, a quantity constantly changing with increasing speed, and finally to supply various changing losses in the motive power and its system of control. The straight-line diagram furnishes the simplest means of attacking the speed-time problem, and it also furnishes the fundamental data for all energy-consump-

Digitized by Google

tion curves, as it eliminates the question of motive power with its internal losses, and considers only the moving train itself.

**90. The energy required to move a train from rest to a given velocity** is represented by

$$W = \frac{ms^2}{2} + F_0 L \qquad \text{(ft-lb.)} \qquad (18)$$

wherein $m$ is the mass; $s$ the velocity in ft. per sec.; $F_0$ the total train resistance in lb., and $L$ the distance in ft. covered.

The most convenient form of expressing energy values is in watt-hours per ton-mile. Fig. 29 has been constructed from the speed-time data in Fig. 22, giving the energy consumption for any rate of acceleration and elapsed time for a distance of 5,280 ft. or 1 mile run. This set of curves is plotted with train resistance = 0, and hence represents the value of the energy of acceleration only.

**91. Energy dissipated in braking.** In bringing a train to rest by means of brakes, the energy stored in the train during acceleration and represented by $ms^2/2$ is all wasted in heating the wheels and brake shoes, and the values in Fig. 29 therefore represent the energy thus dissipated as heat. The curves have no value as applying directly to service conditions as all moving trains have more or less running resistance, but they are useful as indicating the energy required to accelerate the mass, all of which reappears as heat in the brake shoes and car wheels, unless some method of regenerative braking be used (Par. 115). At best, however, such regenerative methods are vastly inefficient and the energy values given in Fig. 29 represent the price paid for a high schedule speed coupled with frequent stops.

**92. Curves of energy consumption.** Unless the train reaches a speed of more than 40 miles per hr. it is a sufficiently close approximation for preliminary calculations to assume a constant rate of train resistance of from 10 to 15 lb. per ton, the latter figure being the more conservative value. Hence, Figs. 30 and 31 are plotted with a constant value of train resistance at all speeds of 10 and 15 lb. per ton respectively. These curves used in conjunction with the speed-time curves of Fig. 22 permit of the complete solution of any acceleration problem so far as relates to performance of the train and its net energy consumption. For convenience, both speed-time and energy curves are made up with the same elapsed time for a mile run as abscissa, this distance run being chosen as being a convenient basis for comparison.

Having determined the watt-hours per ton-mile for a mile run, the same value holds true for any other distance run as long as the speed-time curve is entirely similar in every respect and the areas are proportional to the respective distances run. Thus, a mile performance in 120 sec. with a tractive effort of 90 lb. per ton (including 15 lb. per ton train resistance) will require an output rate of 73 watt-hr. per ton-mile, and the same energy, 73 watt-hr. per ton-mile, would be required to perform a run of half the distance in $1/\sqrt{2}$ times 120 sec., or 84.8 sec.

Thus while the speed-time curves must be changed in area proportional to the distance travelled, the value of energy consumption found for one distance holds equally true for any other distance made with a similar speed-time curve.

**93. Example of calculation of energy consumption.** Given a run of 1,760 ft. to be made in 75 sec., train weight 100 tons, 33.5 per cent. on drivers, coefficient of adhesion 12 per cent., train resistance 15 lb. per ton. Find energy consumption.

Available tractive effort = $200{,}000 \times 0.335 \times 0.12 = 8{,}000$ lb. = $8{,}000/100 =$ 80 lb. per ton.

To reduce to mile basis $\sqrt{5{,}280/1{,}760} \times 75 = 130$ seconds. (See Par. 43.)

From Fig. 31, 1 mile in 130 sec. with 80 lb. tractive effort gives 60 watt-hr. per ton-mile.

The same value, 60, is true for 1,760 ft. made by similarly shaped speed-time curve in 75 sec.

**94. Motor-curve acceleration.** Instead of being able to accelerate a train at a uniform rate until maximum speed is reached, all types of electric motors operate best with a certain amount of motor-curve acceleration at a rate constantly falling off from the initial or straight-line acceleration which

Digitized by Google

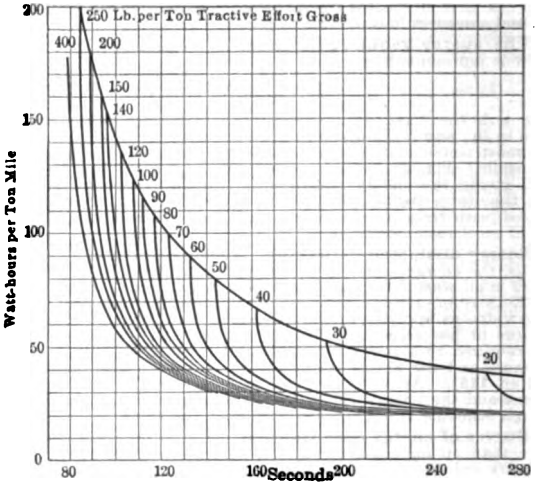

FIG. 30.—Energy consumption (train resistance equals 10 lb. per ton).

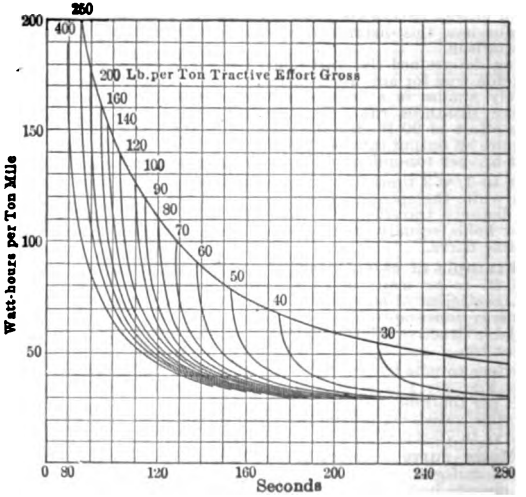

FIG. 31.—Energy consumption (train resistance equals 15 lb. per ton).

Digitized by Google

is only carried part way to full speed. Also, the electric motor has internal losses, electrical and mechanical, which together with certain losses inherent to its system of control make it necessary to add a greater or less percentage to the net energy-consumption curves given in order to obtain the *input* to the train. The different types of motors have their distinctive internal losses and type of control, and the performance relation of the several motor equipments to the net energy-consumption curves is best expressed by the efficiency of acceleration of the several systems.

**96. The efficiency of acceleration** is the percentage of the net energy consumption of motor output, to the gross input of the train. The values given in Figs. 30 and 31 hold true as the net output of any type of motor and control system, hence, given the efficiency of acceleration of any system, the net energy values form the basis of calculating train inputs for any operating conditions. See Par. **98**, **108** and **113**.

The losses in the motor equipment during acceleration are divided into: internal motor losses including loss in gears, and losses incident to method of control.

**96. Internal motor losses** consist of copper $I^2R$ in armature and field, hysteresis and eddy-current losses in the iron circuit, brush-friction and $I^2R$ loss, bearing friction and gear losses. All these losses are included in the curves furnished by the manufacturers for normal 500 volts constant potential at the brushes, but no such values are readily available for fractional-voltage operation during the accelerating period.

**97. Starting resistance losses.** It is customary to assume full-load current of a railway motor during the straight-line acceleration period, and at standstill the $IR$ drop in the motor copper will approximate 50 volts. It is necessary, therefore, to provide sufficient starting resistance in series with the motor to take up the remaining 450 volts or the difference between the line potential and the motor copper drop. This starting resistance is cut out in successive steps as the motor armature gains speed and establishes its own counter-electromotive force, until a period is reached, when the starting

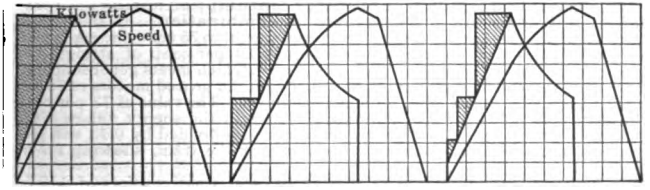

FIG. 32.—Direct-current control of series-wound motors (shading shows loss in starting rheostat).

resistance is entirely short-circuited and the full line e.m.f. is just sufficient to maintain full-load current through the motor. This period completes the straight-line acceleration, as after this point the series-wound motor will still accelerate the train, but at a constantly decreased rate, until full constant speed is attained. It is evident then, that a large amount of power is consumed in the starting resistance and to reduce this excessive loss at starting, the method was introduced of connecting two motors in series during half the period of straight-line acceleration, thus reducing the amount of starting resistance required (Par. **50**).

A current-input curve is plotted for the three methods of control of direct-current railway motors in Fig. 32 the shaded portion indicating the energy lost in heating the starting resistances, and showing the economy gained by starting with motors in series. This economy is expressed numerically in Par. **98**.

Digitized by Google

**98. Efficiency of acceleration direct-current series-wound motors (Par. 95)**

| Per cent. of straight-line acceleration. (See Par. 99) | Motors, parallel. (Per cent.) | Two series parallel. (Per cent.) | Four series, two series-parallel. (Per cent.) |
|---|---|---|---|
| 100 | 43 | 56.0 | 60.5 |
| 90 | 46 | 59.0 | 62.5 |
| 80 | 49 | 62.0 | 65.0 |
| 70 | 52 | 64.0 | 67.0 |
| 60 | 56 | 67.0 | 69.0 |
| 50 | 58 | 69.0 | 71.0 |
| 40 | 62 | 71.0 | 72.5 |
| 30 | 65 | 72.5 | 73.5 |
| 20 | 68 | 73.5 | 74.0 |
| 10 | 72 | 74.5 | 74.5 |
| 0 | 75 | 75.0 | 75.0 |

**99. The per cent. of straight-line acceleration** is the ratio of the time constant current is supplied, to the total time current is supplied to the motors, and it thus becomes a measure of the shape of the speed-time curve. In typical rapid transit service, the constant accelerating period is from 25 per cent. to 35 per cent. of the total time during which power is supplied before coasting and braking begins.

Hence, 100 per cent. of straight-line acceleration denotes the fact that the cutting out of starting resistance has just been accomplished, while 0 per cent. of straight-line acceleration means that the train is running free, at full speed, at the free-running efficiency of the motors.

**100. Example of calculation of energy consumption during acceleration with the two-motor series-parallel combination.** In this system the efficiency of acceleration ranges from 56 per cent. to 75 per cent. A typical speed-time curve will require approximately 30 per cent. of straight-line acceleration, hence, the efficiency of acceleration which meets general operating conditions, will be approximately 73 per cent. for geared motors of 75 h.p. or over and 68 to 73 per cent. for smaller motors. The value of 73 per cent. efficiency may be used directly in connection with the energy values given in Figs. 30 and 31, that is, the energy-curve values divided by 0.73 will give the gross train-input watt-hours per ton-mile at the train, allowing for no losses in the distribution system.

*Example:* Given a mile run made in 135 sec., tractive effort of 110 lb. per ton including 10 lb. train resistance, find average input for 100 ton train.

*Answer:* From Fig. 30, energy consumption net = 38 watt-hr. per ton-mile. Input = 38/0.73 = 52 watt-hr. per ton-mile.

Train makes 1 mile in 135 sec. = 1 mile in 147 sec., including 12 sec. stop = 24.5 miles per hr. schedule speed.

Hence, the power input is

$$P = 52 \times 100 \times 24.5 = 127 \text{ kw.}$$

**101. Relation between schedule speed and frequency of stops** is shown in Par. **102.** In other words, an effort has been made to proportion properly the maximum free-running speed of the equipment to the schedule speed obtaining for a given number of stops per mile. Thus an equipment operating with one stop per mile can make 24 miles per hr. schedule with stops of 12 sec. and should properly be geared for 40 miles per hr. If the equipment were geared for higher maximum speed than 40 miles per hr., the resulting schedule speed would not be much in excess of the 24 miles per hr. given, while the power consumption would have been considerably greater. On the other hand, an equipment geared for somewhat lower maximum speed than 40 miles per hr. could still make 24 miles per hr. schedule with a 12-sec. stop occurring at every mile, but requiring a higher rate of acceleration than the 1.1 mile

Digitized by Google

per hr. per sec. assumed. As a high rate of acceleration is undesirable with high-speed equipments, the rates given in the table should not be greatly exceeded unless there are strong local reasons making such high rates necessary.

**102. Interruptions to service treated as "equivalent stops."** The table of schedule speed includes little or no leeway to make up for lost time, and where such interruptions of service are liable to occur they should be treated as additional stops per mile, and the proper schedule speed, maximum free-running speed, etc., should be taken for the *equivalent* number of stops per mile, including actual stops, slow-downs for curves, crossings, etc., and a margin for unexpected delays. Thus, with one actual stop of 15 sec. duration occurring every 2 miles, there may be slow-downs for curves, etc., making the equivalent number of stops approximate one per mile, in which case a 24-mile per hr. schedule with 40 miles per hr. maximum speed of equipment would be a safer estimate of speed possible than the 32 and 45 miles per hr. respectively given for one stop in 2 miles. In other words, keep the maximum speed of the equipment at the lowest value that will admit of maintaining the schedule desired with the frequency of stops given. Not only is there a saving in energy consumption resulting from the use of lowest possible maximum speed, but, as will be shown later, there is also a large saving in the capacity of motor required to perform the service.

**103. Train input in kw., frequent-stop service, tangent level track**

| Stops per mile | ⅛ | ¼ | ½ | 1 | 2 | 3 | 4 | 5 | 6 | 7 |

**104. Suburban cars in city service.** While the values given in the table cover the entire field of rapid transit service from seven stops per mile to one stop in 8 miles, it frequently happens that the relation between maximum and schedule speed given cannot be approximated in actual service operation owing to peculiar local requirements. Thus a suburban car, operating at 40 miles per hr. maximum, may be called upon to operate in city service at terminals or en route where the frequency of stops approximate six per mile, a condition properly calling for a maximum speed of 20 miles per hr. The power consumption given for six stops per mile would be greatly increased in the case of a high-speed suburban car operating on such service, even though series running were adopted exclusively in the city service. Series running would then correspond to the efficiency of acceleration given in Par. **98**, for all motors in parallel, and would thus be 10 per cent. or more lower than for series-parallel operation; hence the figures for kilowatts input at train given in the table represent minimum values resulting from a proper proportion between the maximum free-running speed of the equipment, the schedule speed and the frequency of stops.

**105. For rates of acceleration other than those given in the table** (Par. **103**), where the frequency of stops is greater than one per mile, any special case should be worked out from the general watt-hour-per-ton-mile curves (Figs. 30 and 31).

**106. Frequent-stop service for electric locomotives** is not treated here as it is assumed that the legitimate field of the locomotive is in express service having very infrequent stops, in which case the energy of acceleration forms but a small percentage of the total input of the train.

**107. The single-phase railway motor,** being a series-wound type, can be operated by means of non-inductive external starting resistance as in the case of the direct-current series-wound motor. Owing, however, to the facility with which alternating voltage may be varied by static transformers, a better method of control is offered by means of shifting the motor terminals from tap to tap, brought out from the step-down transformer or compensator constituting part of the car equipment. The potential control thus made possible introduces no losses commensurate with the starting resistance losses of direct-current motor control. and is the most efficient form of control yet evolved for railway work.

Owing to the fact that the characteristic curve of the single-phase motor is more sloping than even that of the direct-current series-wound motor, Figs. 23 and 25, the period of straight-line acceleration will be a lesser percentage of the total time power is supplied to the car; that is, the motor-curve running will commence at a lower speed than in the case of direct-current motor operation, thus giving rise to a factor of 20 per cent. as the percentage of straight-line acceleration to the total acceleration period of a typical run.

**108. The efficiency of acceleration for the single-phase motor equipment** may be assumed to be 70 per cent. This value includes all losses in the step-down transformer required, and hence the net energy values given in Figs. 30 and 31 when divided by 0.70 will give the total input at the car for such equipments. Where cars are operated over city streets, it is sometimes necessary to run on direct current in which case the motors are controlled like direct-current motors.

**109. The free running efficiency of single-phase equipments** may be taken at from 70 to 75 per cent. for equipments ranging in capacity from 50 to 200 h.p. per motor, hence giving to the alternating-current equipment an all round efficiency of about 70 per cent., whether accelerating or running at constant speed, a performance closely approximating that of the direct-current motor equipment.

**110. The three-phase induction motor** is installed upon but a few roads. It is practically a synchronous motor, there being a maximum of but 5 per cent. difference in speed between full-load and free running. The variation from synchronous speed is proportional to the tractive effort. The efficiency of acceleration corresponds to that of a direct-current shunt-wound motor with constant field.

**111. There are two methods of control of induction motors** available for railway service, reduced voltage in the primary and variable non-inductive resistance in the secondary. Reduced voltage introduces an exceedingly

Digitized by Google

poor power-factor during the starting or fractional speed period, and also entails a prohibitive $I^2R$ loss in the secondary, if this be of the short-circuited (squirrel-cage) type. Voltage variation is only used in special cases where the excessive size of the required motor is no handicap.

**Secondary-resistance control of three-phase slip-ring motors** is the method ordinarily employed. The rotor winding is terminated in three rings, which allow the insertion of non-inductive resistance in the rotor circuit. This resistance is decreased as the motor comes up to speed, and the rings short-circuited at approximately 10 per cent. below synchronous speed. This method of starting results in a poor efficiency of acceleration (Par. 112).

112. **Concatenation control** may be employed to increase the efficiency of acceleration of three-phase slip-ring motors. As the speed of the induction motor is fixed by its frequency of supply and not by its impressed e.m.f. it is not possible to connect two such motors in series. It is possible, however, to connect the stator winding of motor No. 1 to the line, the rotor winding of motor No. 1 to the rotor winding of motor No. 2 short-circuiting the stator winding of motor No. 2; this constitutes the concatenated method of connecting induction motors and corresponds in results to the series connection of direct-current series-wound motors. With induction motors so connected, stability is obtained with half-speed of the rotors and a concatenated set can be treated in all respects as a single induction motor having double the number of poles in its field.

Concatenation is feasible only with motors of low frequency, 25 cycles or less, owing to the low power-factor incidental to such a combination. In general, however, concatenation is used with railway induction motors, not to effect a possible increase in the efficiency of acceleration, but to provide a second efficient running speed for the low-speed requirements in terminal yards.

113. **Efficiency of acceleration; three-phase induction motors**

| Per cent. straight-line acceleration | 100 | 90 | 80 | 70 | 60 | 50 | 40 | 30 | 20 | 10 | 0 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Efficiency per cent | 40 | 43 | 46 | 49 | 52 | 55 | 58 | 61 | 64 | 72 | 75 |

The accelerating efficiency of an induction-motor railway equipment is indicated for parallel operation only, concatenation not being considered. As straight-line acceleration will constitute fully 50 per cent. of the total period during which power is supplied in a typical rapid-transit run, an induction-motor equipment will have an efficiency of acceleration not to exceed 55 per cent. This represents the power efficiency and does not include the power-factor which will approximate 80 per cent. during acceleration with non-inductive resistance inserted in the secondary circuit, thus making the *apparent* efficiency of acceleration approximately 44 per cent.

Hence, for acceleration problems involving a consideration of railway induction motors of the polyphase type, divide energy values given in Figs. 30 and 31 by 0.44 to obtain the volt-amp. input at the train and *not including* any trolley or distribution losses. The proper field of the induction motor is the haulage of trains at constant speed behind locomotives and the use of this motor will be further discussed under Locomotion.

114. **Regenerative (dynamic) braking.** In service calling for frequent starting and stopping of trains, it is evident that the $mS^2/2$ constituting the energy loss in heating brake-shoes and wheels, forms a considerable percentage of the total energy input to the train. As the electric motor is reversible, that is, can absorb power and give out mechanical energy, or can give out electric power when mechanically driven as a generator, it seems feasible to expect that some means of control can be designed which will enable a train to be braked electrically with reduced wear and expense of brake-shoe maintenance, besides returning to the line a considerable percentage of the energy delivered to the train during acceleration. Also on roads having excessive continuous grades, it is desirable to return energy to the line partly for the economy thus effected, but largely in order to reduce the danger that goes with braking long heavy trains by means of brake-shoes.

115. **Motor capacity for regenerative braking.** The standard direct-current motor, being of the series-wound type, cannot be used directly as a

Digitized by Google

direct-current generator, and some modification of shunt winding or excitation of the series field at low potential must be used in order to enable the motor to act as generator when braking the train. Of the total energy delivered to the train during a typical city run, nearly one-third of the amount is wasted due to the inefficiency of the motor, gears, and method of control. Of the remaining two-thirds, fully 25 per cent. is to overcome train resistance, leaving 50 per cent. of the original train input as available for regenerative purposes. Owing to the complications required to brake a series direct-current motor equipment available for generation, it would not be possible to effect the same efficiency of deceleration as the 70 to 75 per cent. possible during acceleration. Furthermore, the capacity of a railway motor to do work is limited by its heating, and this heating is dependent upon the superficial area and weight of the motor, hence, if the motor is chosen with due regard for its safe temperature rise when used for accelerating the car, its thermal capacity must be increased in due proportion to the amount of extra motor loss entailed in electrically braking the car. This extra weight of equipment will in turn entail an additional expenditure of energy during the accelerating period, so that the effect of braking the train electrically with the same motive power used for acceleration, will be to increase the duty of such motors considerably, and, hence, their weight and first cost.

**116. Economy of regenerative braking.** Assuming that an efficiency of 60 per cent. could be obtained during retardation by electric braking, it would mean the possible saving of 30 per cent. in the energy consumption of the car, provided the car weight were not increased due to the larger motor capacity demanded. It is not possible, however, to effect any such economy as the figure indicated, and from 15 to 20 per cent. saving of gross input would more nearly represent the possibilities of regenerative control, on a class of service calling for very frequent stops. It is evident that where stops are infrequent as in high-speed interurban service, the effect of regeneration would become negligible so far as economy of operation is concerned.

**117. The first cost of regenerative control,** and the increased cost of maintenance offset the advantages derived from a possible smaller energy consumption of the car. It is not too much to expect that the car equipment will be increased fully 50 per cent. in weight and first cost if regenerative control be adopted, and the possible 15 to 20 per cent. energy must be balanced against the interest on the additional first cost and cost of maintaining the equipment.

As any system of regenerative control depends upon the counter e.m.f. of the revolving armature, it is evident that when approaching zero speed there will be no torque developed by the motor, and hence, regenerative braking must be used in connection with air brakes, with resultant decreased saving in economy. For street-car service, including interurban service, it can be said that there is small attraction in regenerative control, not because such control is not possible, but because the added complication and expense brings no adequate return in the cost of the energy saved.

**118. Regenerative control used in connection with locomotives for heavy passenger or freight service on mountain-grade sections,** offers many advantages far outweighing in importance the possibility of a small amount of energy saved. One of the disadvantages attending the operation of long heavy trains on mountain grades, is the danger incurred in braking the trains on the down grades. More accidents occur when trains are running down grade than when operating up grade, due to the fact that overheated brake shoes and car wheels may cause a derailment, and also due to breaking apart of long trains when the brakes are released momentarily for the purpose of recharging the train pipe. On such classes of service, a regenerative system of control offers safer means of holding trains on down grades than exists with present air-brake control, and its claims in this direction make it worthy of very careful consideration for this class of service.

## RAILWAY MOTOR CAPACITY

**119. Limitations of design.** The capacity of railway motors to do work cannot be measured by the same standards governing the rating of motors of the stationary type. Conditions of operation demand that the motors shall conform to the requirements of a 4 ft. 8½ in. gage track, and frequently a wheel base of not over 78 in., and preferably less. The re-

Digitized by Google

stricted space thus available makes it imperative that the weight and outside dimensions of railway motors shall be scaled to the lowest possible limit consistent with the average and momentary output demanded by service requirements. It is customary, therefore, in railway-motor design, to force the density of the magnetic circuit far in excess of what is considered good practice in the design of stationary motors. The effect of this high saturation of the iron circuit is to entail an iron hysteretic and eddy-current loss of such a high value as to preclude the possibility, in many cases, of running the motor continuously at full voltage without overheating it due to the iron loss alone. It is evident, therefore, that recourse must be had to methods of comparative rating of railway motors other than the usual continuous running at full voltage, obtaining in the case of stationary motors. On locomotives these space restrictions have been largely overcome by use of the side-rod drive with the motor mounted above the wheels.

**120. The nominal rating** of a railway motor shall be the mechanical output at the car axle, measured in kilowatts, which causes a rise of temperature above the surrounding air not exceeding 90 deg. cent. (162 deg. fahr.) at the commutator, and 75 deg. cent. (135 deg. fahr.) by the thermometer, at any other normally accessible part after 1 hr.'s continuous run at its rated voltage (and frequency, in the case of an alternating-current motor) on a stand with the motor covers arranged to secure maximum ventilation without external blower. The rise in temperature, as measured by resistance, shall not exceed 100 deg. cent. (180 deg. fahr.) during the test.

The statement of the nominal rating shall include the power, voltage and armature speed at rated volts and kilowatts.

**121. The continuous-rating input** of a railway motor shall be defined by the current in amperes at which it may be operated continuously at half, three-quarters and full voltages respectively, without exceeding the specified temperatures, when operated on test stand with motor covers and cooling system, if any, arranged as in service. Inasmuch as the same motor may be operated under different conditions as regards ventilation, it will be necessary in each case to define the system of ventilation which is used. In case motors are cooled by external blowers, the volume of air on which the rating is based shall be given.

**122. The maximum load** on railway motors does not usually exceed 150 per cent. of the nominal rating.

**123. Two factors determine the capacity of railway motors,** namely: commutation and heating. During the accelerating period the current input demanded by a railway motor is always considerably in excess of the current afterward required to run the car at full speed on level tangent track. The value of this current will depend upon the several conditions entering into the problem, weight of train, schedule speed, and frequency of stops, these factors determining the rate of acceleration and maximum speed required as previously outlined. A motor must be selected which can commutate the abnormal current required during the accelerating period without excessive sparking at the brushes.

**124. Division of load between motors.** For close calculations it is necessary to plot the actual speed-time curves obtaining with any individual motor. In dividing the total current input to the train by the number of motors, in order to obtain the current per motor, it can be assumed that each motor will take its equal share of current at all speeds, provided the motors are of the same type and capacity, and have the same gear ratio.

**125. Effect of acceleration rate and maximum speed on capacity.** It is evident from working out a few examples, that high rates of acceleration can be used only when low maximum speeds are possible, and that an abnormally large motor capacity will be essential if high rates of acceleration are demanded in connection with high maximum speeds. Thus, although motor equipments of the direct-current series-wound type can always furnish enough current to slip the driving wheels, such high current inputs will be demanded as will considerably exceed the safe rated commutating capacity of motors operating cars at the 50 miles per hr. or more, common to interurban high-speed service. Various devices have been brought out for the purpose of limiting starting currents to safe predetermined values, and the current-limiting device now forms a component part of certain types of control equipment.

Digitized by Google

**126. The heating of railway motors** in operation is caused by internal copper, iron and brush losses. These losses vary not only in intensity but also in distribution with different types of motors and classes of service. At zero speed, the losses are all in the copper of field and armature, being divided according to their relative resistance. As the armature speed increases there is an iron loss distributed between the iron of armature and pole face and tips, depending upon the design of the motor. This iron loss starts from zero at standstill and increases to a maximum at the moment of cutting out starting resistances, after which it decreases somewhat: this again is a matter of motor design. As the various losses are the cause of temperature rise in the motors, it is necessary to trace their influence upon the individual part of a motor under study.

**127. Internal motor losses.** As the heating of a motor is the result of the average losses within it, the average losses and their distribution up to any moment of shutting off power must be determined.

Internal motor losses during fractional-speed running are indicated in Fig. 33 where abscissas give elapsed time and ordinates represent power lost. In other words, the losses depicted are not instantaneous losses at any given speed, but integrated losses from the time of starting from rest, to gaining that speed.

Equally important with the determination of the various internal losses is their distribution. Thus in a closed motor the armature loss must be conducted through the field structure before it can reach the outside surface of the motor and be dissipated into the surrounding air. Added to the heat imparted to the field structure by its own $I^2R$ losses and pole face losses, there is, therefore, considerable heat delivered to it by virtue of its service as a conducting medium for the armature heat. On the other hand, the field structure would conduct the armature heat at a more rapid rate were it not for its own internal loss. It becomes important to establish a relation for this interchange of heat between field structure and armature, the relation being best expressed by the ratio of armature loss to field loss, as indicated in Fig. 33.

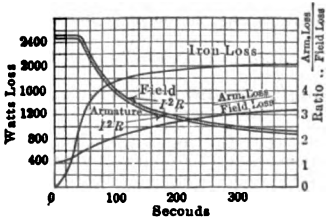

FIG. 33.—Starting losses.

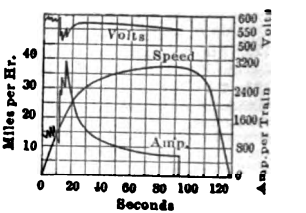

FIG. 34.—Speed-time run (series parallel control).

**128. Thermal-capacity curves** furnish the foundation for all determinations of motor capacity for any service; it is, therefore, important to understand the method of their construction. A typical speed-time run, Fig. 34, is performed over a tangent level track with proper weight of car and gear ratio for a given motor, a succession of these runs being made for 8 or 10 hr., or until the motors have attained a constant temperature. This typical run will call for certain internal losses in the motor having a fixed ratio between armature and field losses, and there is a direct connection between these losses averaged over the 8 or 10 hr. run and the temperature rise of the several parts of the motor. Fig. 35 is thus constructed from results of a series of such temperature runs, each separate 10-hr. run giving rise to a certain ratio of armature to field losses, and therefore establishing one point upon the field and armature thermal-capacity curve.

**129. Application of continuous rating.** The continuous rating of railway motors (see Par. 121) differs from that of constant-speed motors in that it is based not on the normal voltage of the motor but on voltages which, combined with the rated continuous current, will give the average core loss corresponding to the particular service. For convenience the continuous

Digitized by Google

rating is given in amperes at half, three-fourths and full voltages. To determine the sufficiency of the motor for a given service, a typical speed-time run should be plotted and from that the square-root-of-the-mean-square (r.m.s.) current should be obtained. This should correspond to the rated continuous current. With the modern self-ventilated motors, this practically controls the temperature, since the increased speed that goes with higher core losses, also causes a better circulation of air through the motor and carries off more heat. It is found that ventilated railway motors carry practically the same current at all voltages. Enclosed motors carry 5 to 10 per cent. more current at the lower speeds corresponding to low voltages and frequent stopping service than at higher speeds and voltages corresponding to interurban service.

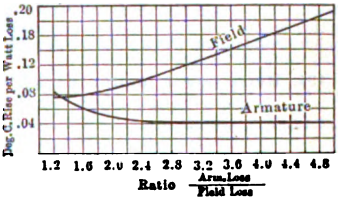

FIG. 35.—Thermal characteristics.

**130. Application of thermal-capacity curves.** Any given service operation, although made up of short and long runs, can be resolved into a single typical speed-time curve which will call for the same internal losses and the same distribution of motor losses as would obtain under service conditions. By utilising data as given in the thermal capacity curve, Fig. 35, for a given motor, it is possible to predict, with reasonable accuracy, the temperature rise of a motor for any operating conditions coming within the limits of the motor capacity. As such calculations demand a vast number of experimental runs, the expense of which can only be borne by railway-motor manufacturers, some better form of expressing the relation of railway motor capacity and service performance is necessary for approximation work. Owing to the fact that railway motors of the direct-current series-wound type have become standardised along certain lines, it is possible to establish a working relation between the commercial 1-hr. rating of a motor and its ability to do work under service conditions.

**131. Service capacity curves.** Applying results similar to Fig. 35, to a series of speed-time curves for different distances run, a curve similar to Fig. 36 is obtained for an equipment having a fixed gear ratio, in this case proportioned for a maximum speed of 45 miles per hr. on tangent level track. This curve, called a service capacity curve, gives directly the temperature rise for a given equipment, in this case a 125-h.p. motor, for any schedule speed that can be performed with a varying number of stops per mile, the equipment being geared for 45 miles per hr. maximum speed when running free.

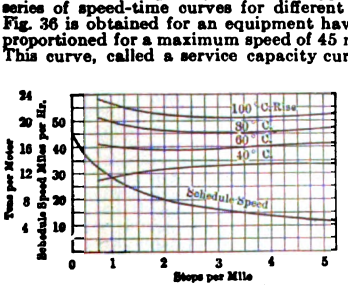

FIG. 36.—Motor service capacity.

**132. Application of service capacity curves.** It will be noted that the tons train weight per motor for a given temperature rise do not vary greatly over the whole range from five stops per mile down to less than one stop per mile. In other words, a railway motor equipment of fixed gear ratio when mounted on a car of fixed weight, will attain approximately the same temperature rise above the surrounding air, irrespective of the number of stops per mile demanded by service conditions. Thus from Fig. 36 16 tons per motor gives temperature rise of 60 deg. cent. for the motor under consideration, and this temperature rise holds good whether the car is making a schedule speed of 11.5 miles per hr. with five stops per mile, or 29 miles per hr. with one stop per mile.

This fact furnishes a means of simplifying the expression giving the relation between the 1-hr. commercial capacity test and service capacity of the railway motor. It is sufficient for purposes of approximation to rate a

Digitized by Google

given motor at the tons train weight per motor which can be hauled for a given maximum speed or gear ratio, taking say 60 deg. cent. rise as a basis.

**133. Allowable temperature rise under working conditions.** Owing to the fact that preliminary calculations do not start with any given motor as a basis, it becomes preferable to express the values given in curves similar to Fig. 36 in a more convenient form. Such values are given in the following tables expressing the relation between the maximum train speed when running free on tangent level track and the horse-power commercial rating of railway motors required to limit the temperatures rise to 60 deg. cent. above the surrounding air taken at 25 deg. cent. A temperature rise of 60 deg. cent. has been taken in order to ensure a reasonably long life to the motor insulation, a much higher temperature rise causing a too rapid deterioration. In this connection may be mentioned the possibility of running motors at much higher temperature when they are provided with mica and asbestos insulation with no fabric.

**134. Horse-power motor capacity required standard direct-current motors**

SINGLE-CAR UNITS

These tables are based upon the temperature rise of 60 deg. cent. above surrounding air, assumed to be 25 deg. cent. The horse-power capacity required conforms to the commercial rating of railway motors, that is, the 1-hr. horse-power rating which will occasion a temperature rise of 75 deg. cent. above surrounding air, taken at 25 deg. cent

The capacities given are approximate only, and are intended as a guide in preliminary calculations. Where accuracy is demanded, or where operating conditions are abnormal, it is necessary to plot speed-time and distance-time curves for the particular motor characteristics nd conditions obtaining, from which the motor temperature should be calculated from a detail knowledge of the motor thermal constants. The method is indicated previously in this description.

**135. Division of train horse-power capacity.** The horse-power capacity given for any train weight may be split up into the required number of units. Thus, a train composed of five 40-ton cars running at 45 miles per hr. requires 1,180 h.p. motor capacity. This may be divided into six units of 200 h.p. each, that is, three motor cars equipped with double 200 h.p. motors hauling two trailers, or each car of the train may be a motor car and be equipped with a pair of 120-h.p. motors. Approximately the same temperature rise will obtain in either case.

Certain motors of modern construction provide for longitudinal ventilation either with blower on armature or with external blower. In either case, the armature and field losses are carried off independently of each other by the introduction of external air, hence the ratio of losses in such motors becomes of secondary importance.

**136. Division of capacity for single cars and trains.** For single-car operation a four-motor equipment is preferred for double-truck cars, this being especially true where snow or heavy grades are characteristic of the service. For train operation, two-motor equipments are used, as the disabling of a single unit will not incapacitate the train.

The horse-power capacity specified in Par. **134** for train operation should be made use of only when cars are always operated in trains and never singly. For example, five 40-ton cars operating in a train at 60 miles per hr. require a motor capacity of 1,770 h.p., or 354 h.p. per car, a motor capacity too low for single car operation, which demands 525 h.p. Hence, where cars are run indiscriminately, singly and in trains, the full motor capacity per car should be taken as given in the table of single-car operation.

**137. Power requirements with single-phase equipment.** Owing to the short period during which single-phase motors have been operated, their design has not yet become standardized, nor is there sufficient operating data upon which to base anything more than general conclusions of the horse-power required for a given service. The single-phase motor is essentially a high-speed motor, having a high copper loss and low core loss, hence, is more particularly adapted to constant-speed running, and suffers in comparison with the direct-current series wound motor when used for acceleration work. There is no lack of starting torque with the alternating-current motor, but a large tractive effort is obtained only at the expense of a large copper loss, so that alternating-current motors are unsuitable for rapid transit service demanding repeated high rate of acceleration, not because such motors cannot furnish the tractive effort required, but because the copper loss incident to such high tractive efforts will heat the motors unduly if used exclusively for acceleration service. Thus the alternating-current motor becomes much heavier than the direct-current motor on the basis of service performed with frequent stops.

**138. Single-phase equipment for a service embracing infrequent stops.** In interurban or express service with infrequent stops, the smaller core loss of the alternating-current motor brings it more nearly on a par with the direct-current series wound motor as regards output per pound weight of motor. It is possible therefore to use the figures of Par. **134** as applying to alternating-current motor capacity, where stops are not greater than one in 2 miles. However, the table should not be used in connection with higher frequency of stops given, as then the resulting motor capacity indicated in the table must be largely increased when applied to alternating-current motors.

Owing to the fact that the chief advantage of the single-phase motor lies in its ability to utilize the benefits of trolley potentials of 11,000 to 15,000 volts as compared with the 600 to 3,000 volts used with direct-current

Digitized by Google

motors, questions of safety limit the field of operation of alternating-current motors to lines operating over private rights of way except where alternating current-direct-current equipments are used or a lower alternating-current voltage is used on the trolley as is sometimes done.

**139. Three-phase equipment.** Owing to the few applications of three-phase induction motors to railway conditions, no statements can be made regarding the capacity of such motors for service performed. The induction type of alternating-current is not at all adapted for acceleration work, owing to the poor efficiency of the car equipment during fractional speed running. The field of the three-phase induction motor lies in the direction of a service calling for constant effort at constant speed, and the problems wherein this type of motive power can be considered are so special and infrequent as to place it entirely outside the lines of standard apparatus.

**140. Locomotive motors.** Locomotive operation demands a special treatment of the motor capacity subject, in most cases requiring such special knowledge of the motor construction as to prevent any general conclusions being drawn with the limited data at hand. The locomotive motor is designed more along the lines of a stationary motor, that is, owing to the necessity for operating a locomotive close to the tractive limit, its motive power is running continuously at nearly its full-load. With a locomotive working at 75 per cent. or more of the slipping point of the drivers, there is a possibility of but small overload and hence the motors may be designed with lower density, in fact like a stationary motor. With the absence of extreme overloads, the question of commutation becomes secondary and the selection of a motor becomes a matter of its ability to radiate the heat generated for the service specified. The whole question of motor capacity for locomotives is so intimately connected with mechanical problems of locomotive design, that it must be placed in the list of special problems requiring the careful cooperation of the manufacturers. Locomotives for switching service use the motor intermittently, and the above remarks do not apply.

**141. Standard General Electric railway motors, non-commutating pole type, 600 volts**

**142. Forced ventilation** is being resorted to especially in the case of the larger motors for locomotives, as owing to the limits imposed by standard gage and allowable wheel base it often becomes extremely difficult to concentrate the required motor power without exceeding safe temperature limits. As the size of locomotive motors is largely determined by their ability to radiate heat, the use of forced ventilation naturally follows as the next step in advance.

## RAILWAY-MOTOR CONTROL

**145. Classification.** There are two general types of control used with direct-current series-wound railway motors, namely: drum control and multiple-unit control. With each of these types there are two systems which may be used, these being known as the straight rheostatic control system and the series-parallel control system.

**146. With the straight rheostatic system of acceleration** the motors are connected permanently in series or parallel according to the arrangement desired, and the full starting resistance is connected in series with the motors. This resistance is then notched out of circuit, step by step, until full potential is applied to the motors. This arrangement is used for single-motor equipments; two-motor equipments on double voltage (two 600-volt motors insulated to withstand 1,200 volts on a 1,200 volt circuit), and for slow-speed industrial cars or mining locomotives of small capacities.

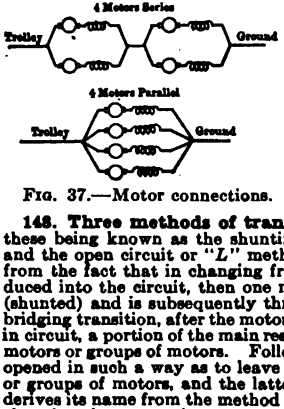

FIG. 37.—Motor connections.

**147. The chief advantages of a series-parallel control system** are that two running speeds are obtained, and that economy is effected during acceleration. The motors or groups of motors (Fig. 37) are first connected in series with the full starting resistance in the circuit. This resistance is then notched out of the circuit, step by step, until full-line potential is applied to the motors or groups of motors in series. A portion of the resistance is next re-introduced in the circuit, and the motors or groups of motors are connected in parallel. Finally, the resistance is cut out of the circuit step by step until full-line potential is across the motors or groups of motors in parallel.

**148. Three methods of transition from series to parallel** are in use, these being known as the shunting or "*K*" method, the bridging method, and the open circuit or "*L*" method. Shunting transition derives its name from the fact that in changing from series to parallel, resistance is re-introduced into the circuit, then one motor or group of motors is short-circuited (shunted) and is subsequently thrown into parallel with the other. In the bridging transition, after the motors are running in full series with no resistance in circuit, a portion of the main resistance is thrown in parallel with each of the motors or groups of motors. Following this, the circuit between the motors is opened in such a way as to leave resistance in series with each of the motors or groups of motors, and the latter in parallel. The open-circuit transition derives its name from the method of opening the power circuit entirely before changing the connections.

**149. The distinctive feature of cylinder (drum) control** is that the various electrical connections are made and broken manually, by means of a hand controller. This consists of an upright cylinder upon which are mounted the contacts and against which stationary fingers press. When the cylinder is rotated (by means of a handle) the contacts connect the proper fingers to form the required electrical connections.

**150. Cylinder (drum) controllers are classified as follows:** Type "*K*" Controllers are of the series-parallel type and include the feature of shunting and short-circuiting one motor or group of motors, when changing from series to parallel connection.

Type "*L*" controllers are of the series-parallel type, but completely open the power circuit during transition from series to parallel connection.

Type "*R*" Controllers are of the rheostatic type and are designed to control one or more motors by means of resistance only. Certain of these controllers are arranged so that the motors may be grouped either in series or in parallel at the option of the operator, but as this must be accomplished by throwing a separate lever, these controllers are not used as series-parallel controllers and their field is limited.

Type "*B*" controllers may be either of the rheostatic or the series-parallel types, but they differ from the ordinary rheostatic or series-parallel controllers by having the contacts arranged so that if desired, the power may be cut off, the motors reversed and then short-circuited through a variable resistance, the motors thus acting as series generators. Beside the braking effect of the motors acting as generators, use is sometimes made of magnetic rail brakes or axle brakes, the coils of these magnetic brakes being in series with the short-circuited generators.

**151. The rated capacity of drum controllers** is based upon the maximum horse-power of the motors with which they can be used, the motors being rated in accordance with standard practice, that is, the 1-hr. or nominal rating as defined in the standardization rules of the American Institute of Electrical Engineers. This rating is usually based upon a pressure of 500 volts, so that controller ratings are based upon a nominal potential of 500 volts. If the controllers are used with motors wound for lower voltages, the horse-power ratings will, in general, be proportionately less.

**152. Standard series-parallel controllers**

| Title | Capacity at 500 volts | Controlling points | Maximum potential |
|---|---|---|---|
| K–10 | 2–40 h.p. | 5 series<br>4 parallel | 600 volts |
| K–11 | 2–60 h.p. | 5 series<br>4 parallel | 600 volts |
| K–12 | 4–30 h.p. | 5 series<br>4 parallel | 600 volts |
| K–28 | 4–40 h.p. | 5 series<br>5 parallel | 600 volts |
| K–34 | 4–75 h.p. | 6 series<br>4 parallel | 750 volts |
| K–35 | 4–55 h.p. | 5 series<br>3 parallel | 750 volts |
| K–36 | 2–60 h.p. | 4 series<br>4 parallel | 750 volts |
| K–51 | 2–60 h.p. (Field control motors) | 5 series (1 with short field)<br>4 parallel (1 with short field) | 750 volts |

**153. Auxiliary contactor control.** In order to increase the reliability and efficiency of drum types of controllers there has been developed a system whereby the main power circuit is broken by means of remote-control switches mounted under the car, when the controller is moved to the "off" position. The use of these additional power-operated switches relieves the main controller fingers of the serious arcing and burning, especially when opening the circuit under overload conditions.

Digitized by Google

The remote-control switches for use with hand controllers may be either of the electromagnetically operated type or of the electropneumatically operated type, and are enclosed by sheet-iron covers making them suitable for mounting under the car. The switches are equipped with the magnetic blowout feature, which enables them to open the power circuit under practically any condition.

**154. Tripping mechanism.** In connection with the remote-control switches a tripping mechanism is provided, arranged so that it will be actuated by any current above a predetermined value. When actuated, the control circuit operating the switches is opened, thus dropping the switches and opening the power circuit. The tripping mechanism for use with the magnetic switches is a separate piece of apparatus arranged for mounting in the cab, and may be reset by hand after tripping. Where the pneumatic switches are used, this overload device is mounted on the end plate of the frame holding the switches, and is arranged to be reset either electrically by means of a control wire, or mechanically, by releasing a latch.

**155. Cylinder (drum) controllers which are designed for use with auxiliary switches** are similar to the standard controllers of the same type, except that in addition to the main circuit fingers, two control fingers are provided for making and breaking the circuit controlling the auxiliary switches. These fingers are operated by a pivoted arm, which is actuated by a cam on the controller drum, and are equipped with magnetic blowouts. When turning

FIG. 38.—Multiple unit control.

the controller cylinder from the "off" position, the main circuit fingers make contact, and then the cam arrangement allows the control fingers to close. When turning the cylinder in the opposite direction, this sequence is reversed, so that the control circuit and the auxiliary switches are opened before the main circuit fingers leave the contacts.

A projection is also provided on the disc to open the contactors in passing from series to parallel. It may readily be seen that with this arrangement all heavy arcing occurs at the contactors and not in the controller.

**156. Multiple-unit control.** The distinctive features of multiple unit control are: the various main circuit connections are made and commutated by means of individual power-operated switches (either electrically operated or electropneumatically operated); the various switches are controlled by means of secondary or control circuits. The multiple-unit type of control was brought out primarily for the control of motors in a service requiring that cars be operated singly or severally coupled together in a train and operated simultaneously. This control is also used very extensively at present on car equipments where the motors have a capacity of 60 h.p. or more at 500 volts. When several cars are coupled together in a train, the control "train lines" of the cars are connected together by means of jumpers between cars so that if the train-line wires are energized from any master controller on any car, similar control circuits in each car are energized, thus causing the simultaneous operation of all motor cars. The control circuits of each car are arranged so that when operating in trains, the movement of all cars will be in the same direction regardless of whether any of the cars are turned end for end. See Fig. 38.

The principal pieces of apparatus which, in general, make up a multiple unit control equipment are as follows:

| Main circuit apparatus | Control circuit apparatus |
|---|---|
| Current collectors | Control switches |
| Switches and fuses | Master controllers |
| A number of remotely controlled switches mounted in groups | Junction boxes |
| Resistors | Receptacles |
| Reverser | Jumpers |
| | Relays (if necessary) |

Two general types of multiple unit control are used in this country, these two types differing chiefly in the method of operating the individual switches. The control system manufactured by the Westinghouse Elec. & Mfg. Co. operates the main switches pneumatically, whereas that manufactured by the General Electric Co. closes the main switches by means of solenoids. Both companies manufacture automatic as well as manually operated control for multiple-unit acceleration.

**157. General Electric multiple-unit control** is described in detail in Par. **158** to **167**. In the automatic system the acceleration is effected by current-limiting relays and interlocking switches on the contactors. The multiple-unit system of control with hand-operated or manually controlled acceleration is in general use both for train and single-car operation. It is, in effect, identical with the hand-operated cylinder type of control except that instead of combining all the various circuit-breaking contacts upon a single cylinder operated by hand, it divides each contact into a separate circuit-breaker or contactor, and actuates these electrically through train wires by means of a small master controller. The motor control therefore comprises those parts which handle motor current, all of these parts being electrically operated and located underneath the car.

**158. The master controller** (Par. **157**) Fig. 39 comprises those parts which switch the control current operating the motor-control apparatus. The master controller (Par. **159**) is operated by hand, and is located in the vestibule at either end of the car. The motor control is local to each car, and current for this circuit is taken directly from the trolley or third-rail through the contactors, starting resistance and reverser to the motors, thence to the ground. Where it is necessary to operate with a gap in the third-rail system, it is sometimes customary to install such a train line that any car may supply the motor current for the other cars of the train.

The master control includes train wires (Par. **167**) made continuous throughout the train by means of couplers between the cars. On each car the operating coils of the motor control are connected to this train line through a cut-out switch, these train wires being energized in proper sequence by the hand-operated master controller on the platform. Current for the master control is taken directly from the trolley or third-rail through the master controller, which is being operated by the motorman, to the train-line, and

Digitized by Google

thus to the operating coils of the contactors forming the motor control on all cars of the train. In Fig. 40 is shown the control apparatus for single-car operation.

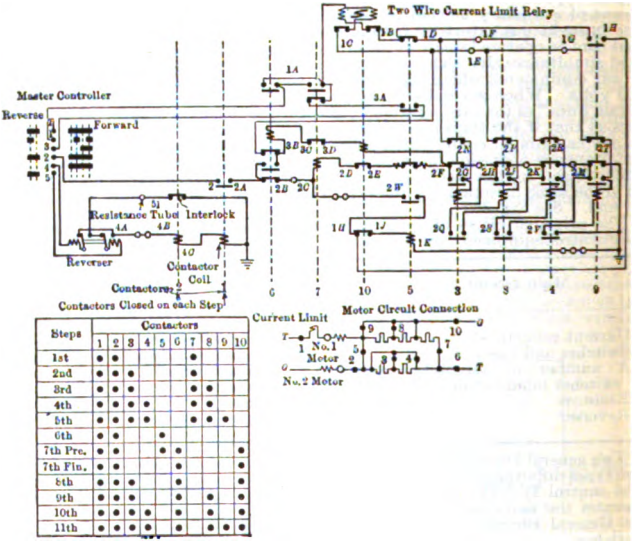

FIG. 39.—Sprague General Electric multiple-unit control.

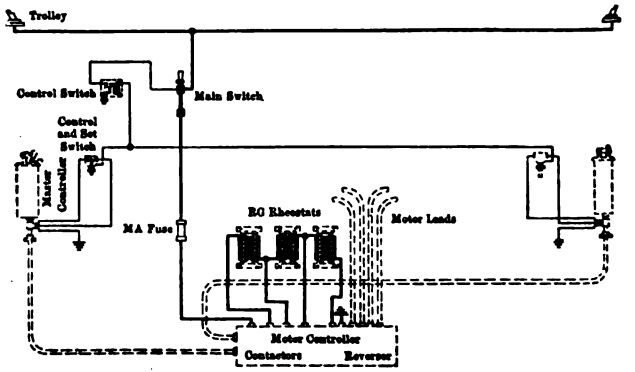

FIG. 40.—Sprague General Electric Automatic type M control.

**159. The master controller** (Par. 157) is similar in design to the original cylinder controller in that it contains a movable cylinder and that stationary contact fingers are used to supply current in proper sequence to the different

Digitized by Google

wires of the train line, for energising the operating coils of the motor control. The value of the current required is very small, not exceeding 2.5 amp. for each car in the train. The master controller is provided with two handles, one for operating and one for reversing the train movement.

**The operating handle** is provided with a button which must be kept down except when the handle of the controller is in the off position, as releasing this button permits an auxiliary circuit to open, cutting off the supply of current to the master controller, and thus de-energising the train-line and opening up the motor-control apparatus. This button is intended to serve as a safety appliance in case of physical failure of the motorman.

**The reverser handle** is connected to a separate cylinder which establishes control connections for throwing the electrically operated reverser either forward or reverse position when the master-controller handle is on the off point. The operating circuit for the reverser is so interlocked that unless the reverser itself corresponds to the direction of the movement indicated by the reverser handle of the master controller, the line contactors on that car cannot be energised.

160. **The contactor** (Par. 157) is a switch operated by solenoid coils, and each contactor may be considered as the equivalent of a finger and its corresponding cylinder segment in the hand-operated "*K*"-type controller. It consists of an iron magnet frame with an operating coil and two main contacts, one fixed and the other directly connected to the movable finger. These main contacts open and close in a moulded-insulation arc chute provided with a powerful magnetic blowout. Interlocks are provided for making the necessary connections in control circuits to ensure proper sequence in operating the different contactors.

All of the contactors are mounted in a box placed beneath the car, this box being provided with a sheet-iron cover lined with insulating material.

161. **The reverser** (Par. 157) is a switch, the movable part of which is a rocker arm operated by two electromagnets working in opposition. The coils receive their energy from the master controller through the train-line, and the connections are such that only one coil can be operated at a time. Leads from the motors are connected to the main reverser fingers, and by means of copper bars on the rocker arm, the proper relations of armature and field windings are established for obtaining forward or backward motion of the car. Also see Par. 173.

162. **Circuit couplers between cars** (Par. 157) are so designed as to give a corresponding connection of train wires, this being secured by means of proper mechanical design of plug and sockets, it being rendered impossible to insert the plug in the socket improperly.

163. **Automatic multiple-unit control.** Sprague General Electric (Par. 157) provides for the acceleration of the train at a predetermined value of current in the motor, this feature being provided without preventing the manual operation of the master controller at less than the predetermined current if desired.

The operation of the contactors is controlled from the master controller, but is governed by a notching or current-limit relay in the motor circuit, so that the accelerating current of the motors is substantially constant.

This is accomplished by having small auxiliary interlocking switches on certain of the contactors, the movement of each connecting the operating coil of the succeeding contactor to the control circuit. The contactors are energised under all conditions in a definite succession, starting with the motors in series and all resistance in circuit; the resistance is subsequently cut out step by step; the motors are then connected in parallel with all resistance in circuit, and the resistance again cut out step by step. The progression can be arrested at any point, however, by the master controller, and is never carried beyond the point indicated by the position of the master controller. The rate of the progression is governed by the current-limit relay, so that the advance cannot be made at a rate so rapid that the current in the motors will exceed the prescribed limit. One of these relays is provided with each car equipment, so that while the contactors on each car of a train are controlled from the master controller in use for the application and removal of power, the rate of progression through the successive steps is limited by the relay on each car independently, according to the adjustment and current requirements of that particular car.

**164. The control for 1,200-volt, 1,500-volt and 2,400-volt car equipments** (Par. 157) is essentially the same as that described for 600-volt service except that two motors are usually connected permanently in series. Series-parallel connection of the two groups of motors provides for half speed and full speed, but when full speed is desired on 600-volt supply, a commutating switch is provided with the 1,200-volt equipments, thus changing the motors from two in series to all in multiple. Usually, however, two motors remain permanently in series, and provide half speed when 1,200-volt cars run over terminal tracks supplied with energy at 600 volts. A dynamotor or motor-generator set run from the trolley supplies current at low voltage for actuating the contactors. The air compressor and heaters operate direct from the trolley circuit.

**165. A control cut-out switch** (Par. 157) is provided in each car, so that in an emergency the operating coils of the contactors, the reverser, and the circuit-breaker on a particular car may be disconnected from the control circuit. It is necessary to energize positively two distinct train wires in order to operate the contactors required for starting the motors. Several small fuses are provided in the control circuit for effective protection of the control apparatus. Should the train break in two, the control current would be automatically and instantly cut off from the detached rear portion without affecting the ability of the motorman to control the front part of the train.

**166. Protection against failure of power** (Par. 157). Another automatic protection for individual cars is provided by a second or **potential relay**, which has its coil connected to the lead from the collecting shoes of the respective car. The contacts are so connected in the contactor circuits, that in case of failure of power to any car (such as would be caused by passing over a dead section of rail), this relay is de-energised and causes the control circuits on that car to be thrown back to the series position with resistance in circuit. When power is re-applied the control progresses step by step to its former advanced position. This method prevents any surging or overloading in such contingencies.

**167. Train-wire circuits** (Par. 156). There are five circuits leading from the master controller, and five corresponding train wires. The five circuits comprise one for forward direction, one for reverse, one each for series and parallel, and the fifth for controlling the acceleration. When the master controller is moved to its first forward point a direction wire is energised which throws the reverser to its forward position, if it is not already so thrown. The reverser is electrically interlocked so that it cannot be manipulated when the motors are taking current.

The operating circuit is so arranged that unless the reverse is thrown for the direction of car movement indicated by the master-controller handle, the contactors and motors on that particular car are inoperative. When the reverser has moved to the proper position, connections are made by it from the direction wire, through the forward reverser-operating coil, to the coils of the contactors which control the main or trolley leads to the motors.

**168. The Westinghouse unit-switch system of control** is arranged for use either on alternating-current or direct-current circuits, and for capacities varying from the smallest double-motor equipments to those of the largest locomotives. The control circuits for an alternating-current installation are usually energized from a storage battery, while those for a direct-current installation may either be operated from a storage battery or by the use of energy from the line. When the latter is used for the control, a resistance is inserted between the trolley and the ground whenever the master controller is in one of the operating positions; taps leading from this control resistor provide various low voltages at which the control circuits may be energized.

Westinghouse unit-switch control equipments are classified according to whether they are arranged for hand (manual) or automatic acceleration, whether they employ energy from the line or a battery for control, and whether they have any other distinctive features, such as field control or multiple operation with General Electric Co.'s. type "*M*" control. Some of these standard designations are as follows: *HB, AB, HLF, AL, ALM*, etc. Thus it will be noted that "*H*" signifies hand acceleration, "*A*" automatic, "*B*" battery control, "*L*" line control, "*F*" field control of motors, etc.

**169. The HL system of control** (Westinghouse) is widely used for the control of direct-current motors on city and interurban cars and is described in detail in Par. **170** to **179**. A standard car equipment for the control of 4-40-h.p., 500-volt motors arranged for double end operation in trains includes the following part:

| Main circuit apparatus | Control apparatus |
|---|---|
| 2 Trolleys | 2 Master controllers |
| 1 Lightning arrester | 2 Control and reset switches |
| 1 Main knife switch | 1 Control resistor |
| 1 Main fuse box | 3 Train line junction boxes |
| 1 Switch group | 2 Train line receptacles |
| 1 Reverser | 1 Train line jumpers |
| 1 Main grid resistor | 1 Set of pneumatic details |

In Fig. 41 is shown the control connections of the above apparatus. This system of control uses the shunting method of transition from series to parallel for the smaller sizes of motor equipments, but for the larger equipments, the bridging method is used Par. **148**.

**170. The main knife switch** (Par. **169**) is arranged for mounting underneath the car and is enclosed in a box, which protects it from the weather, and insures against accidental contact.

The **main fuse box** (Par. **169**) is of the magnetic-blowout, copper-ribbon type, arranged for mounting under the car. The connection of this fuse box in the main circuit is shown clearly in Fig. 41.

**171. Switch group.** The various main-circuit connections are made by means of a number of independent switches known as unit switches, each provided with a strong magnetic blowout, and normally held open by a powerful spring. Each switch is closed, when desired, by compressed air acting on a piston. This action forces the switch jaws together against the spring pressure, the force being sufficient not only to compress the spring, but also to apply a heavy pressure at the switch jaws. The air is admitted to or exhausted from the cylinder through a valve which is operated by means of a solenoid in the control circuit. The switch group consists of a number of these unit switches mounted with blowout coils, in a common frame, and completely enclosed by removable sheet-iron covers lined with asbestos. Switches for cutting out damaged motors are mounted on one end of the group, and the overload trip relay is mounted on the other end.

**172. Line switch.** In larger equipments, where it is necessary to have a larger number of switches, two of the switches are mounted in a separate frame with the overload trip. This assembly constitutes what is termed a line switch.

The **overload trip** mechanism (Par. **169**) consists of a core, which is drawn into the end blowout coil of the switch group or line switch, when an excessive current passes through this coil. The core is normally held out by means of a spring, but when drawn into the blowout coil, is latched and must be released either manually or by energizing a reset coil. When actuated, the trip opens the control circuits of certain switches which cut off the power. Calibration for various currents is accomplished by an adjustment of the air gap.

When the position (whether closed or open) of a switch necessitates a change in the control circuits, an interlock must be employed to effect this change. This **interlock** consists of a block carrying contacts so mounted on the switch that it will be moved from one position to another according to the position of the switch. Pressing against this block are stationary fingers to which the control wires are attached.

**173. Reverser** (Par. **169**). The direction of rotation of the motors is changed by reversing the main fields. The reverser consists of the necessary number of main circuit fingers mounted on a stationary base, and arranged to press against contacts carried on a movable drum. The drum with its contacts is moved to the forward or to the reverse position by one or the other of two pneumatic cylinders closely resembling those in the switch

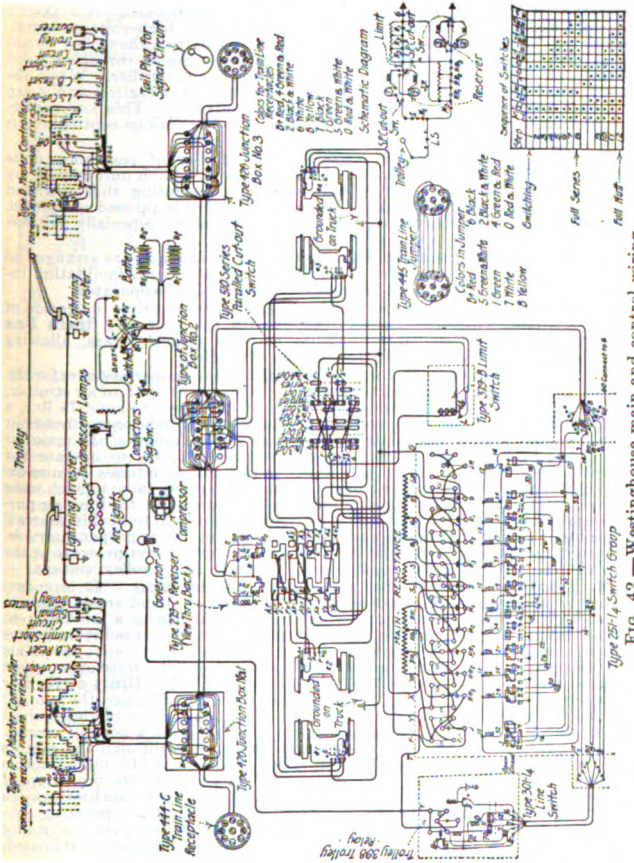

FIG. 42.—Westinghouse main and control wiring.

Digitized by Google

group. Each cylinder is controlled by a magnet valve, also similar to those in the switch group. Also see Par. 171.

174. **Master controller** (Par 169). The various control-circuit connections are commutated by means of the master controller. This controller is similar in the general plan of construction to a main drum controller, having one handle governing the direction of motion, and another governing the acceleration, the two handles being mutually interlocked. A magnetic blowout is also provided for rupturing the arc at the high-voltage fingers. Energy for the control is obtained through a tap taken from the trolley circuit ahead of the main knife switch. This control power passes through a fused control and reset switch, and thence to the master controller. When the master controller is thrown on, the control resistor is energised and a tap from this resistor is led back to the master controller. This low-voltage energy (125 to 150 volts approx.) is transferred to the various control circuits by the master controller.

175. **The control resistor** consists of a number of resistance units mounted in a common frame with a sheet-iron cover. Each unit is made by insulating a slotted steel ribbon with mica and enclosing this insulated ribbon in a sheet-iron scabbard. This scabbard is firmly pressed against the mica insulation, and being waterproof renders the resistor especially suitable railway service.

176. **The control junction boxes** are made of iron and are arranged to receive conduit. Each includes a multiple terminal board, facilitating installation of the control wiring between various pieces of apparatus.

177. **Train line receptacles** are provided when multiple operation of cars is desired. These receptacles together with the necessary **train line jumpers** complete the control circuits between adjacent cars, allowing simultaneous operation of all equipments so connected.

178. **Pneumatic details**, for supplying air at the proper pressure for the control, are furnished with each equipment. These consist of an air strainer, a reducing valve (when the main reservoir air pressure is above 75 lb.), a check valve and a control reservoir. The check valve and control reservoir permit the operation of the control system in event of failure of the main air supply, the control reservoir having sufficient air capacity to operate the control a great number of times. Local conditions sometimes require extensive control operation even though the main air supply fails; in such cases an emergency control reservoir is employed. The use of air for braking purposes has proven that very little trouble may be expected from this source if the piping is properly arranged and the reservoirs drained at proper intervals. The use of air for operating switches insures a heavy contact pressure at the switch jaws, which pressure is, of course, independent of trolley voltage.

179. **Extra equipment for automatic acceleration.** Equipments arranged for automatic acceleration differ from those for hand acceleration in the master controller, switch group, and by the addition of a limit switch. The operation of the control is such that the first controller point institutes series operation with all resistance in the circuit. The other controller points give full series with no resistance and full parallel with no resistance, there being, in general but three notches on the controller. The **limit switch** or current-limiting relay is a device consisting of a coil and plunger, the plunger carrying a disc contact. This relay may be so set that at any predetermined current through the coil the plunger will lift and open a control circuit. Thus, if a resistance step is short-circuited, the current through the motors will rise, and since the limit coil is in series with one of the main motors the plunger will lift, thereby opening a control circuit. As the motor speed increases, the current will fall until a value is reached where the limit-switch plunger will drop, closing the operating control circuit. This operating control circuit closes another main switch, which again causes a rise in motor current and again lifts the limit plunger. This performance is repeated, cutting out resistance step after step until all has been removed.

Fig. 43 shows the main and schematic connections for a quadruple equipment of 75-h.p., 600-volt, direct-current motors and type "AL" control.

The chief difference between the switch groups of a hand-accelerated equipment and one arranged for automatic acceleration, lies in the interlocking of the control circuits and in the number of control circuits. The interlocking for an automatic equipment is a great deal more complicated than for other types of control, as may be seen by reference to Fig. 42.

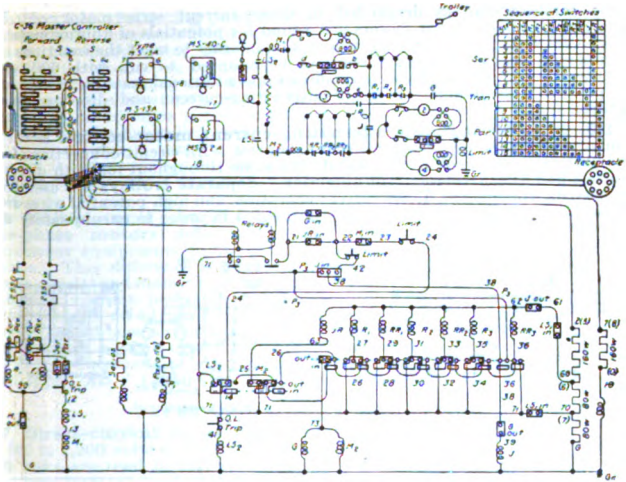

FIG. 43.—Westinghouse 600-volt direct-current motor-car main and control schematic.

**180. Tap-potential control of single-phase motors.** The single-phase motor is essentially the same in its characteristics as the direct-current series-wound motor, and can be started at low voltage by means of inserting series resistance according to the direct-current standard method. With alternating-current supply, however, it is possible to obtain fractional voltage without sacrificing efficiency, as the step-down transformer forming part of the alternating-current car equipment can be constructed with taps so that it will furnish fractional voltage without the necessity of introducing starting resistance. The universal method of starting single-phase motors is, therefore, by the so-called tap-potential control, and the function of the control, whether it be hand-operated "*K*" type or multiple unit, is to connect the motor terminals successively to transformer taps of increasing potential while starting.

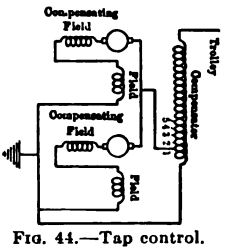

FIG. 44.—Tap control.

**181. The hand-operated control of single-phase motors** is identical with the type "*K*" controller used with direct-current motors, except that advantage is taken of the fact that alternating-current arcs of considerable size can be broken in the air without the aid of the magnetic blowout. Where the cars are to be operated from both alternating-current and direct-current trolley with the same equipment, the hand-operated control is provided with magnetic blowout for direct-current operation, using the same controller without the magnetic blowout for alternating-current operation, unless the motor equipment be of large capacity.

**182. Control of single-phase motors for combined alternating-current and direct-current service.** The control of single-phase motor is effected by connecting the motor terminals to transformer taps of increasing potential in order to vary the speed, while reversal is effected by reversing the series field-winding connections, thus calling for practically the

Digitized by Google

same combinations as demanded in direct-current series motor control. Alternating-current series motors are wound for potentials of approximately 225 to 300 volts per motor, and such motors in order to meet the exactions of commercial operation must sometimes be adapted to run with 600-volt direct-current. In such cases it requires some additional features in control to perform this double service of alternating-current and direct-current control.

**183. The Westinghouse alternating-current motor-control** is very similar to the direct-current unit-switch control. All circuit connections for the unit-switch control are practically the same throughout for both direct-current and alternating-current operation. **Separate trolleys** are used for alternating-current and direct-current operation, and high-potential wires are enclosed in metal tubing, thoroughly grounded in order to ensure safety to operator and passengers.

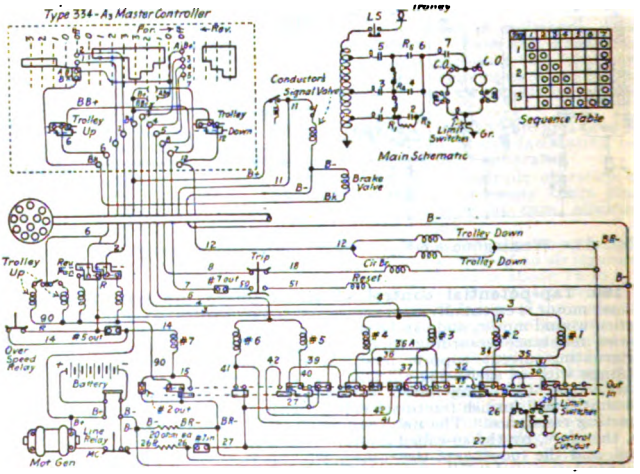

FIG. 45.—Westinghouse automatic alternating-current motor control.

When passing from one compensator tap to the next it is evident that any metal contact bridging the gap between the two will cause a short circuit in the active transformer winding, and hence, it is necessary to introduce either a dead-resistance or an inductance in the circuit when passing from one step to another on the compensator. The inductance, called a preventive coil, is more often used in locomotive work.

**184. Combined alternating-current and direct-current equipments.** At times existing conditions may require the operation of an equipment on both alternating-current and direct-current systems, an example of this being the equipments of the N. Y., N. H. & H. R. R. Co. which enters the Grand Central Terminal in New York City. No change is required in the single-phase motor for direct-current operation, but since the control is necessarily of a different character, some means must be provided for re-arranging circuits. This is usually accomplished by means of a drum type of change-over switch, but if heavy currents are to be handled, individual knife switches are employed. The control apparatus used with a combination alternating-current-direct-current equipment is, in general, more complicated than equipments for straight alternating-current or straight direct-current operation.

Digitized by Google

**185. Number of starting points.** Owing to the fact that the alternating-current motor characteristic is more drooping than even that of the direct-current series-wound motor, fewer starting points are required for alternating-current control. The General Electric Company uses five steps, and the Westinghouse uses six steps when the speed does not exceed 40 to 45 miles per hr. maximum. As each point on the controller, with potential-tap control, constitutes a running point at full efficiency, it is not necessary to use series-parallel connection of motors as is done with direct-current motors.

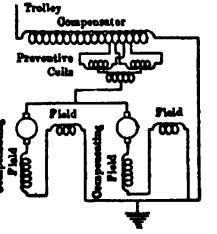

FIG. 46.—Westinghouse tap control.

**186. Multiple-unit control equipments for single-phase motors** differ somewhat from direct-current equipments in the general plan of operation. This difference is confined chiefly to the main circuits and main-circuit apparatus. The high-tension current passes from the overhead collector through an oil circuit-breaker, to a transformer. Low voltage currents are fed to the main motors through a group of unit switches, which can be arranged for automatic or non-automatic acceleration. Fig. 45 shows the connections for a typical type "*AB*," 11,000-volt single-phase equipment.

## TYPES OF RAILWAY MOTORS

**187. Direct-current series-wound motor.** Wound for potentials of from 500 to 1,200 volts is the standard railway motor. Motors of from 500 to 600 volts are used in and around large cities, 1,200-volt motors being adopted on interurban electrified lines. Armature and field windings are connected in series and the use of motors of the commutating pole type is increasing. All motors designed for street, interurban and rapid transit car or train service have four field poles, the structure being entirely enclosed with hand hole covers making it waterproof. Such motors transmit power by single-reduction gear, motors being suspended at one end upon the car axle and spring suspended at the other end.

For locomotive work, the General Electric Company has brought out a two-pole gearless motor, which design is also adapted for high-speed single-car service calling for large motor outputs. The two-pole series motor is especially adapted to very high speed service; it minimizes cost of repairs and operates with decreased noise and greatly increased efficiency for express service. For further description of gearless motors see locomotives (Par. **280**).

**188. The single-phase series motor** has been developed along several lines of which the series-wound compensated motor is the one most generally used in the United States. The single-phase motor differs from the direct-current series-wound motor in having two fields, the series or energising field and the **compensating field.** The office of the latter is to compensate for or neutralise the inductance of the armature produced by the alternating current therein. Compensation may be the means of raising the power-factor of a single-phase motor to values closely approximating 100 per cent., and having an operating value above 95 per cent.

This compensating field may be either conductively or inductively produced, depending upon whether the winding is traversed by the main motor current, or by the current produced in its own short-circuited winding by the alternating armature flux. So far as concerns operation from alternating-current supply, one form is about as efficient as another, but the conductive compensation is an aid when the alternating-current motor is called upon to operate as a direct-current motor.

The series-field winding of the single-phase compensated motor is connected in series with the armature, and the direction of rotation can be reversed by reversing the field-winding connections similar to direct-current operation. The series-field winding may be distributed in a number of slots in the field-magnet structure similar to the compensating-field winding, or it may take the form of a concentrated winding, in which case it is similar to the winding of a direct-current series motor embracing inwardly projecting poles. The concentrated field winding is largely used in alternating-

Digitized by Google

current motors of the series type, while the distributed field winding i required for motors of the repulsion or similar types. As the series-compen sated motor is universally used in this country, and the repulsion and simila types are limited to special cases demanding special characteristics of th motive power, the series type motor alone will be considered.

As the armature rotates in an alternating field, there is a short circui developed when brushes touch two commutating segments at once. Thi short circuit is very large at starting, being reduced to a reasonable amoun when running at full speed. To reduce the amount of this short-circuit cur rent, and better the low-speed commutation, the alternating-current serie compensated motor is sometimes provided with resistance leads connectin armature winding with commutator bars. Such leads are desirable wit motors of the series compensated type, where full field strength is used i starting and there is no commutating-pole effect to neutralize the short circuit voltage when moving.

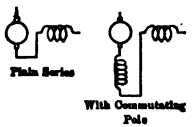

FIG. 47.

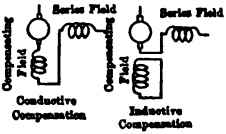

FIG. 48.

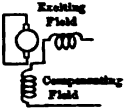

FIG. 49.

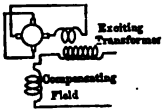

FIG. 50.

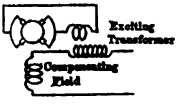

FIG. 51.

**189. The repulsion motor** as originally developed by Thomson and perfected is shown in Fig. 49. The field winding is very similar to the field winding of an induction motor. The armature is an ordinary series-wound armature short-circuited upon itself. The repulsion motor is very similar in its operating constants to the single-phase compensated motor but cannot be used for speeds much higher than 100 per cent. of synchronism, owing to the imperfect commutation at the higher speeds. It has the advantage of having its field circuit distinct from the armature circuit, hence, permitting of a field winding of any potential best suited for control or operation. With this type of motor it is possible to operate 3,000 volts direct on the field winding if desired.

Best results appear to be obtainable from a combination of repulsion-motor connections for starting and operation at low speeds, changing to series-motor connections for speeds above synchronism. This is effected automatically by relays.

**190. In the Latour motor**, which is a modification of the Winter-Eichberg motor the armature winding is short-circuited in part only, rather than through diametrically opposite brushes, with the result that the armature $I^2R$ loss is reduced. This type is limited in its field of application to special cases.

**191. The three-phase induction motor** has all the characteristics of a direct-current shunt-wound or constant-speed motor, and comprises a three-phase primary winding either star or delta connected, with a three-phase secondary winding either star or delta connected. The secondary terminates in collector rings across which non-inductive resistance is inserted during the accelerating period, after which the collector rings are short-circuited. The induction motor may be wound for the trolley potential if desired, as the potential of the secondary winding is entirely independent of that of the primary. The constant-speed characteristic of this type of motor is especially adapted for duty of a constant nature, such as hauling

Digitized by Google

over a regular profile, either level or up a uniform gradient, in other words, where there is no combination of slow-speed grade haulage and high-speed level service.

**192. The single-phase induction motor** has been used for railway purposes on experimental roads, but owing to the zero starting torque of this motor it is necessary to operate it in conjunction with an auxiliary starting device and throw the motive power into action by mechanical clutches or other means after full motor speed has been obtained. This type of motive power is very limited in its field of application.

**193. The split-phase converter system** comprises a method of obtaining polyphase current from a single-phase trolley, for the operation of polyphase motors. It consists of a phase converter which is essentially a polyphase induction motor the capacity of which is approximately 75 per cent. of the capacity of the motors it supplies. As the phase converter is operated from one phase only, it requires a starting motor to bring it up to near synchronous speed. In all applications of this principle, the single-phase current has been converted into two-phase current. In the Norfolk & Western locomotives, these two phases are changed to three-phase by a connection similar to the well-known Scott system. The advantage claimed for the three-phase is that the motor has a better performance and is also better for pole changing while it entails no more regulating switches and has fewer leads.

## BRAKING

**194. Retarding factors.** In order to bring a moving train to a stop, it is evident that some external force opposed to the motion of the train must be applied. The ideal force would be applied at the centre of gravity of the car (producing no tendency for the car to rotate) and would be sufficient to stop the train in case of emergency in the shortest possible time, without undue shock to passengers or equipment. With the exception of a few instances, such as short cable roads up a mountain side, the only available force which may be utilized in stopping a train is the friction which exists between the wheels and the rails. This force, besides being applied at the lower rim of the wheel and consequently not at the centre of gravity of the car, is also a variable quantity of uncertain magnitude, and therefore not an ideal retarding force. For instance the adhesion between a dry rail and wheel may be equal to about 30 per cent. of the pressure between wheel and rail, whereas with a wet rail it may be only half that amount. The addition of sand to a slippery rail will increase the adhesion from 15 per cent. to about 25 per cent. of the weight on the rails, and this amount can usually be relied upon in making emergency stops. This force of 25 per cent. of the weight on the rails applied to a car will produce a retardation equal to one-quarter the acceleration due to gravity, or 8.04 ft. per sec. per sec., or nearly 5.5 miles per hr. per sec. If it were possible to apply this force instantly and uniformly throughout the stops, a stop from an initial speed of 60 miles per hr. could be made in about 11 sec., or in a distance of 480 ft. This force, however, is only available when the wheels are rolling on the rails, for as soon as slipping occurs the adhesion rapidly decreases. Therefore the force which opposes the revolution of the wheels, namely the brake-shoe friction, must never exceed that which is keeping the wheels turning, namely the adhesion between the wheels and rails. This opposing force is obtained in several different ways, the most familiar being by applying brake-shoes to the rim of the wheels with considerable force by means of hand or power brakes. Another method, which is applicable in electric traction, is known as electric braking, as distinguished from mechanical braking, and consists in opposing the revolution of the wheels with the counter-torque of the motors or by the friction of electrically operated brake discs.

**195. Tests to determine friction coefficients.** About the first systematic tests to determine the value of the **coefficient of friction between brake shoes and wheel**, and between wheel and rail were conducted by Sir Douglass Galton and Mr. George Westinghouse in 1878 and 1879 on the London, Brighton & South Coast Railway, England. A report of these tests appears in the proceedings of the Institute of Mechanical Engineers of London, for April, 1879. The table in Par. **196** gives the results of these tests:

Pressure of 336 lb. per sq. in..... 347

**197. Variation of friction coefficient with speed.** From the vals given in Par. **196**, Mr. R. A. Parke has developed the following formula

From the mean values $$f = \frac{0.326}{1+0.03532\,S} \qquad (1$$

from the maximum values $$f = \frac{0.382}{1+0.2933\,S} \qquad (2$$

where $f$ = coefficient of friction, and $S$ = speed in miles per hr. The latte formula gives values corresponding more nearly to recent experiments.

**198. Coefficient of friction as affected by time***

| Miles per hr. | Commencement of experiment† | After 5 sec. | After 10 sec. | After 15 sec. | After 20 sec. |
|---|---|---|---|---|---|
| 20 | 0.182 | 0.152 | 0.133 | 0.116 | 0.099 |
| 27 | 0.171 | 0.130 | 0.119 | 0.081 | 0.072 |
| 37 | 0.152 | 0.096 | 0.083 | 0.069 | ..... |
| 47 | 0.132 | 0.080 | 0.070 | ..... | ..... |
| 60 | 0.072 | 0.063 | 0.058 | ..... | ..... |

**199. Decrease of the coefficient of friction with length of brak application** is represented by Mr. R. A. Parke's formula, which is t follows:

$$f = \frac{1+0.000472\,l}{1+0.00239\,l} f, \qquad (3$$

* Sir Douglas Galton has also published the following values of the c efficient of dynamic friction as affected by time of brake application.

† The figures in this column are somewhat different from those that h just been given in the altered table, because they resulted from the aver of fewer experiments; but the effect of time in reducing the coefficient friction may be accepted as correct.

Digitized by Google

wherein $f$ is the coefficient of friction at beginning of application: $f'$ the coefficient of friction after brake application of $T$ sec.

**200. General laws affecting friction coefficient.** The absence of more extended observations and the complex nature of fluctuations of the coefficient of friction make it impossible to formulate a practical mathematical equation which will determine the rate of retardation under varying conditions. However, the results of the tests shown in the tables above indicate a law of variations which may be briefly stated as follows, regardless of the materials used.

(a) The coefficient of friction increases with the decrease in speed;
(b) Decreases with the increased distance through which brakes are applied, and
(c) Decreases with the increase of pressure.

**201. To obtain a uniform braking effort throughout the stop,** the brake-shoe pressure must be varied to compensate for the fluctuations in the coefficient of friction, that is, the brake-shoe pressure must be decreased as the diminution in speed increases the coefficient of friction, and increased as the distance of brake application decreases the coefficient of friction, and further increased to compensate for the decrease of the latter with increased pressure.

For certain speeds the increase in coefficient of friction with decrease in speed is practically neutralised by a decrease due to increased distance of frictional contact. For lower speeds, however, the increase from the former cause is more rapid than the decrease from the latter, necessitating an almost abrupt decrease in brake-shoe pressure near the end of a stop, in order to avoid slipping the wheels on the rails and discomfort to passengers.

**202. Efficient emergency braking.** For the same pressure, the coefficient of brake-shoe friction at 60 miles per hr. is only about half that at 30 miles per hr. It is therefore evident that an emergency stop for high speed is less efficient than for a low speed, since an emergency application implies that the maximum pressure which will not slip the wheels near the end of the stop, is instantly applied at the very outset. A considerably shorter stop may be made if the pressure applied during the earlier periods of the stop is greatly in excess of that which will slip the wheels at low speed, but in the absence of the motorman's skill, some means must be provided to decrease the pressure near the end of the stop, in order that the limits of rail friction will not be exceeded, and the efficiency of the stop thereby decreased. This provision, however, requires additional apparatus, which on general principles is objectionable unless the showing is so favorable as to warrant further complications.

**203. Application of the retarding force.** Thus far, attention has been devoted to outlining methods for overcoming the obstacles presented by the complex nature of the fluctuations of the coefficient of brake-shoe friction which prevent the utilisation of the theoretically possible retarding forces. The nature of the application of these forces imposes difficulties which prevent the full utilisation of the weight on the trucks and wheels, thereby directly affecting the braking force.

At the present time it is customary to equip double-truck cars with either two motors or four motors, depending upon the nature of the service. In the former case both motors are usually placed on one truck thus permitting the use of a lighter truck for a trailer. The pressure which may be safely applied to the wheels of the motor truck without causing the wheels to slip, cannot be applied to the wheels of the trailer truck. Hence the brake rigging must be so proportioned that the greatest portion of the braking is done upon the wheels of the motor truck. Considering, however, the case where the normal distribution of weight is equal for all wheels, it is found that, during braking, a greater pressure may be applied to the wheels of the forward truck without causing them to slide than may be applied to the wheels of the rear truck. The explanation is somewhat simplified when considering single-car operation, since draw-bar forces may be eliminated.

**204. Vertical thrust on forward truck.** The resultant of all the parallel forces, which act on the elementary masses of the car tending to keep it in motion, is equal to the sum of all these forces acting through the center of gravity of the car and in the direction of motion. Directly opposed to the motion of the car is the wind pressure, which is exerted normal to the ele-

Digitized by Google

mentary surfaces, the resultant passing approximately through the centre of gravity of the car. Wind pressure, however, is sufficient to cause only a slight retardation compared to that obtained with the brakes, and its effect has been neglected in this consideration. The retarding force of the brakes acts at the surface of the rail and as all parts of the structure are retarded equally, the king pins must transmit the force required to produce the same retardation in the car body as is produced in the truck. The total retarding force less the amount required for retarding the wheels and trucks therefore

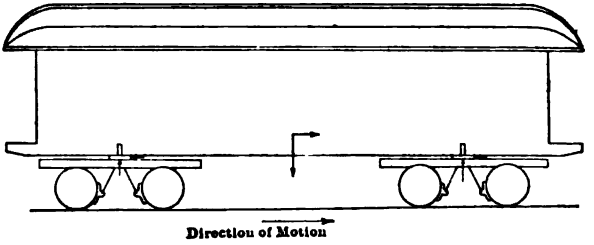

FIG. 52.—Braking-stress diagram.

acts at the points of support, which are somewhat lower than the centre of gravity of the car body. The moment of these forces about the centre of gravity of the car, is balanced by the moment produced by the increased pressure of the forward truck acting upward through the point of support; at the same time the weight on the rear truck is decreased.

**205. The distribution of weight on the wheels of each truck** is affected in the same manner, except that the retarding force transmitted through the king pins to the car body, also reacts to further increase the pressure on the front pair of wheels of each truck. Because either end of the car may at some time become the rear end, it is essential that the brake-shoe pressure be kept the same for all wheels which necessarily restricts the maximum pressure which can safely be employed to that which will not slip the wheels with the least weight. In the case of the eight-wheel passenger car, the effective wheel pressure which may be utilized in braking is only about 85 per cent. of that permissible with the total weight on the wheels.

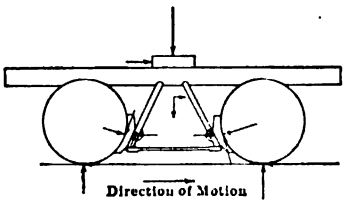

FIG. 53.—Stress diagram.

**206. Location of brake-shoes affecting recoil at instant of stopping.** On account of the stored energy in the revolving wheels, gears and armatures, which may amount to 5 or 10 per cent. of the total stored energy of the car, a consideration of the effect of these forces upon the truck through the brake hangers is essential. With outside-hung brake-shoes the pressure due to the friction between brake-shoes and wheel, is downward for the leading wheels, thereby causing compression of the forward springs of the truck. For the trailing wheel the pressure is upward, thereby relaxing the rear springs of the truck. The recoil of the forward springs results in the backward motion of the car body so disagreeable to passengers at the instant of stopping. With inside-hung brake-shoes, the brake-shoe friction force acts upward through the hanger links of the forward portion of the truck and downward through the hanger links of the rear portion of the truck, thus tending to neutralise instead of aggravate the effect of the rotating influence of the car body. The problem of proportioning the length of brake-shoe hangers and the proper inclination of the same to the tangent at the point of contact

Digitized by Google

of the centre of the shoe, in order to compensate exactly for the rotating influence of the car body, is too involved for presentation here. For this reason reference is made to Mr. R. A. Parke's excellent paper in the Proceedings of the American Institute of Electrical Engineers, Vol. XXII, Dec., 1902.

**207. A common form of hand brake** consists of a vertical shaft at each end of the car fitted at the top with a ratchet handle or crank, or geared to a hand wheel. By means of this mechanism, the motorman can wind up a chain, one end of which is fastened to the lower end of the vertical shaft and the other end to a rod which connects with a system of brake levers. By means of a pawl (or dog) which engages in a ratchet wheel on the vertical shaft near the floor of the car, the motorman is enabled to maintain a pressure on the brake-shoe while he gains a more favorable purchase for applying more pressure, or until such times as he desires to release the brakes. This

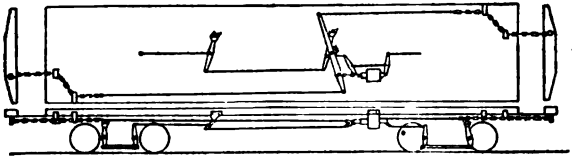

FIG. 54.—Diagram of brake rigging.

brake has been found capable of supplying sufficient braking power for the safe control of light cars running at moderate speed, but for heavy cars and high speeds the physical effort and time required to properly apply the brakes render it necessary to provide other means of supplying the proper force in a minimum length of time. Hand brakes, nevertheless, are always provided as an additional safeguard, even though the cars may be equipped with power brakes, as it is always customary to set up the hand brakes on all cars when they are left standing.

**208. Air-brakes** (Par. **209** to **229**) in some form, have been universally adopted on all steam roads for braking both passenger and freight trains, and the results have been attended with such success that modifications and improvements of the old steam-railroad air-brake system have been developed and adopted by a vast majority of electric lines operating heavy high-speed interurban cars, either singly or in trains. On account of the varying character of the service on different electric roads, it has been found necessary to develop several systems, or modifications of the same system which will be best adapted for the service in hand.

The most familiar types at present are known as the following: *the straight air-brake system* (Par. **209**), recommended for single-car operation only; *the emergency straight-air system* (Par. **215**), suitable for two-car operation, particularly when one is operated single most of the time and with a trailer added during rush hours; *the automatic air-brake* (Par. **218**), suitable for electric trains of three cars or more; *the combined straight and automatic air-brake* (Par. **227**), designed for locomotive operation, no matter whether steam or electric; *the electropneumatic air-brake* (Par. **228**), at present in an experimental state, but particularly adapted to train operation, inasmuch as the time element in the application and release of the brakes on the rear end of a long train is practically eliminated.

**209. The straight air-brake system** described in detail in Par. **210** to **214**, consists essentially of a source of compressed air (either a tank filled at intervals from a compressor at charging stations, or an air compressor, motor or axle driven, located upon the car); a reservoir which receives the air from the charging tanks or from the compressor and in which the pressure is maintained practically constant by means of a reducing valve, or by a governor which automatically controls the operation of the compressor; a brake cylinder, the piston of which is connected to a system of brake levers in such a manner that when the piston is forced outward by air pressure the brakes are applied; an operating valve mounted in each vestibule by means of which the compressed air is either admitted or released from the brake cylinders; a pipe system connecting the above parts, including cut-out valves, extra hose,

Digitized by Google

and angle fittings between cars. In order to prevent any possibility of accumulating an excessive pressure, a safety valve designed to open at 100 lb. per sq. in. is placed in the air-supply system. A set of pressure gages is usually supplied with each complete equipment in order that the motorman may observe the pressure in the reservoir and remedy any defects in the governing apparatus.

**210. To operate the motorman's valve** (Par. **209**), the handle is inserted when the valve is in lap position, where the slot in the body of the valve is enlarged for this purpose (in order to prevent its removal in any other position). In this position the valve is set so that air can neither pass into nor out of the brake cylinder. Moving the handle to the left places the valve in "full release," that is, connects the brake cylinder to the atmosphere and allows the air which holds the brakes applied, to escape, and the spring which is opposed to the air pressure, restores the piston and releases the brakes. After the brakes have been released the valve is returned to lap position, which is the normal running position. To partially release the brakes, which is necessary in braking in order to prevent shocks as the car stops, the handle is moved to the right and quickly returned to lap. This reduces the pressure on the brake-shoes, but does not entirely release them.

**211. To apply the brakes for a service stop** (Par. **209**), the handle is moved to the right a little past the lap position, then back to the lap. This connects the reservoir with the brake cylinder through a small opening in the

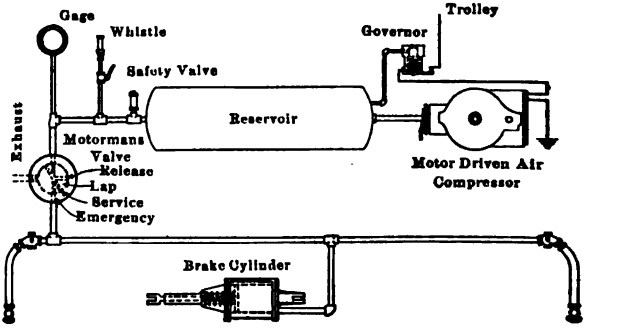

FIG. 55.—General Electric straight-air brake system.

valve, then holds the pressure constant until it is necessary to release or apply more pressure. Moving the handle further to the right connects the reservoir to the brake cylinder through a large opening, thus causing the cylinder to fill rapidly and instantly apply the brakes with maximum pressure. Sand is usually applied to the tracks as soon as the handle is turned to the emergency position in order to avoid skidding the wheels.

**212. In descending grades** (Par. **209**), a light application of the brakes should be made and the handle returned to lap. A sufficient length of time should be allowed for car to feel the effect of the brakes before applying more pressure. If speed is higher than desired a second light application should be made and operation repeated as often as necessary until the desired speed is obtained, or until the car has left the grade.

**213. Use with trailer** (Par. **209**). The straight-air system of air-brakes, although only recommended for single-car operation, may be used when operating with a trailer. The equipment for trail cars consists of a brake cylinder and system of levers similar to the ones on the motor car, and a length of pipe running the entire length of the car and provided with hose couplings and cut-out cocks for connections to the forward and rear cars. In connecting up train cars, all the hose couplings must be thoroughly united

Digitized by Google

to insure that air will apply throughout the entire train. All the cut-out cocks must be open except those on the rear of the last car, and the front of the first car.

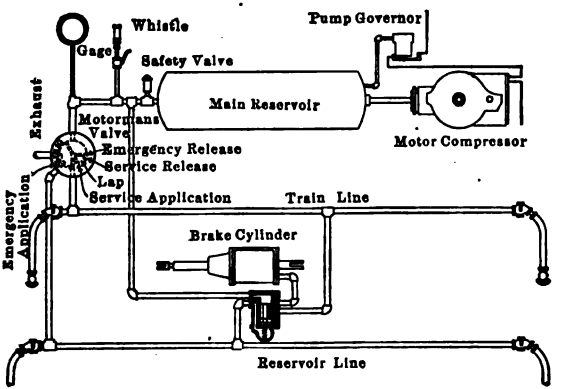

FIG. 56.—General Electric emergency straight-air brake system.

**214. Field of application** (Par. **209**). So far as single-car operation is concerned, the straight air-brake system is very satisfactory, as the desired flexibility in the matter of graduations of applications and release of the brakes with due regard to the passengers standing can readily be secured, and this apparatus is usually so simple in construction that the motorman may become familiar with its operation to such an extent that accurate stops may be secured with a minimum amount of instruction. In trains of considerable length, however, the response of the brakes on the rear cars is too slow, since all the air must pass from the main reservoir on the front car through the opening in the motorman's valve to the brake cylinders of each car. As the addition of each car adds to the volume of the brake system, the main reservoir on the first car must be considerably increased. The reservoir capacity must be so proportioned that the pressure will not be reduced to such an extent that the brake application will be insufficient and result in overrunning the desired stopping place. These latter objections would not necessarily prevent the use of this type of air-brakes on short trains of two or three cars, but add to the objection that a broken hose connection or leaky train pipe renders the brakes on the whole train inoperative.

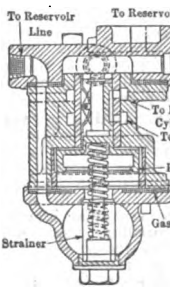

FIG. 57.—Emergency valve.

**215. The emergency straight air-brake**, described in detail in Par. **216** and **217**, differs from the straight air-brake in the details of the motorman's valve and in the addition of an emergency valve and reservoir line which connects the motorman's valve with the emergency valves (Figs. 56 and 57). In the case of a trail car, an auxiliary reservoir (Par. **217**) is also added, as shown in Fig. 58.

In the ordinary operation of single cars or short trains, the emergency valve is seldom brought into play. It is necessary, however, to provide a short direct passage from the reservoir to the brake cylinder in order to ensure the quickest possible action in time of emergency and to provide some means of automatically braking the rear cars should a break occur in the train line. At oth-

Digitized by Google

times when it is desired to make a service application or release, the air is admitted or exhausted through the motorman's valve the same as in the straight air-brake.

**216. Emergency application** (Par. 215). With the motorman's valve in the emergency position, it allows air to escape from the reservoir line and causes the reservoir pressure, which is above that in the emergency valve, to compress the spring which holds the valve in its normal position, thus opening a port in the valve casing which communicates with the brake cylinder for the direct passage of the reservoir air. The line from the reservoir supplying the air for this process should not be confused with the reservoir line. During an emergency application, all communication with the train and reservoir lines is cut off. To release the brakes, therefore, it is necessary first to return the emergency valve to its normal position by recharging

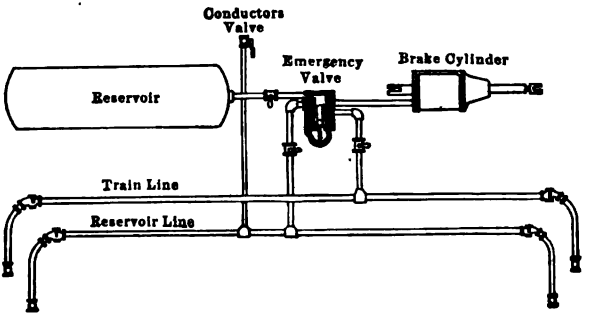

FIG. 58.—General Electric emergency straight-air brake for trail cars.

the reservoir line to the reservoir pressure. This equalising of pressures allows the spring under the valve to return it to its original position, and the brakes can be released in the same manner as after a service application by exhausting the air from the train line. The recharging of the reservoir line is accomplished by moving the motorman's valve to emergency-release position at the extreme left of the slot in the body of the valve. With the motorman's valve in this position, a connection is opened between the main reservoir and the reservoir line and also a connection between the train line and atmosphere. With the emergency valve in normal position there is a direct passage to the train line and brake cylinder, and the service applications and release are made by increasing or decreasing the pressure in the train pipe.

**217. Auxiliary reservoir with trailer** (Par. 215). In the case of a trail car, the auxiliary reservoir is charged during emergency release by the air pressure equalizing on both sides of the slide valve through charging grooves in the valve casing. At other times it is charged from the main reservoir through the charging grooves in the emergency valve on the motor car.

In case of accident to the reservoir line the air can be exhausted from the auxiliary reservoir and the train operated on straight air without interrupting the service. An accident to the train line has no effect upon the action of the emergency valve which still can be employed as ordinarily by throwing the motorman's valve to the emergency position. As the straight air-brake principle predominates in this system, it is subject to the same objection which prevents the use of the straight air-brake on longer trains, namely the time limit. For this reason, the automatic air-brake is used on trains of three or more cars.

**218. The automatic air-brake,** described in detail Par. 219 to 224, differs from the straight air-brake in that the former requires a decrease in the train-pipe pressure to apply the brakes, and an increase in pressure to

Digitized by Google

release them, whereas in the latter, air is admitted to the train pipe to apply the brakes and exhausted to release them.

**219. The apparatus required** (Par. 218) for this system in addition to that already mentioned for the straight air-brakes is as follows: a set of duplex pressure gages, which indicate simultaneously the pressure in the main reservoir and in the train pipe; an auxiliary reservoir, for storing the air used by each car in braking; a triple valve, the function of which is to admit air from the auxiliary reservoir into the brake cylinder and to release it therefrom (in release position, the auxiliary reservoir is recharged), and an air-whistle reservoir, with suitable check valve for supplying air to the air whistle.

This system is capable of a great many refinements which may be added or omitted as requirements of a particular service may prescribe. The main points of difference between particular automatic air-brake equipments will generally be found in the details of the triple valves, and the addition of pressure maintaining and reducing valves. These features are essential in certain classes of grade work in order to prevent brakes "leaking off." These particulars have been intentionally omitted from this consideration in order to avoid undue complexity. Two forms of triple valves, however, need to be considered here inasmuch as the plain triple valve, Fig. 59, is only used on comparatively short trains, about five cars in length, whereas the quick-action triple valve, Fig. 60, is designed to be used on much longer trains.

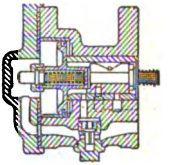

FIG. 59.—S. I. triple valve.

**220. Emergency application** (Par. 218). For the emergency position shown in diagram, Fig. 60, the train line is open to the atmosphere, allowing auxiliary reservoir pressure on the right of the slide-valve piston forcing it to the left against the graduating spring, compressing it and uncovering the brake cylinder port. Air is thus permitted to flow from the auxiliary reservoir directly into the brake cylinder; at the same time the ports leading to the atmosphere and to the train pipe are closed.

**221. To release the brakes** (Par. 218), the main reservoir air is admitted through the train to the chamber at the left of the slide-valve piston, forcing it to the right, and connecting the brake-cylinder port to the exhaust pipe. At the same time, air at the main reservoir pressure raises the check valve and recharges the auxiliary reservoir to main reservoir pressure.

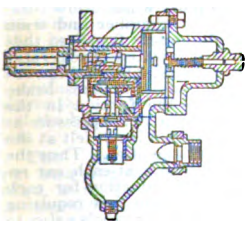

FIG. 60.—K triple valve.

A **graduated release** of the brakes may be obtained with this type of valve, by piping the exhaust from the triple valve to the motorman's valve where a movement of the valve handle will release the air the same as in the straight air-brake.

**222. Necessary train-line reduction** (Par. 218). A service application requires only a slight reduction in train-line pressure (from 5 to 7 lb.) which is sufficient to permit the slide-valve piston to slightly compress the graduating spring and partially open the brake-cylinder port. When the auxiliary reservoir pressure has been reduced to about the same value as the train-line pressure, the graduating spring will return the slide valve to lap position, closing all the ports before the brakes are fully applied. The auxiliary reservoir and brake cylinder are usually so proportioned that the brakes are fully applied when the brake piston displacement is sufficient to reduce the auxiliary reservoir pressure about 15 lb. Therefore, a train pipe reduction greater than 15 lb. fully applies the brakes and is wasteful of air, because the train pipe and the auxiliary reservoir must be fully charged after each application.

**223. The quick-action triple valve** (Par. 218), shown in Fig. 60, is designed to be used on freight trains of considerable length, its function is to apply and release the brakes on the rear cars so quickly that the running in and out of the slack is avoided. Fig. 62 is a diagrammatical section of the

Digitized by Google

triple valve shown in Fig. 60. In the full release position shown, air is allowed to pass from the brake cylinder through ports in the slide valve, the same as in the plain triple valve. The auxiliary reservoir is charged through grooves around the slide-valve piston, and also through the raised check valve and the uncovered port in the slide valve. The operation of the automatic air brake (Par. 218) in conjunction with this valve is described in Par. 224 to 226.

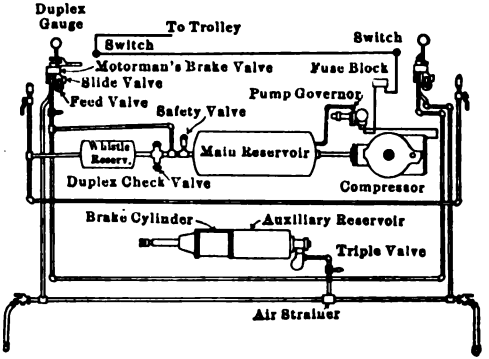

FIG. 61.—Westinghouse automatic air-brake.

**224. Release with quick-action triple valve** (Par. 218 and 223). In release position, the decrease in train line pressure allows the valve piston to move to the left, closing the charging grooves and feed port, *J*, and exhaust port, *P*. Just before valve piston strikes the graduating stem, a cavity in the grading valve on top of the slide valve connects ports which allow communication from the brake cylinder to the emergency chamber and train pipe. The piston in the emergency chamber is only loosely fitted, so that the air which is admitted from the train pipe to the unseated check valve passes into the brake cylinder before communication is established between the auxiliary reservoir and the brake cylinder. Owing to the friction in the train pipe, a reduction of air pressure at the front end of the train is not felt at the rear end until some time later. Thus the venting of the train pipe at each car results in hastening the reduction for each car following; at the same time requiring a less reduction at the engineer's valve to apply the brakes with a given pressure, since the auxiliary reservoir is not required to supply all the air to the brake cylinder.

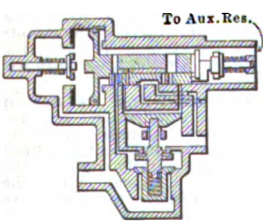

FIG. 62.—K triple valve.

When the brake-cylinder pressure is reduced below that in the train line, the slide-valve piston moves to the right with the graduating valve and closes all ports leading to the brake cylinder. The tendency for the brake-pipe and auxiliary-reservoir pressures to equalize through the connections to the brake cylinder is prevented by the proportioning of the respective ports, so that the auxiliary-reservoir pressure decreases faster than the brake-pipe pressures, and insures the travel of the piston to the right.

**225. In retarded release with quick-action triple valve** (Par. 218 and 223) the train line is quickly re-charged, forcing the valve piston to the extreme right. Thus is prevented the re-charging of the auxiliary reservoir

Digitized by Google

through the charging grooves before opening a small port in the slide valve, would permit the train line pressure to raise the check valve and slowly re-charge the auxiliary reservoir. The function of the charging device (shown on the outside of the valve in Fig. 60) is to prevent the inertia of the slide valve from forcing it to the extreme right of its travel when the valve piston is brought up against its stop. The restricted area at the left end of the exhaust cavity of the slide valve partly closes the exhaust port, and allows the brake-cylinder air to flow slowly into the atmosphere. On account of the friction in the train pipe, it is impossible to re-charge the train line at the rear of the train faster than the air will flow through the charging grooves of the triple valves. As a result, only the triple valves of the foremost cars move to retarded release, the others remaining in full release, which releases the brakes on the rear cars quickly.

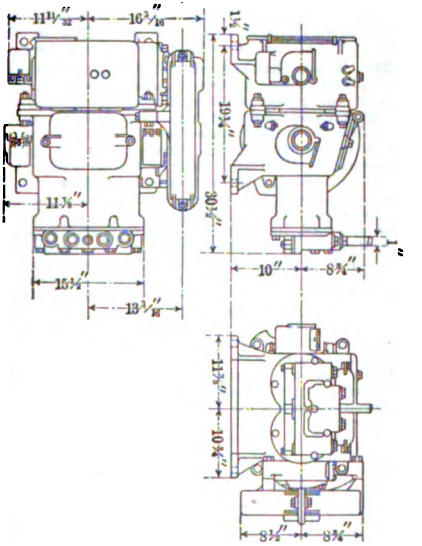

FIG. 63.—Air compressor.

**226. Emergency application with quick-action triple valve** (Par. **218** and **223**). The sudden reduction of train pipe pressure in the emergency position of the engineer's valve, moves the slide-valve piston to the left, compressing the graduating spring and opening a port directly to the brake cylinder, and also opening another port to the emergency chamber which unseats the emergency valve. At the same time the train-line pressure opens the check valve and air flows from the train line directly into the brake cylinder, applying the brakes with maximum pressure. The quick venting of the train line insures the rapid serial action of the brakes on the rear cars.

**227. The combined straight and automatic air-brake**, as the name implies, consists of two sets of motorman's valves for the control of each system. The straight air-brake, operating with pressure between 55 and 70 lb. per sq. in., applies and releases the brakes on the front car independently of the brakes on the other cars. The automatic brakes operate with air pressure from 100 to 110 lb. per sq. in., and apply the brakes on the remainder of the train independently of the brakes on the front car. The chief advantage of such an arrangement is the possibility of holding the brakes on the locomotive applied while the train brakes are released for the purpose of re-charging the auxiliary reservoirs.

**228. The electropneumatic system** is practically the same as the present automatic system, except that the valves are operated by solenoids in much the same way as the contactors in the multiple-unit train control. At the present time air control is retained as a safeguard in case of failure of the electric control. With electric traction, the possibilities of this system seem to be unlimited and automatic retardation as well as acceleration is quite feasible.

**229. The air reservoirs** should have a capacity sufficient to supply air for three or four applications without reducing the pressure more than from 12 to 15 lb. Otherwise every ordinary application of the brake will throw

Digitized by Google

the compressor into action, thus keeping the latter in a constant state o starting and stopping, and causing unnecessary wear to both compressor and governor. The Westinghouse Traction Brake Company recommended the following sizes of reservoirs:

With 8-in. brake cylinders use 16 in. × 48 in. reservoirs.
With 10-in. brake cylinders use 16 in. × 60 in. reservoirs.
With 12-in. brake cylinders use 16 in. × 72 in. reservoirs.

The lengths given above are over all.

These reservoirs are fitted with drain cocks, and should be drained frequently in order to prevent any water, oil, or dirt, brought in by the compressed air, from being carried further into the brake system. If allowed to stand for several days, the reservoir will fill with water, thereby reducing its capacity, and will also allow moisture to pass into the piping system and collect in pockets, where it will be likely to freeze in cold weather.

**230. Track brakes** have been developed for operation in connection with either power or hand brakes, the distinctive feature being the utilization of the power generated by the motors, when properly connected, to energize a powerful electromagnet, thereby drawing a suitable track shoe to the rail with considerable force. The friction between the track shoe and rail is transmitted to the brake shoes on the wheels through a system of brake levers, thereby adding to the braking effort of the brake shoes on the wheels an amount equal to the drag of the track shoes on the rails and the counter torque of the motors acting as generators. It is possible, because of the automatic regulation of the magnetic attraction between the track shoe and rail, to utilize as great or possibly greater brake-shoe pressure than is customary with either hand or air brakes without skidding the wheels, but in practice this is seldom required and considerably less braking pressure is customary. The friction, between the track shoe and rail, necessary to produce the requisite brake-shoe pressure will depend upon the design of the link motion and the speed of the train. However, this is usually greater than the braking effort exerted by the wheel brakes, and where the speed is low, advantage can be taken of a high coefficient of friction which is impossible where the wheels are apt to skid, as in the case of power brakes. It is thus evident that the retardation possible with track brakes is at least twice as great as with power brakes, rendering the former particularly well adapted as emergency brakes for heavy grades, which are characteristic of scenic railways, etc.

It should be noted, however, that since this brake depends upon the electromotive force generated by the motors when running as generators, it cannot be depended upon to hold a train on a grade or bring it to a stop unless a connection is made with the trolley for this purpose. There are various objections to resorting to this means of energising the brake solenoid, except in an emergency, consequently the electric track brake is limited in its applications to roads where it is necessary to provide an additional safeguard at the expense of considerable complications to the ordinary form of brakes.

## TRUCK AND CAR BODIES

**231. Classification of trucks.** The development of the self-propelled car has led to some modifications in standard truck design. The several types of trucks all fall in two general groups—namely, the single-truck (Par. **232**), and the double or bogie truck (Par. **233**).

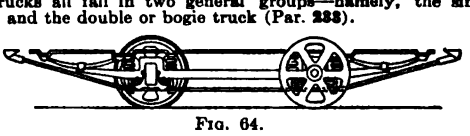

FIG. 64.

**232. The single-truck car** is intended for city-street service, and where the maximum speed does not exceed 25 miles per hr. The two axles of the single-truck are rigidly aligned by side frames, so that of necessity the rigid wheel base must be short in order to negotiate sharp curves, thus limiting the length of car used, because too much overhang is productive of much rocking and unsafe riding, and is objectionable also when rounding sharp curves in city streets. In order to provide easy riding, the car superstructure is sup-

Digitized by Google

ported upon **elliptic and coil springs** designed to take up the shock resulting from riding over uneven track. Single-truck cars are limited to a maximum length of about 30 ft. over all and a maximum weight including car body and trucks, but exclusive of electrical equipment of approximately 15,000 lb.

**233. The double-truck** car is equipped with two distinct trucks joined together through the medium of the car-body framing. The swivel or **bogie truck** consists essentially of two or more axles centred in common side frames which are joined by a cross piece or bolster carrying a centre plate and also side-bearing plates upon which the car body rests.

The bogie truck may comprise two or more axles mounted in a single structure. the prevalent type, however, is composed of two axles for cars weighing up to 50 tons total weight. For very high-speed service or for heavy cars, three-axle trucks are to be recommended.

**234. Classification of bogie trucks.** The standard four-wheel bogie truck is built along different lines depending upon the service which it is to perform. As the weight of the car body is carried upon the cross piece or **bolster** connecting the side frames, it is evident that the construction of this bolster and its support offers a means of cushioning the effect of shocks given the car wheels when riding over uneven track. There are three general types of bogie trucks, namely: the rigid-bolster type (Par. **235**), the floating-bolster type, (Par. **236**); and the swinging-bolster type (Par. **237**).

**235. The rigid-bolster type** (Par. **234**) is suitable for locomotive work only, as the cushioning effect of the car body by means of springs is not carried to sufficient length for easy riding qualities. The bolster is solidly fastened to the side frames and forms an integral part therewith. The spring-suspended car superstructure is sustained by means of box springs

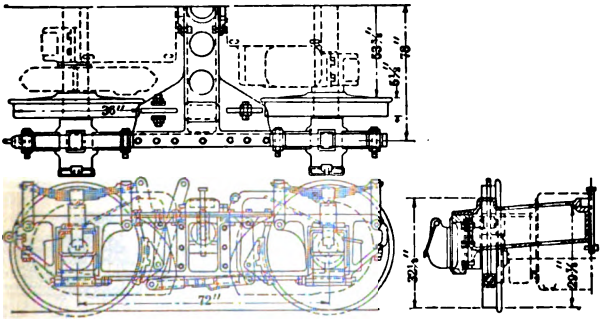

FIG. 65.—Motor, locomotive-frame, rigid bolster.

placed between the side frames and the journal boxes. These springs may be of semi-elliptic (Fig. 65) or spiral type (Fig. 68). This type of construction offers no compensation for the swaying of the superstructure, and is therefore not adapted for high-speed or passenger service.

**236. The floating-bolster construction** (Par. **234**), comprises in part a bolster mounted upon elliptic springs which rest upon the side frames. The bolster thus has an independent vertical movement, and travels in ways in the side frame. This type of construction is best adapted to locomotive trucks designed for slow-speed service, as the superstructure is not sufficiently cushioned to provide easy riding for high-speed passenger service.

**237. The swinging-bolster construction** (Par. **234**) comprises a movable bolster traveling in a guide or transom and mounted upon elliptic springs, a construction very similar to the floating-bolster type. In the former, however, the elliptic springs do not rest directly upon the side frames, but rest in a saddle hung from the transom or side-frame construction in such a manner that opportunity is provided for a transverse swing of the super-

Digitized by Google

structure. This arrangement permits the superstructure to swing or r when rounding curves, and offers a very easy riding truck for high spe passenger service. To increase the cushioning effect still further, the si frames are not directly mounted upon the journal boxes but have coil sprin interposed, either placed directly over the journal boxes (Fig. 68) or betwe the side bar and the truck frames (Fig. 67) or a combination of both.

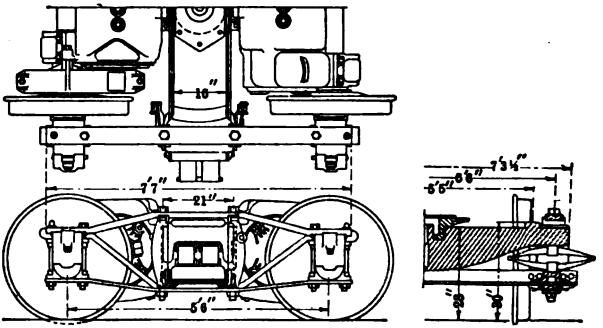

FIG. 66.—Arch-bar type, floating bolster.

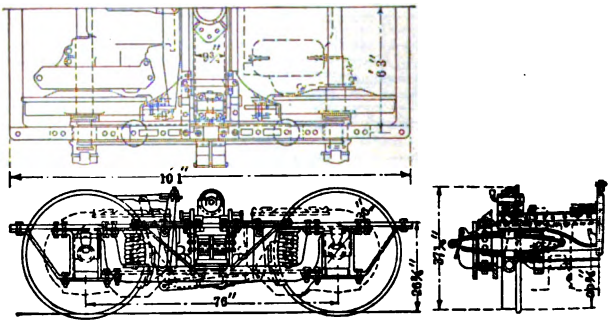

FIG. 67.—Bar frame, swinging bolster.

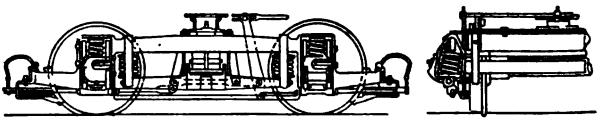

FIG. 68.—Swing bolster truck (Brill Co.).

The swinging-bolster truck is designed for high-speed passenger service, and is satisfactory for maximum speeds up to 70 or 80 miles an hour. For very high speeds it is preferable to provide a bogie truck construction consisting of three axles, the two outside axles carrying less weight than the centre axle, and preferably carrying no motors geared thereto.

Digitized by Google

**238. Construction of bolster and side frames.** The truck bolster may be made of wood or metal, and both the centre plate and side-bearing plates which it carries, may be ball or roller bearings, in order to reduce the friction and permit the truck to respond readily to the demands of track curvature. The side frames may be built up of steel plates riveted together, or forged or cast in a single piece. The construction is rigid and provides for good alignment of the axles.

**239. Maximum traction trucks** are designed for city service at speeds not much exceeding 30 miles per hr., and are useful where it is desired to mount a single motor on a truck providing for four wheels, having a short wheel base, and carrying 70 per cent. of the total car weight upon the driving wheel, which is larger in diameter than the trailing wheel. Maximum traction trucks are not suitable for high-speed service.

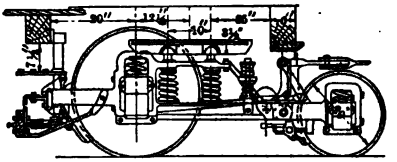

FIG. 69.—Maximum-traction truck (Brill Co.).

**240. Classification of car bodies.** Car bodies differ in construction according to local requirements. They may be divided into two general types, namely: open cars, and closed cars. The dividing line between these two types is not sharply defined owing to the introduction during the past few years of the convertible and semi-convertible type of car body, which permits the complete closing in of the car body sides, or partial removal thereof according to climatic conditions. The true type of open-car body is arranged with cross seats which will seat five passengers per seat and in the larger cars seating 75 passengers per car.

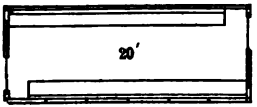

FIG. 70.—Seat capacity 24.

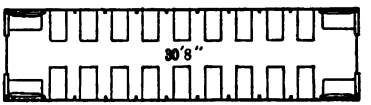

FIG. 71.—Seat capacity 44.

Besides the convertible and semi-convertible type of closed cars, a combination open and closed car is used for warm climates, as it offers the greatest advantages for all-the-year operation.

**241. Arrangement of seats.** The closed-body car may be provided with either longitudinal or cross seats, the former being used in the shorter cars of 30 ft. overall and under, and the latter in the larger city and suburban cars. In general it may be stated that longitudinal-seat cars are suitable only for short runs and medium rates of acceleration, and transverse seats should be used in order to provide comfort for the passenger where the accelerating rates are high or the run extended.

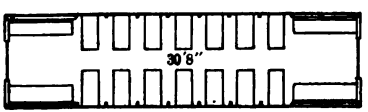

FIG. 72.—Seat capacity 44.

The prevalent type of transverse-seat car is indicated in Fig. 71, and usually contains short longitudinal end seats in addition. Owing to the possibility of crowding at the car entrance, it has been found advisable to provide more standing room at these points. This leads to a composite type of car having longer longitudinal end seats and providing transverse seats in the centre portion of the car only.

In some instances it is necessary to provide narrow city cars, and insufficient space is allowed for transverse seats capable of seating to people on the side. A modification of transverse-seat car is constructed for such cases having the longitudinal aisle and providing a two-passenger seat on one side and a one-passenger seat on the other.

Digitized by Google

**242. Entrances and exits.** In rapid-transit service, where large crowds must be handled with a minimum time allowed for stops, it is desirable to use doors at the sides so arranged that the crowd can circulate rapidly, with as little interference as possible between the boarding and the leaving passengers. In some cases this is accomplished by end doors for entrance and a centre door for exit, while in one type of side-door car there is a door opposite each seat, all doors being operated from one point by compressed air. In the west a type of car with a single side door in the middle is becoming popular. The **pay-as-you-enter-cars** have greatly simplified the fare-collector's problem in large cities and are rapidly displacing the other types. In these cars the entrance and exit are kept distinct, so that the passengers are obliged to circulate.

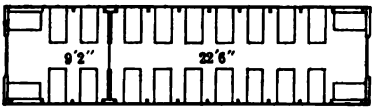

FIG. 73.—Seat capacity 44.

**243. Extra compartments on suburban cars** (Par. **244**). For suburban service it is desirable to provide a **smoking compartment** divisioned off from the main portion of the car and connected to it by a door. Such a car should preferably be run single ended with the smoking compartment in front. However, it is common practice to run such cars double ended, in which case all passengers may be compelled to pass through the smoking compartment in order to reach the main seating portion of the car.

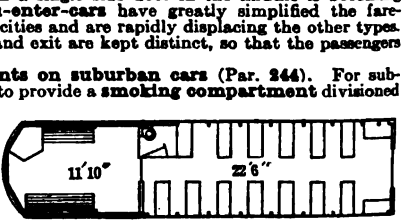

FIG. 74.—Seat capacity 37.

Owing to the necessity of taking care of baggage or express material on suburban lines, many such cars are supplied with a **baggage compartment** which is also used as a smoking compartment, and in addition a **toilet** should be provided where the run is of considerable length.

**244. Arrangement of interurban cars.** Many **cars are heated** (Sec. 22), with hot water instead of electrically, and the more elaborate high-speed interurban cars operating over long distances provide a compartment for express matter, smoking compartment, main passenger compartment, toilet rooms, etc. The motorman's compartment is divisioned off from the baggage compartment and such cars are generally run single-ended, requiring the use of a loop or Y at the terminals, see Fig. 75.

FIG. 75.—Single-ended car.

**245. Double-deck cars.** For certain classes of city service where the track capacity is limited and speeds are moderate, recourse may be had to a double-deck or top-seated car. Unless enclosed these cars are only suitable for climates having small temperature change and must be operated at low speed (25 miles per hr. or less) in order to prevent possibility of overturning. Access is had to the upper seating portion of the car by means of stairways.

## SELF-PROPELLED CARS

**246. Classification.** Self-propelled cars are divided into three general types, as follows: storage battery (Par. **247**); gasoline or oil motor (Par. **248**); gas-electric (Par. **249**).

**247. The storage-battery car** is suited to very special conditions, and has not yet been considered for general railway service owing to the limitations in weight, cost and restricted mileage of the battery. (See Section 20.)

**248. The gas-motor car** has come into limited use on interurban lines and on feeder lines of steam roads. Its greatest disadvantage lies in the mechanical transmission of power between motor and driving wheels.

Digitized by Google

**249. The gas-electric car** (Fig. 76) claims as its advantage the elimination of all mechanical troubles by substituting electric drive through generator and motors. Such cars are in service to a limited extent where operating conditions are favorable. Gas-electric locomotives are possible only when the service demand can be taken care of by the maximum output of the gas motor, not much exceeding 250 h.p. The possibilities of the gas-electric drive are not yet fully worked out or appreciated by operating men, and the use of such equipment is influenced largely by the possibility of using a cheap fuel. Cars are now in interurban service that consume approximately $\frac{1}{10}$ gal. of gasoline per car-mile.

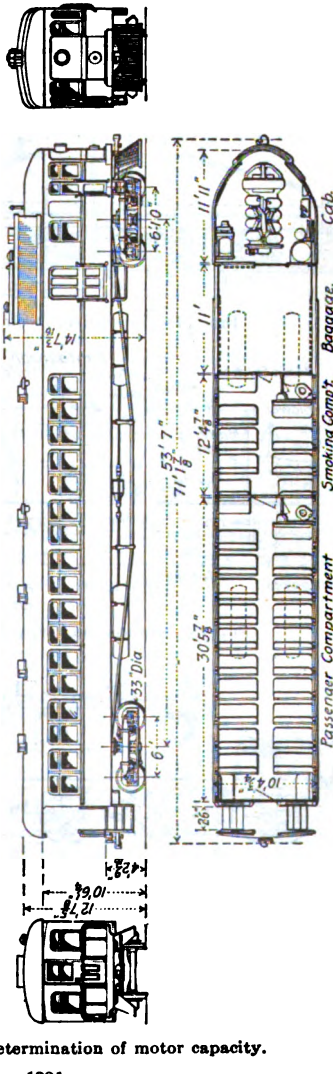

FIG. 76.—General Electric gas-electric car.

## ELECTRIC LOCOMOTIVES

**250. Classification.** Electric locomotives may be divided into four general classes as follows: a, miscellaneous interurban freight service; b, yard-shifting and interchange freight; c, main-line freight; d, main-line passenger.

**251. Locomotives for interurban lines** are all of the same general type of construction and comprise a cab carried on two four-wheel trucks upon which are mounted single-geared motors in the usual manner. The locomotive is of construction similar to interurban cars, except as to superstructure and gearing of motors. The service performed by electric locomotives on suburban and interurban lines can generally be taken care of by a locomotive weighing from 30 to 50 tons, all weight being disposed on the drivers, and equipped with four geared motors of standard types. These motors have an aggregate capacity not greatly exceeding 1,000 h.p. at a 1-hr. rating. The trains hauled may reach 15 or 20 cars, totalling 500 to 800 tons as a maximum, while the average service comprises the movement of freight trains of considerably less number of cars. The duty of interurban locomotives is very variable and is of such an intermittent character as seldom to require accurate predetermination of motor capacity.

Digitized by Google

**252. Switching (yard) locomotives** are of the same general type as those in use on interurban lines, except that the speed is much lower and that the total weight may reach 100 tons when such locomotives are used between large yards for the interchange of freight. The service is intermittent and the average speed is below 4 miles per hr. The average energy input is less than 80 kw. for a 60-ton locomotive. Slow-speed armatures and a maximum

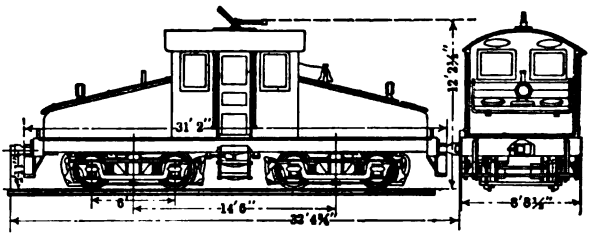

FIG. 77.—Interurban locomotive (elevation).

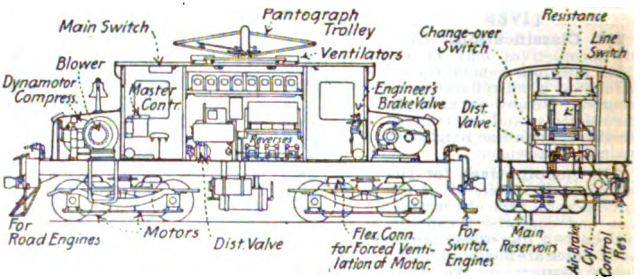

FIG. 78.—Interurban locomotive (cross-section).

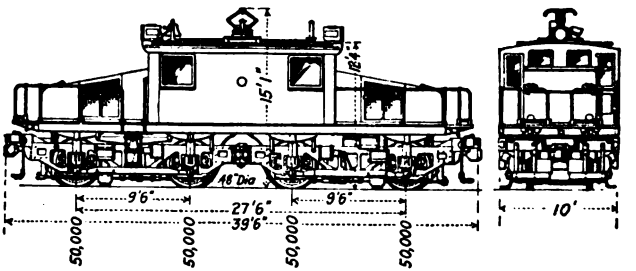

FIG. 79.—Switching locomotive.

gear ratio are best suited for the service. Often two motors are connected permanently in series in order to limit the maximum speed and power demand to reasonable amounts. While yard locomotives will vary from 30 to 100 tons total weight, good examples of the heavier types are given in succeeding paragraphs.

Digitized by Google

**253. Main-line freight locomotives** present a great variation in design and motor equipment. Main-line service demands a locomotive equipment capable of withstanding a large sustained output, and hence calls for different motor characteristics than those which meet the requirements of city and interurban-railway service. Steam-locomotive practice provides for a locomotive rating on ruling grade, based upon a tractive effort corresponding to a coefficient of adhesion of approximately 18 per cent. of the weight upon the drivers. This is exceeded somewhat under favorable rail and climatic conditions, but a lower rating is found necessary during winter months in cold climates. Hence assumption of 18 per cent. coefficient of adhesion may be considered good practice in determining electric locomotive rating on ruling grades.

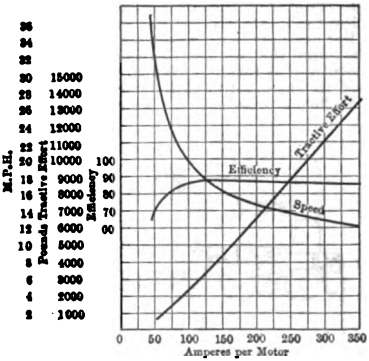

FIG. 80.—Motor characteristics Butte Anaconda & Pacific direct-current locomotive.

**254. Example of calculation of permissible trailing load.** An electric locomotive weighs 100 tons, all weight being disposed on drivers, what trailing load rating can it be given on 1 per cent. grade?

| | Lb. |
|---|---|
| Tractive effort due to grade of 1 per cent. = | 20 |
| Tractive effort due to train resistance = | 6 |
| Total, | 26 |
| Locomotive tractive effort = 200,000 × 18 per cent. = | 36,000 |

36,000/26 = 1,385 tons gross train weight
1,385 − 100 = 1,285 tons trailing

In Fig. 80 are presented the characteristic performance curves of the Butte, Anaconda and Pacific type of locomotive motor. This operates with direct-current supply at 1,200 volts (two in series for 2,400 volts).

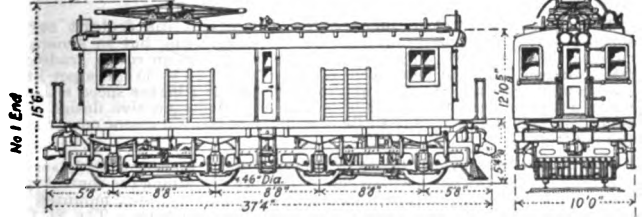

FIG. 81.—Butte Anaconda and Pacific 2,400-volt, direct-current locomotive.

**255. The maximum tractive effort of a main-line freight locomotive** should correspond to a coefficient of adhesion of 30 per cent., as this value is reached under good rail conditions with electric locomotives. The difference between 18 per cent. and 30 per cent. gives the range in tract-

Digitized by Google

ive effort available for starting on ruling grade and is ample with fair rail conditions.

As the ruling grade existing upon the profile of steam railways does not extend unbroken for distances greatly exceeding 15 to 20 miles, it is possible to proportion the continuous rating of a main-line locomotive for somewhat less than a tractive effort corresponding to 18 per cent. coefficient of adhesion. For example, with modern locomotive motors of the fully ventilated type, it is found that the 1-hr. rating is approximately 25 per cent. more than the continuous rating. Hence, where the ruling grade is short, the average duty of the locomotive will be less than would correspond to an 18 per cent. coefficient of adhesion. In consequence it is becoming recognized that main-

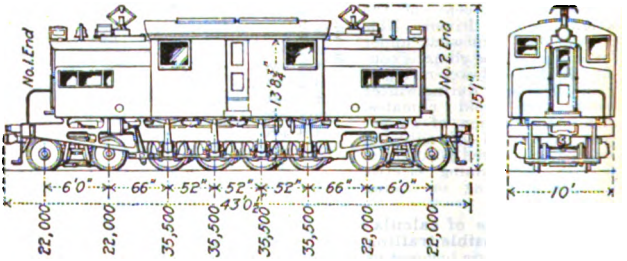

FIG. 82.—New York Central 600-volt direct-current gearless locomotive (type of 1907, 4 motors).

line freight locomotives should be provided with motors capable of supplying continuously and without injurious heating, a tractive effort corresponding to approximately 16 per cent. coefficient of adhesion of the weight upon the drivers, see Par. **256.**

**256. Rating of typical slow-speed main-line freight locomotive**

| | |
|---|---|
| Weight on drivers | 200,000 lb. |
| Rated tractive effort, ruling grade | 36,000 lb. |
| Corresponding coefficient of adhesion | 18% |
| Continuous tractive effort | 32,000 lb. |
| Coefficient of adhesion | 16% |
| One hour output | 40,000 lb. |
| Coefficient of adhesion | 20% |
| Starting tractive effort for 5 min. | 60,000 lb. |
| Coefficient of adhesion | 30% |

**257. Speed of electric locomotives for main-line freight service** will, of course, be proportioned to meet requirements, but in general for mountain grades it will approximate 15 miles per hr. on ruling grade with rated tonnage, and will reach a maximum of from 25 to 35 miles per hr. on level tangent track. Special conditions calling for a higher speed either on ruling grade or level track can be met in electric-locomotive design to an almost unlimited extent, due to the flexibility of electric motor construction and control.

**258. There are several types of heavy freight locomotives** in service:

(a) Those comprising a cab or superstructure containing the control apparatus, air compressor, blowers, operating compartment, etc., mounted permanently on the side frames which carry the drive wheels. The St. Clair Tunnel single-phase locomotive is an example of this type.

(b) Those in which the cab is carried on two bogie trucks which are coupled together by some form of link or hinge coupling. In both this type and the one previously described, the motors are geared to the axle like an ordinary street car motor except that in the case of large motors it is usual to have twin gearing. The Cascade Tunnel three-phase and the Detroit Tunnel direct-current locomotives are examples of this type.

Digitized by Google

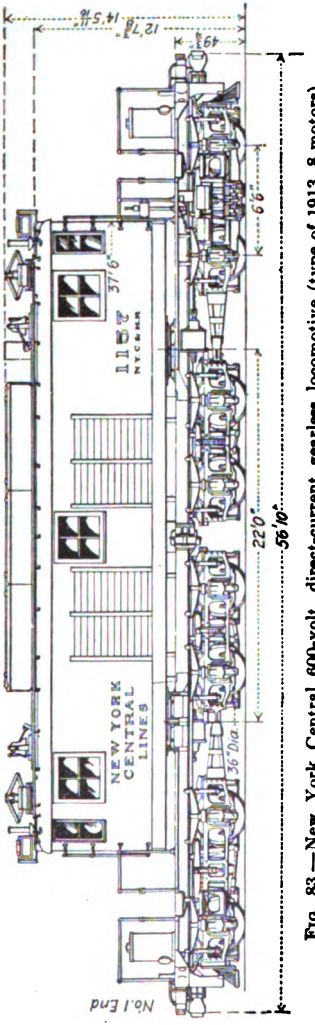

FIG. 83.—New York Central 600-volt, direct-current gearless locomotive (type of 1913, 8 motors).

Digitized by Google

(c) Those in which the cab is carried on two trucks each having two driving axles and one radial or pony axle. The motors are mounted above the axles on the truck frame and geared to quills surrounding the driving axles, the quills being connected to the driving wheels by long helical springs. The cab rests on four spring-supported surface plates on each truck. The trucks are coupled together as in (b) so that no draw bar strain is carried by the cab. The New Haven single-phase freight locomotives given in Par. **261**, are of this type. They are also used for heavy passenger service up to 60 miles per hour.

(d) Those having cabs mounted on trucks as in (c) but having two motors mounted rigidly between the side frames of each truck, geared to a jack shaft through twin gears, and the jack shaft connected to the driving wheels through side rods. The Norfolk & Western split phase locomotives (see Par. **261**) are of this type.

**259. Main-line passenger locomotives** are required to operate safely at speeds of 60 to 75 m.p.h. and the heaviest service requires that trailing loads of 1,000 tons be handled at these high speeds in order to meet the requirements.

**260. Construction of main-line passenger locomotives.** The gearless construction operated upon the New York Central electric zone since 1907 has proved very successful with high operating efficiency and low cost of maintenance, see Fig. 82. The full advantages of gearless construction can only be realized with direct-current bipolar motors. The original installation of forty-seven locomotives on the New York Central have been supplemented by sixteen additional locomotives of the gearless direct-current motor type, but with a different wheel arrangement better adapted to higher-speed main-line operation, see Fig. 83.

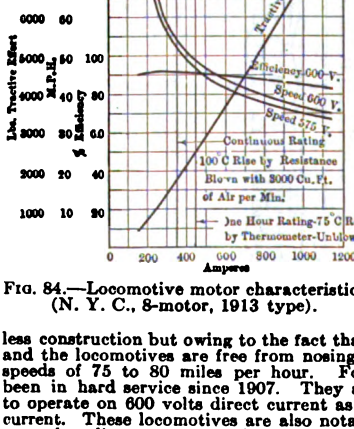

FIG. 84.—Locomotive motor characteristics (N. Y. C., 8-motor, 1913 type).

Gearless-motor construction provides the simplest form of mechanical drive possible to use, and is well adapted to meet the requirements of high-speed passenger service. For the characteristic curves of a typical direct-current gearless-motor locomotive, see Fig. 84.

The New York, New Haven & Hartford single-phase passenger locomotives are of gearless construction but owing to the fact that the motors are spring supported and the locomotives are free from nosing tendency, they operate safely at speeds of 75 to 80 miles per hour. Forty-one of these locomotives have been in hard service since 1907. They are handicapped by being obliged to operate on 600 volts direct current as well as on single phase alternating current. These locomotives are also notable for the fact that they have field control on direct current, and voltage control on single phase.

The electric locomotives on the Pennsylvania Terminal electrification in New York (see P. T. & T. locomotive in Par. **261**) are built for the arduous service of taking the heavy trains of steel cars through the tunnels leading to and from the terminal and across the meadows. They regularly haul trailing loads of 800 tons up the 1¼ and 2 per cent. grades at speeds of 30 to 40 miles per hr. These locomotives have established good records for reliability and low cost of maintenance. They have the motors mounted high in the cab thoroughly protected from dust or dirt, and connected to the driving wheels through jack shafts and side rods. See Fig. 85. Field control is also an important feature as will be seen from the table under Par. **261**.

## POWER DISTRIBUTION FOR RAILWAY ELECTRIFICATION

**263. There are three systems of power distribution** that may be considered for the electrification of main line railways, as follows:

(a) Single phase alternating current;
(b) Three phase alternating current;
(c) Direct current.

**264. Single phase.** One of the prime requisites for main-line electrification is a high voltage for distributing the power from substations to cars and locomotives. This is necessary, first, to minimize the copper in the distributing system; second, to secure maximum efficiency of distribution; third, to simplify the collection of currents for large amounts of power. The use of single phase alternating current permits the use of very high voltages on the trolley—as high in fact as there is any reason for using. In this country the voltages vary from 3,300 and 6,600 which are used on interurban lines and some of the earlier main-line electrifications, to 11,000 which is now accepted as the standard for main lines. In Europe voltages as high as 15,000 are in use, but it is felt in this country that this is higher than necessary. With the exception of one small installation, 25-cycle current is used for all single phase railways in this country. In Europe, however, the preference is given to 15 or 16⅔ cycles. A frequency of 25 cycles has the advantage of being a standard for power distribution in many localities, and in lower cost of power station and substation apparatus. It has the disadvantage of greater size and weight of commutator-type motors, and thus limiting the output from a given space on a locomotive.

On short single-phase lines the energy may be fed directly from the generators to the trolley, but for long lines, it is necessary to use a high voltage for transmission and feed the trolley from step-down transformers. These transformers are usually located in substations but are sometimes of the outdoor type. In either case regular attendants are not required.

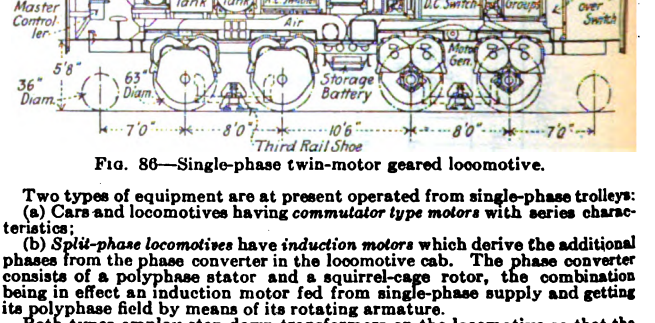

FIG. 86—Single-phase twin-motor geared locomotive.

Two types of equipment are at present operated from single-phase trolleys:

(a) Cars and locomotives having *commutator type motors* with series characteristics;

(b) *Split-phase locomotives* have *induction motors* which derive the additional phases from the phase converter in the locomotive cab. The phase converter consists of a polyphase stator and a squirrel-cage rotor, the combination being in effect an induction motor fed from single-phase supply and getting its polyphase field by means of its rotating armature.

Both types employ step-down transformers on the locomotive so that the motors have low voltages applied to them. The former type is particularly suited for passenger service with both multiple trains and locomotives. It is also well suited for high-speed freight and switching service. In such service the variable speed characteristics are valuable. The split phase locomotive is particularly desirable where heavy grades are encountered which necessitate high tractive efforts and where the automatic regeneration of the motors down grades saves power and decreases the liability of accidents.

The disadvantages attending the use of single-phase current are in the relatively high cost and low efficiency of motive power, the cost of supplying

Digitized by Google

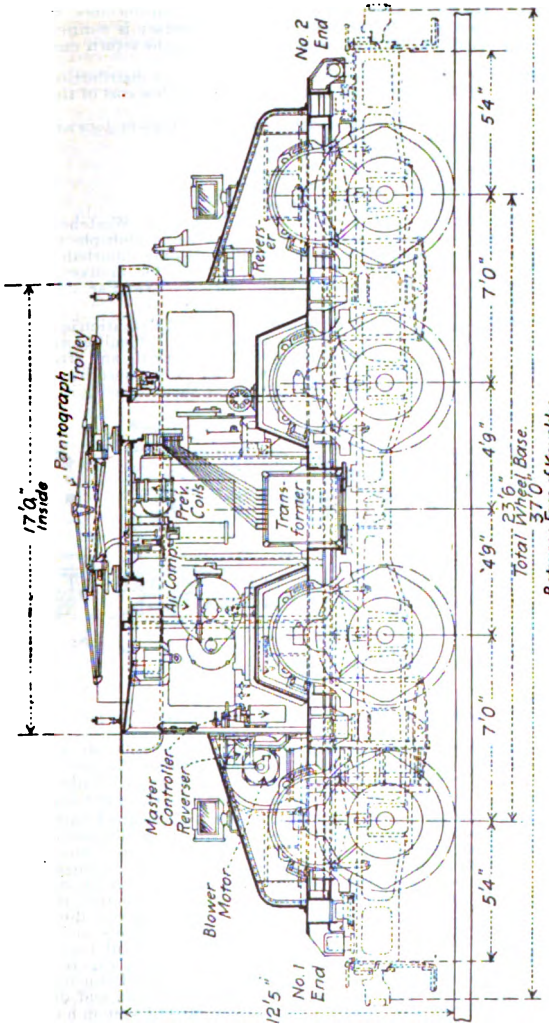

FIG. 87.—Single-phase switching locomotive.

Digitized by Google

single-phase power and the inductive interference of the single-phase trolley with neighboring telephone and telegraph circuits. The latter has been largely overcome by the installation of series track transformers, the primary of which carries the trolley current and the secondary is connected in the track return circuit. This has the effect of keeping the return current in the track.

The great advantages of the single-phase system of distribution lie in the high efficiency of the substations and trolley, and the low cost of the distributing system.

Large single-phase locomotives with commutator type motors are in service on the following main line electrifications:

New York, New Haven & Hartford Railway.
Grand Trunk Rwy., St. Clair Tunnel.
Boston and Maine Railway—Hoosac Tunnel.
Spokane and Inland Empire Railway.

This system has also been adopted for the New York, Westchester & Boston Rwy., and the Pennsylvania Railway, both using multiple unit trains, the former for New York and the latter for Philadelphia suburban service.

The Norfolk and Western Rwy. is using split phase locomotives with three-phase motors for heavy mountain grade service. See Par. **261**. Liquid rheostats are used in starting these locomotives.

**265. Three phase.** The three-phase system of distribution is not used to any extent in this country chiefly on account of the difficulties arising from the double overhead trolley which complicates the yards and cross-overs so much. It is used extensively in Italy, and the three-phase locomotives in use there are the lightest electric locomotives of their capacity in the world.

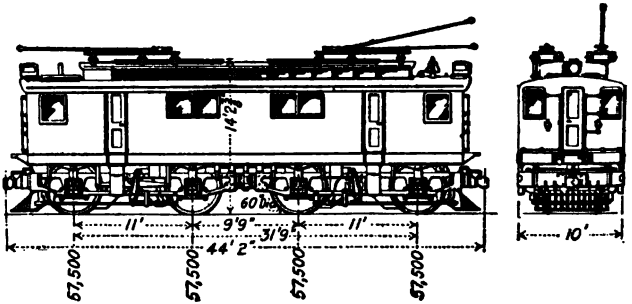

FIG. 88.—Great Northern Cascade Tunnel three-phase locomotive.

Three-phase locomotives are usually used with about 3,300 volts on the trolleys and this voltage is applied to the motors without the use of lowering transformers. The Cascade Tunnel of the Great Northern Railway has the only three-phase locomotives in operation in this country. See Fig. 88.

**266. Direct-current electrification** consists of a direct-current motor equipment fed from an overhead trolley or third rail which receives power from substations containing rotary converters or motor-generator sets. It is the system in almost universal use in city and interurban electric railways, but varies as to the voltage of the direct-current supply. As a result of perfecting the commutating or interpole motor, it has been possible to wind motors for higher voltages, and 1,200-volt direct-current motors are now in commercial operation. These motors are connected two in series and are fed from a 2,400-volt trolley. Still higher voltage equipments are entirely possible, as indicated by factory experimental apparatus built and tested, and every requirement of the heaviest main-line service can be provided for at moderate cost of locomotives and distribution systems. The chief disadvantage of the direct-current system has been the relatively high cost of feeder copper and substations and their low efficiency but this has been largely overcome by the adoption of higher voltages. The

Digitized by Google

advantages of this system include simplicity, low cost and high efficiency of the locomotives, the option of trolley or third-rail distribution, the choice of locomotive or multiple-unit trains, the benefits of bi-polar gearless-motor construction, and the use of balanced three-phase power supply of any frequency and entailing no serious telephone or telegraph interference.

Large direct-current locomotives are in service upon the following main-line electrifications.

| | |
|---|---|
| P. R. R. New York Terminal | 600 volts |
| B. & O. Tunnel Railway | 600 volts |
| New York Central Railway | 600 volts |
| Detroit Tunnel Railway | 600 volts |
| Butte, Anaconda & Pacific Railway | 2,400 volts |
| Canadian Northern Railway | 2,400 volts |
| Chicago, Milwaukee & St. Paul Railway | 3,000 volts |

## DISTRIBUTING SYSTEMS

**267. Train diagrams** represent in graphic form the movement of all trains over a given division during the 24 hr. of operation. Such diagrams are usually plotted with distance as ordinates and elapsed time as abscissas, and they are of the greatest value in determining the average and maximum sustained demands upon the distributing and generating systems.

The average train input for a given service is determined according to methods outlined in Par. **78** to **118**, so that a train diagram is useful for indicating the local demand upon any part of the distributing system during any period of 24 hr. The train diagram also furnishes means of obtaining the total average load upon the entire division covered by the diagram, by plotting in curve form the total average kilowatts demanded by the several train movements intersecting equally spaced ordinates. Thus, referring to Fig. 89, representing a typical train diagram wherein is depicted the per-

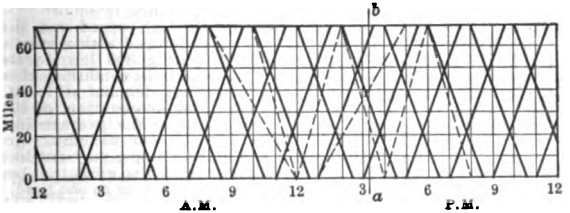

FIG. 89.—Typical train sheet (suburban service).

formance of both local and express trains, the ordinate, $a-b$, intersects the graphs of five trains. Assume that the various trains demand the following average input:

| | |
|---|---|
| Local passenger | 100 kw. |
| Express passenger | 130 kw. |
| Freight | 210 kw. |

The line, $a-b$, intersecting the various train movements, therefore, calls for a station output at 3:15 P.M. as follows:

| | |
|---|---|
| Three local passenger trains | 300 kw. |
| One express passenger train | 130 kw. |
| One freight train | 210 kw. |
| | 640 kw. |

**268. Calculated load curve.** By erecting other ordinates upon the 24-hr. performance sheet it becomes possible to plot a detailed generating-station load curve for the 24 hr. with the train movements as predetermined. This train load curve does not show momentary fluctuations, and these must also be considered in determining the character of the distribution system,

Digitized by Google

especially in suburban and other systems where the train units are large and operate at infrequent intervals.

**269. Classification of service.** As affecting the distributing system, railway service may be divided into two broad classes as follows: a, frequent or congested service; b, infrequent operation. Under class a is grouped all city systems, underground or elevated roads and certain suburban roads where the headway between train units is small. Under class b is grouped all interurban and most suburban roads, in fact, all classes of service where the interval between trains is fairly large, as 10 min. or more, and where the train unit operates at a high maximum speed and thus demands considerable input. The treatment of classes a and b service as affecting the distribution system must be somewhat different as in class 1 momentary fluctuations due to starting of cars have little effect upon the size of conductor determined upon for feeders, or location and capacity of substations if these are used. In class b the momentary input demanded during acceleration is often the determining factor in selecting the amount of feeder conductor and substation capacity required.

**270. Classification of distribution systems.** Distribution systems may be divided in general into two classes, which are secondary systems (Par. **271**), and primary systems (Par. **283**).

**271. Secondary systems** consist of the trolley wire, third rail or other conducting medium, extending from the generating station or substation and the feeders connected thereto; also the track return with its feeders and boosters, if used. The conductivity and physical characteristics of the secondary distributing system are determined partly by the momentary demand of each train unit and partly by the average input required by an aggregation of such units, where the interval between trains is short. For instance, in suburban service a high speed car may be equipped with motors aggregating 300 h.p. to the car, and the conditions of service may demand an input, during acceleration, of 400 kw., while the average input to the car including acceleration, coasting, braking and standing still during stops, may not be much greater than 100 kw. per car. As the train interval is so great that possibly not more than two cars receive power from a substation at one time, it becomes necessary to determine carefully the amount of over-load during starting as influencing the conductivity of the distributing circuit and the substation capacity. On the other hand in city service, a substation or generating station may feed fifty or more cars, and individual feeders may carry the load of perhaps fifteen cars, thus, making the momentary demand of any one car a matter of small importance. In such cases the determination of conductivity and substation capacity would rest upon the sum of the average load of all the cars.

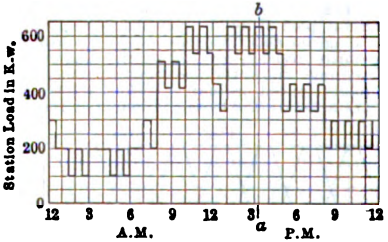

FIG. 90.—Typical load diagram.

**272. The permissible drop in voltage** of the conducting system between car and bus bar with a specified load, determines its conductivity. This permissible drop varies under different conditions of operation and types of apparatus used. Following are approximate percentages of allowable voltage drop:

| | | |
|---|---|---|
| City systems | 8 per cent. average | 12 per cent. maximum |
| Suburban direct-current systems | 10 per cent. average | 20 per cent. maximum |
| Interurban direct-current systems | 12 per cent. average | 25 per cent. maximum |
| Interurban alternating-current systems | 5 per cent. average | 10 per cent. maximum |
| Three-phase induction-motor systems | 5 per cent. average | 10 per cent. maximum |

Digitized by Google

**273. The conductance of the circuit** between motors and bus bars, is seldom determined by its proper relation with interest on first cost of the conducting system and the cost of energy lost, as the first cost of the distribution conductors so determined is considerably in excess of current practice in this respect. In city systems the average and momentary maximum drop are practically the same owing to the small effect of the starting current of any one of the large number of cars controlled by one feeder. In interurban systems, where generally but two cars are controlled by one feeder, the maximum fluctuation is much in excess of the average drop.

**274. Relation of trolley wire and feeders.** Feeders are differently grouped according to the demands of the service and the physical arrangement of the trolley sections. The simplest conducting system to the car upon the track consists in that shown in Fig. 91, wherein the trolley is connected through circuit-breakers directly to the positive bus bar with no auxiliary

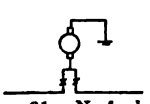

FIG. 91.—No feeders.

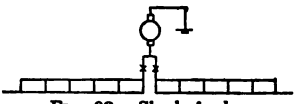

FIG. 92.—Single feeder.

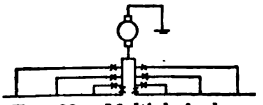

FIG. 93.—Multiple feeders.

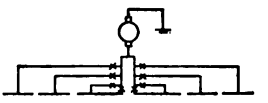

FIG. 94.—Sectionalised trolley wire.

feeders, and the negative bus is connected to the track return. The trolley is generally sectioned at the station and each section controlled by an independent feeder panel.

Where the trolley conductor itself has not a sufficiently high conductivity, it is reinforced with auxiliary feeders connected to it at frequent intervals. See Fig. 92. The result of such feeder reinforcement is simply to increase the conductivity of the trolley circuit, and corresponds to an enlargement of the cross-section of the trolley conductor itself. This grouping is best fitted for feeding a small number of units, and is more useful in the operation of suburban or interurban systems than in city work.

**275. The most economical copper distribution for feeding a large number of train units** would consist in a separate feeder to each train so proportioned that the drop in all feeders would be equal to the maximum drop permissible. As this would be impossible without too great a multiplicity of feeders, the arrangement in Fig. 93 is adopted. A better arrangement of the same feeder connection is shown in Fig. 94 which is identical to that in Fig. 93, except that the trolley itself is sectioned so that each feeder independently controls a single section of trolley and the cars drawing energy from that section (Par. **276** and **277**).

**276. Length of trolley wire sections.** Trolley sections may be from a few hundred yards to 2 miles or more in length in city service, depending upon the lay-out of the streets and the importance of sectionalising different streets or sections of the same street in such manner as to occasion the least possible interruption to general traffic in case of failure of any one trolley section or its feeder.

**277. Segregated trolley-wire sections.** The trolley wire may be solid throughout as shown in Fig. 93, or preferably sectionalized as shown in Fig. 86, in which case the different sections are entirely independent and each feeder and each trolley section is calculated to give the limiting $IR$ drop when feeding the maximum group of cars drawing energy from that section of the trolley. The direct-current feeder distribution shown in Fig. 94, applies more especially to city systems and may be elaborated to any extent required by the complexity of a large-city trolley system. Sectionalising the trolley is desirable from the standpoint of localising the effect of trolley breaks or

Digitized by Google

grounds, and is necessary in large-city systems supplying a considerable number of car units traveling over different routes. Thus, with the sectionalised system, the failure of the trolley on one section will not affect the operation of cars on a different route. The ends of trolley sections should be joined at adjacent ends by a switch or circuit-breaker which normally remains open. This switch may be closed if such procedure be desirable, as in the case of possible failure of an individual trolley feeder. These trolley-pole switches may be operated manually, or they may be controlled electrically from the supply station if they are located at very important points not convenient of access.

**278. Feeder copper calculations** depends upon the character of the service, trolley potential and permissible drop. In and about cities, 600-volt equipment is universally used, while for suburban and interurban service both 600-volt and 1,200-volt systems are in operation. Still higher direct-current potentials are being proposed, but the 1,200–600-volt combination works out so conveniently in practice that the use of higher voltages will probably be restricted to special locomotive installations.

The use of 1,200 volts direct-current or higher makes it possible to install direct-current generators of this potential and feed direct to the trolley, provided the generating station can be centrally located on a road not over 35 to 40 miles long. One such installation is in operation, and a high efficiency results from the elimination of step-up and step-down transformers, transmission line and synchronous converters.

**279. Permanent and booster feeders.** City service demands a feeder distribution capable of taking care of rush daily loads without prohibitive drop. In addition a properly proportioned system should easily carry infrequent heavy loads on certain sections such as those due to amusement parks, race courses, etc. The daily rush load justifies the expense of feeder conductor permanently installed, but infrequent loads are best taken care of by feeders arranged for use with series or shunt boosters in the power house. In other words, the infrequent load occurs so seldom that it does not justify the expense of a large amount of feeder conductor, which may be inoperative during the greater portion of the year. With the pyramidal feeder system, Figs. 93 and 94, it is entirely possible to use the outside feeder as a booster feeder in case the infrequent heavy load should occasion a prohibitive drop.

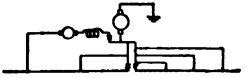

FIG. 95.—Use of booster.

**280. Factors determining sectional layout.** A city feeder system should be so designed that the voltage of no part of the trolley to ground will be more than 100 volts lower than that at the switchboard when momentary fluctuations due to starting cars are eliminated. This 100-volt average drop should apply to the rush load occurring in daily operation. The laying out of a city direct-current network consists in establishing the limits of the territory controlled by each substation (or generating station if separate stations be used); sectionalizing the district according to routes and streets, determining the average load upon each section as obtained from the average input demanded by the several cars on this section; and determining the cross-section of the conductor required for feeder sufficient to limit the *IR* drop including track return, to 100 volts. In crowded city districts the trolley will be cut up into such short sections that the additional *IR* drop occurring therein will not materially add to the combined return track and feeder drop of 100 volts. For the outlying districts less feeder drop must be required, in order to allow for the larger drop occurring in the longer trolley sections. Trolley sections will vary in length, depending upon the density of service, street intersections, etc., ranging from one quarter of a mile up to 2 miles or more in the suburbs.

**281. Components of a city distribution system.**

a. **Trolley**, consisting of a grooved copper conductor upheld by so-called cross-suspension approximately 20 ft. to 22 ft. over the centre of the track. This trolley conductor is sectionalised according to local requirements into lengths of from one quarter of a mile to 2 miles or more.

b. **Feeder system**, consisting of copper conductors extending from the several trolley sections to the supply station. The feeder may be underground in conduits in the congested sections and carried overhead on poles in the suburbs, or in small towns.

Digitized by Google

c. **Booster** in the supply station, which can be connected in series with any feeder extending to a temporarily overloaded section for the purpose of supplying the added voltage required to compensate for the excessive feeder and trolley drop.

d. **Track return**, consisting of the track rails, bonded at the joints.

e. **Track return feeders**, consisting of copper conductors reinforcing the track at points of greatest drop or at points where the track is negative to the neighboring pipes.

f. **Pressure wires** extending to important points on both trolley, track and pipes, and serving to indicate at all times the potential of the several parts of the distribution system.

Such large city systems are a matter of growth and not of calculation, as the practice giving good results in one city may not be directly applicable to the different conditions obtaining in another city.

**282. Feeders for underground trolley or conduit systems.** Such systems are described in Par. **334**. The trolley conductors are two in number and are located underground between the two rails. These conductors are of opposite polarity, and there is no track return circuit. The arrangement, therefore, necessitates double the number of feeders required with the sectionalized overhead trolley used with track return. As both positive and negative rails are insulated from ground, the conduit systems practically eliminate any stray currents and electrolysis. Conduit systems are installed to avoid the unsightliness of the overhead trolley, and can only be considered in the largest cities owing to the enormous expense of their installation.

**283. Primary distribution** comprises the location of substations and the high-tension overhead transmission lines or underground cables connecting the substations to the generating-station bus bars. Primary transmission systems invariably employ alternating-current, and where synchronous converters or motor-generator sets are used, this primary current is of the three-phase type transmitted over three wires or in multiples of three if duplicate circuits are provided. Owing to the novelty of single-phase railway-motor distribution systems and the close interconnection of secondary and primary distribution systems when applied to alternating-current motor operation, this subject will be considered later (Par. **285**).

**284. Methods of serving direct-current substations.** Substations for direct-current systems are located at strategic points along the line of travel best suited for secondary distribution. These substations may be fed from a common trunk line to which all substations are connected; this is common practice in suburban and interurban railways operated by direct-current motors. In such cases the trunk line preferably consists of two independent circuits, each of which may be used alone, providing, thereby, for continuity of service in case of the accidental grounding of one set of lines. It is also common practice to interrupt the transmission line at each substation, providing both incoming and outgoing line panels at each substation in order that the transmission-line troubles may be localized between two adjacent subs rather than that a whole trunk line be put out of commission due to the fault of any portion thereof.

In city systems or in interurban systems where the traffic is very heavy and where freedom from interruption of service that is of greatest importance, it is good practice to connect each substation to the generating-station bus bars through its own individual transmission line or underground cable. In fact, if the substation is very large, this divisibility of the transmission circuit is sometimes carried to the extreme of providing each substation with several cables connected either to individual synchronous converters or to different bus-bar sections. If this bus-bar segregation is resorted to each section is allowed to control two or more synchronous converters. It is evident that this multiplicity of high-tension transmission lines or cables can be made use of only in very large and important cities, or in interurban systems taking care of a very congested traffic.

**285. Single-phase generation and transmission.** Alternating-current single-phase railway-motor systems are best energized by single-phase generation and transmission, owing to the simplicity of single-phase connections throughout the system. The method of connecting the various alternating-current substations to the generating station consists usually in tying all substations to a single trunk line through circuit-breakers designed to open on short-circuit only. Individual transmission lines to

Digitized by Google

each substation may be preferable under certain conditions, but multiplicity of transmission circuits is generally to be discouraged owing to the considerable increase in cost over a single or duplicate trunk line.

**286. Single-phase generation with three-phase alternators.** Owing to the enormous aggregate kilowatt capacity of three-phase 25-cycle generators already in operation for electric railway work, and due to the fact that single-phase railway installations are often an extension of existing direct-current systems, it becomes necessary to consider the different systems of primary distribution for alternating-current roads operating from three-phase generators. The simplest means is to use one leg of the three-phase system for the alternating-current railway distribution, that is, to treat the generator as a single-phase machine and carry out the transmission scheme and substation connections in all respects as though the other two legs of the three-phase generator did not exist. In this case the connections will be as described in Par. 285 for single-phase generators. The objection to this method of connections is the reduction of generator capacity resulting when a three-phase alternator is operated single-phase. For the same heating, the single-phase output of a three-phase generator will approximate two-thirds of its three-phase output on balanced load. Although single-phase distribution is simplest, the resulting reduction in generator capacity may be so serious in certain installations as to necessitate the consideration of three-phase distribution to the transformer substations (Par. 287).

**287. Three-phase transmission "legged" to sectionalized trolley.** Where the road is of extended length, the secondary distribution or trolley

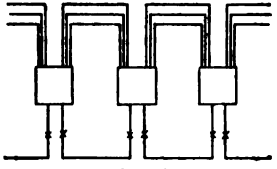

FIG. 96.—Substation systems.

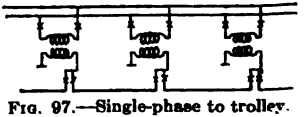

FIG. 97.—Single-phase to trolley.

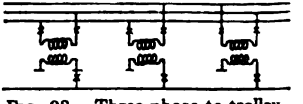

FIG. 98.—Three-phase to trolley.

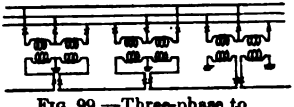

FIG. 99.—Three-phase to single-phase.

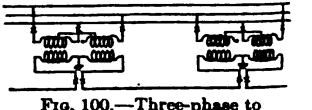

FIG. 100.—Three-phase to two-phase.

circuit may be divided into sections, and each section fed from a separate phase of the three-phase primary-distribution system. This system of connections secures all the benefits of three-phase generation and transmission, provided the load is equally balanced upon the several trolley sections, but requires double the conductivity in the secondary distribution system owing to the impossibility of tying substations solidly together so that trains midway between substations will draw equally on both.

A modification of the three-phase, single-phase, substation connections is shown in Fig. 99, wherein each substation contains two transformers connected in open delta, so that corresponding phases feed each end of a trolley section and each succeeding trolley section will correspond to the different phases of the three-phase primary distribution. This method of connection is often open to the objection that the road may not be of sufficient length to permit of its division into a sufficient number of equally loaded sections to correspond to the three transmission phases or multiple thereof.

Digitized by Google

**288. Three-phase, two-phase transformer connection** (Sec. 6) can be used where the road is of limited extent. This method consists in employing the three-phase two-phase connection of substation transformer, feeding the two-phases to adjacent trolley sections, so that corresponding phases will be fed to a given trolley section from the transformer substation at its terminals. This system of connections will not provide perfect balance upon the three-phase side of the transformers unless the loads are balanced upon the several trolley sections. Sufficient balancing, however, may be obtained in the majority of cases, and this system of connection is in quite extended use.

**289. Two-phase generation and single-phase distribution.** Two-phase generators may be used to supply single-phase railway distribution systems by sending out transmission lines from the two phases in different directions, thus amounting in principle to two separate single-phase transmission systems. This method of connection is open to the objection that unless the loads are perfectly balanced upon the two phases, the voltage regulation will be very poor, and in cases of generators having poor inherent regulation, it may reach such proportions as to endanger the lamps and the general operation of the equipments.

**290. General considerations in design of a new single-phase motor system.** In general a new railway system, favorable for the operation of single-phase motors, operates to best advantage with the single-phase system of generation and transmission, provided the contemplated road has no future connections with neighboring systems and is free from entanglements, such as power distribution, operation of synchronous converters, etc., requiring multiphase generation and distribution. Where it is advisable to provide for the future utilization of three-phase power, three-phase generators may be installed, operating either on one leg as single-phase generators, or using all three legs in connection with three-phase two-phase transformer connections in the substations in order to provide for reasonably good balancing of the three-phase primary distribution.

**291. Three-phase, induction-motor systems** may employ the same method of substation connections and primary distribution as outlined under the head of synchronous converter substations for direct-current motor systems. Owing to the fact, however, that transformer substations of all kinds may be operated without attendance, such substations are best connected to a main trunk line through circuit breakers operated by relays designed to open only on short-circuit. Where the control of the substation is extremely important, attendance should be supplied, or each individual substation should be connected to the generating station by separate transmission lines having automatic control at the generating end only. In all cases the trolley or secondary connection to the transformer substation should be safeguarded by automatic switches designed to open on short-circuit.

**292. Resistance of trolley wire circuits** is dependent upon the weight of trolley copper and track rail, and also upon the composition and bonding of the latter. Trolley conductors are either .000, or 0000 A.W.G., the smallest size being seldom used owing to its lack of strength and the difficulty of clamping its small diameter.

**293. Trolley wire and track resistance per mile**

| Track rail | Ohms resistance 2 rails | 000 Trolley and 2 rails | 0000 Trolley and 2 rails |
|---|---|---|---|
| 50 lb. per yd..... | 0.053 | 0.383 | 0.313 |
| 60 lb. per yd..... | 0.044 | 0.374 | 0.304 |
| 70 lb. per yd..... | 0.038 | 0.368 | 0.298 |
| 80 lb. per yd..... | 0.033 | 0.363 | 0.293 |
| 90 lb. per yd..... | 0.030 | 0.360 | 0.290 |
| 100 lb. per yd..... | 0.027 | 0.357 | 0.287 |
| 110 lb. per yd..... | 0.024 | 0.335 | 0.284 |

000 Trolley = 0.33 ohms. 0000 Trolley = 0.26 ohms.

Digitized by Google

**294. Specific resistance of track rail.** Track rails contain as high as 0.40 to 0.50 per cent. carbon and 0.70 per cent. manganese; these two elements largely affect the specific resistance, hence standard track rail may be taken at approximately 20 microhms per centimeter cube* when bonded with bonds having half the conductivity of the rail.

**295. Impedance.** The use of alternating current in the trolley and rail-circuit necessitates some modification in the above values, as the effective resistance is increased by reason of the inductive reactance of both trolley and rail, and also due to eddy currents set up in the rail itself.

**296. Rail impedance.** The impedance of a rail depends in a considerable degree upon its chemical composition, a reduction in permeability also reducing the internal losses. In general the action is a skin effect, and the impedance and resistance are inversely proportional to the perimeter of the rail and are proportional to the square root of the frequency. This proportion assumes an unbroken rail, and the introduction of short lengths of rail bonded together calls for modifications. Thus at 25 cycles the impedance of track rail of standard outline and composition is approximately eight times the ohmic resistance offered to the passage of direct current; at 15 cycles a ratio of 6.2 obtains, etc. The power-factor at either frequency is approximately 80 per cent. Considering a track circuit with bonding, experimental results show an impedance at 25 cycles of 6.6 times the ohmic resistance.

Under the following conditions the measured impedance of rail of various weights is given below: height of trolley above track, approximately 20 ft.; gage of track standard, 4 ft. 8.5 in.; power-factor of circuit, 80 per cent.; average power-factor of load 80 per cent.; ratio of impedance to ohmic resistance, 6.6 to 1.0; frequency, 25 cycles per sec.

| Weight of rail, lb. per yd. | 60 | 70 | 80 | 90 | 100 | 110 |
|---|---|---|---|---|---|---|
| Impedance ohms per mile 2 rails. | 0.291 | 0.251 | 0.218 | 0.198 | 0.179 | 0.115 |

**297. Trolley-wire impedance.** In addition to the increased impedance of the rail itself, the impedance of the overhead trolley conductor is also increased by reason of its reactance when carrying alternating current. Tests made upon 000 and 0000 conductors indicate an increase in impedance 1.5 the ohmic resistance. The conditions under which the following values were obtained were, with the exception of the impedance ratio, the same as those given in Par. **296**. Impedance per mile of 000 trolley = 0.495 ohms. Ratio of impedance to ohmic resistance, 1.5. Impedance per mile of 0000 trolley = 0.390 ohms. Ratio of impedance to ohmic resistance, 1.5.

**298. The height of trolley-wire above rail** can be varied somewhat from the 20 ft. assumed without introducing an appreciable error. The power-factor of 80 per cent. assumed for the load is somewhat lower than would be experienced in a well-proportioned alternating-current railway installation, but the small error of 4 or 5 per cent. introduced by assuming full impedance drop of the trolley and rail circuit is justifiable in making preliminary estimates where the character of load cannot be very closely determined.

**299. Classification of trolley construction.**

(a) Span construction (Par. **300**).
(b) Bracket construction (Par. **302**).

The costs of typical trolley construction are given in Par. **357** to **361**.

**300. Span construction** comprises poles on either side of the track connected by cable from which is suspended the trolley conductor. The trolley may be hung directly from the span wire through an intermediary insulated hanger or may be suspended from a galvanized steel catenary (Par. **303**) which in turn is supported by the span wire. Span construction may be used to provide a support for the trolley wires over any number of tracks. With more than two tracks it is preferable that the side poles shall be self-sup-

*A cube whose side = 1 cm.

Digitized by Google

porting steel towers joined by very heavy catenary construction, the whole combination being thoroughly anchored to withstand stresses, or else the

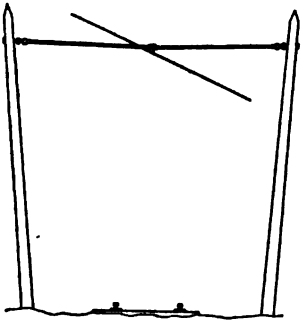

FIG. 101.—Cross suspension.

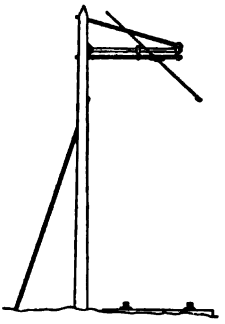

FIG. 102.—Bracket suspension.

side towers should be joined by a light steel truss, forming a bridge construction, this latter being used in steam-railroad electrification where the number of tracks exceeds two.

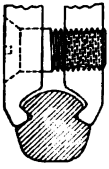

FIG. 103.—Trolley clamp.

**301. Trolley wires** generally have a cross-section equal to 3,000 or 4,000 cm. A.W.G., and are drawn in three sections; round, figure 8, and grooved. The use of round wire is objectionable owing to the difficulty of securely clipping it to the hangers without forming a projection on the wire itself which will tend to throw off the current collector in high-speed operation.

The use of figure 8 wire is open to the objection that owing to its unsymmetrical cross-section it is very difficult to handle during installation, although it affords a ready means of fastening and leaves a clean unbroken under-surface suitable for high-speed operation.

The grooved trolley wire (Fig. 103) is in greatest use and consists of a round wire grooved on opposite sides sufficiently deep to permit gripping by adjustable clamps or hangers. Owing to its round

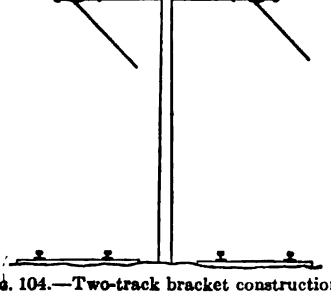

FIG. 104.—Two-track bracket construction.

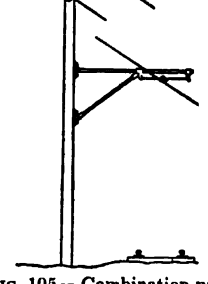

FIG. 105.—Combination pole.

Digitized by Google

cross-section, it is readily unreeled and installed, and presents all the advantages of a smooth under surface.

**302. Bracket construction** comprises a self-supporting pole having a projecting arm or bracket extending over the track and supporting the trolley wire either directly or by means of a steel catenary cable. The pole is generally of wood, and the best construction provides for anchoring each pole to guard against lateral strains due to wind and the unbalanced weight of the overhung trolley.

The trolley is usually not attached directly to the projecting arm or bracket, but to a flexible cable attached thereto, whose office is to provide for the needed amount of flexibility. Span construction is more flexible than bracket construction, but by use of the flexible bracket cable, the latter can be made sufficiently cushioned to permit the operation of trolley wheels up to 60 miles per hr.

**303. Catenary construction** (Par. **300**) has been brought into prominence with the development of the alternating-current motor, but its application is not confined to alternating-current motor installation as its excellent mechanical qualities are of equal benefit in the case of high-speed direct-current motor installations. Catenary construction comprises either a span or bracket-supporting structure over which is hung a stranded galvanized steel cable loosely suspended with 20 in. or more drop between supports, thus giving rise to the term catenary. From this catenary or messenger cable is suspended the grooved trolley wire by means of hangers of different lengths. The number of these hangers varies from a minimum of three between supports to a maximum of a hanger every 10 ft., the object being to secure a practically flat trolley wire of equal height at all points above the track.

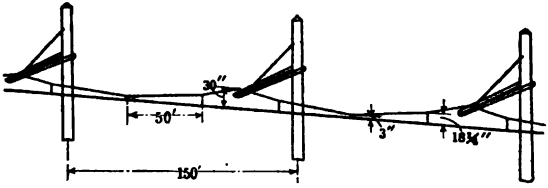

FIG. 106.—Three-point catenary suspension, tangent.

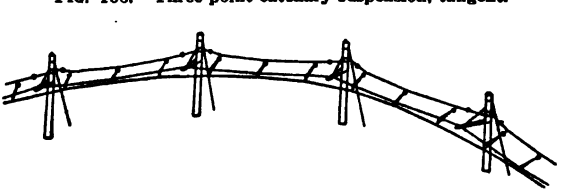

FIG. 107.—Three-point catenary suspension, curve.

**304. Advantages of catenary construction.** The flexible suspension of a catenary-hung trolley and the flat surface which it presents to the trolley collector makes it admirably suited for the operation of high-speed equipments whether these be of the alternating-current, or direct-current type. This form of construction is furthermore especially adapted to withstand the high-voltage stress of the trolley voltages employed in alternating-current, secondary distribution systems, owing to the fact that the catenary is generally suspended from porcelain insulators of the high-potential transmission type, forming both a strong mechanical structure and having high-pressure resisting qualities.

With catenary construction it is possible to adopt a greater spacing

Digitized by Google

between supports than is customary with the self-supporting trolley wire construction.

**305. Distance between trolley-wire supports on tangents**

| | |
|---|---|
| Self-supporting trolley | 110 ft. |
| Catenary wooden-pole bracket construction | 150 ft. |
| Catenary steel-pole bracket construction | 200 ft. |
| Catenary steel-bridge construction | 300 ft. |

The only limit placed upon the distance between supports in catenary construction on tangent track is the likelihood that long spans will have considerable lateral sway. This is corrected in part by suspending the trolley from a double catenary construction, thus forming a triangular truss of considerable rigidity. Catenary construction is only adapted to tangent track and curves of long radius, as it requires additional pull-off poles attended with considerable expense in order to be adapted to sharp curves.

**306. Pole guying.** With wooden-pole bracket construction it is customary to anchor the poles on curves, often on tangents.

**307. Duplication of primary circuits.** Primary transmission circuits may be carried upon the same poles that serve as a support for the trolley. The transmission line so supported may be supplemented by a separate transmission line hung on independent poles, in order to provide greater assurance for continuity of service.

**308. Standard trolley potentials in use** are as follows: 600 volts direct-current, 1,200 volts direct-current, 3,300 volts alternating-current, 6,600 volts alternating-current, 11,000 volts alternating-current.

An alternating-current trolley potential of 3,300 volts has been used in several installations but is being superseded by 6,600 volts in the smaller, and 11,000 volts in the larger installations.

**309. Overhead collecting devices** for use with trolley may be divided into three classes: wheel (Par. **310**), roller (Par. **314**), and sliding-bow (Par. **316**).

**310. The trolley wheel** consists of a grooved wheel of composition metal ranging from 3.5 in. to 6 in. in diameter, depending upon whether the service is low or high speed. Wheels are carried on a self-lubricating bearing and press against the trolley at pressures from 15 to 40 lb. depending upon the maximum speed of the equipment, this pressure being maintained throughout a wide range in height of trolley wire in order to provide for reduction in standard height of 22 ft. made necessary when going beneath bridges, culverts, etc.

**311. Approximate life of trolley wheels**

| | |
|---|---|
| City service 25 miles per hr. maximum | 11,000 miles |
| Suburban service 35 miles per hr. maximum | 6,000 miles |
| Interurban service 50 miles per hr. maximum | 3,500 miles |
| High-speed service 60 miles per hr. maximum | 2,000 miles |

**312. The current capacity of the trolley wheel** is determined by its speed and the pressure of contact between wheel and wire, the higher the speed the greater the pressure necessary to maintain contact without arcing. High speed also demands a very nicely balanced wheel and the maximum speed at which trolley wheels are used, corresponds to a car speed of 60 miles per hr.

Following are the current-carrying capacities of trolley wheels at various speeds.

| Speed in miles per hr. | 5 | 10 | 20 | 30 | 40 | 50 | 60 |
|---|---|---|---|---|---|---|---|
| Current capacity in amperes. | 1,000 | 850 | 650 | 550 | 400 | 300 | 200 |

This table is compiled on the basis of maximum current-carrying capacity at the different speeds with trolley and wheel in good condition. The wheel is balanced for the higher speeds and the contact pressure varies from 20 to 40 lb. between trolley and trolley wheels.

**313. Flexible trolley-wire suspension for the higher speeds.** At the higher speeds it is absolutely necessary that the trolley suspension be very flexible, preferably hung from a catenary and with the clip fastening the trolley wire of as light weight as possible in order to minimize the blow of the trolley wheel striking it.

Digitized by Google

**314. Trolley rollers** are sometimes used in place of trolley wheels where it is desired to make use of a reversible collecting construction or where the trolley potential is so high as to make it desirable that all control of the trolley collecting devices shall be automatic and not manual with cord. Rolling contacts consist of a brass or composition roller about 5 in. in diameter and 30 in. long, supplemented by stationary wings to provide for greater off-centre displacement of the trolley than can be taken care of by the roller. Roller trolleys are being used for high-voltage direct-current locomotives with success, and improvements in design have made it possible to collect any current required for main-line freight or passenger trains with direct-current 2,400-volt supply.

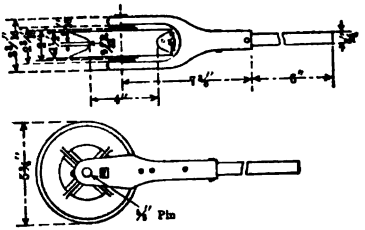

FIG. 108.—No. 12 fork; No. 17 wheel.

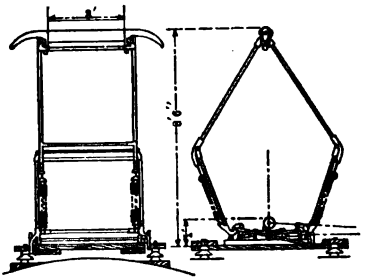

FIG. 109.—Pantograph roller.

**315. Sliding shoe trolleys** are in very general use at moderate speeds, carrying currents of moderate value, and the development of high potential alternating-current trolley collectors has brought this form of construction into prominence. In many alternating-current roads the use of trolley wheels operated by means of insulated linen cord is still adhered to, but the majority of such roads are adopting some form of roller or sliding-bow contact. As the application of the sliding-bow trolley to high speed operation calls for certain modifications in its construction as hitherto made, no complete operating data are extant in regard to its carrying capacity or its life. For speeds between 50 and 60 miles per hr., the sliding contact has an appreciably less life than either the trolley wheel or roller, but continued use of the sliding bow at these speeds is resulting in the selection of metals and forms of construction which will provide for a reasonably long life. A double-shoe trolley has lately been developed for collecting heavy currents which will probably supersede the roller. It is much lighter and will collect much heavier currents.

**316. Sliding-bow construction** may be supported either by a trolley pole mounted upon a spring base along the lines of standard trolley-wheel construction, or the bow or scraper may be held in a horizontal position at

Digitized by Google

all heights by means of the so-called pantograph construction. The pantograph bow is preferable for alternating-current roads as it permits reversal of the car direction without reversing the trolley, and furthermore, by reason of the parallel motion introduced, it does not interfere with trolley construction.

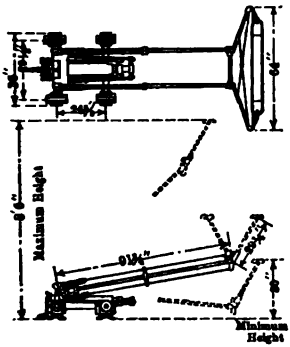

FIG. 110.—Sliding bow.

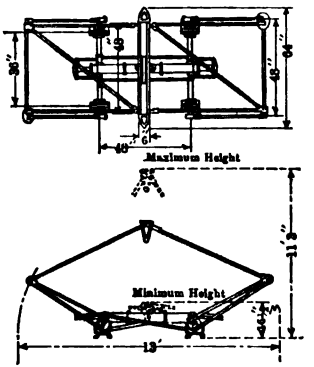

FIG. 111.—Pantograph bow.

**317. Third-rail construction** may be divided into two broad classes: *a*, overrunning contact (Par. **318**); *b*, underrunning contact (Par. **324**).

Third-rail voltages of 600 and 1,200 volts (Central California Traction) are in operation and still higher potentials are being proposed. The limiting third-rail voltage has not yet been reached, and it is probable that the development of improved forms of construction will result in the use of higher voltages for steam-road electrifications. Costs are given in Par. **355** and **356**. **Bonding** of the third-rail is treated in Par. **339**.

**318. Overrunning-contact third rails** were the first introduced and are in more general use. The construction consists essentially in supporting a steel rail, of either standard track or special composition, upon insulators placed every 10 ft. These insulators rest on supports carried upon projecting ties. Rails are joined loosely by fish plates, are bonded, and at intervals are thoroughly anchored to prevent creepage. Contact is made with the collecting surface of the rail by means of a third-rail shoe suspended from the trucks of the car or locomotive.

FIG. 112.—Unprotected third-rail.

FIG. 113.—Protected third-rail.

**319. Protected third-rail** construction is a modification of the above, and consists in providing a wooden or metal shield over the rail in order to protect it from snow and sleet or accidental contact, the rest of the construction being identical with that outlined above. The wood or iron construction is supported by uprights placed every 10 ft. or more, and such protection is usually substantial enough to bear the weight of a man midway between supports.

**321. The location of the third-rail** is determined by physical characteristics of the rail and by the character of the rolling stock passing over it, that is, sufficient clearance must be provided to allow the passage of low-pressure locomotive cylinders, hopper cars, etc., and also the third rail must be laid

[1] Two side guards and slotted covering through stations.
[2] One side guard on outside 6.25 in. distant, extending 6.5 in. above top of rail.
[3] One side guard on outside.
[4] Like that shown in Fig. 113 "Protected."
[5] Farhan System.

Digitized by Google

to provide sufficient clearance through tunnels, etc. The distance from track gage line to centre of third-rail varies from 20 in. to 28 in. and the height above track is from zero inches to nearly 8 in. The smaller distances apply to elevated and subway roads operating only one class of rolling stock, and the greater distances apply to interurban lines or electrified steam lines where provision must be made for the passage of all classes of freight cars and possible steam locomotives.

**322. Third-rail jumpers** are used to connect the third rail severed at crossings and consist of copper cables bonded to the rail and extending through underground conduits. Jumper cables are heavily insulated, are lead covered, and enter the ground through solidly-constructed concrete structures.

**323. Third-rail insulators** consist either of impregnated wooden blocks, reconstructed granite or porcelain insulators designed to be held in chairs fastened to elongated ties and forming a loose support for the third rail. In order to provide for elongation of third rail caused by extremes in temperature there is no solid fastening between the third rail and its insulating support, and jumpers must be of sufficient length to allow for creepage.

FIG. 115.—Underrunning third-rail.

**324. Underrunning third-rails** of the protected type, first installed on the New York Central R.R., offer some advantage over the overrunning type in regard to better protection against accidental contact and against sleet and snow. The contact surface being the under side, is self cleaning, and this form of third rail has successfully operated through heavy snows completely covering the third-rail structure. The Central California Traction Co. operates an underrunning third-rail at 1,200 volts.

**325. Leakage from third-rail** is extremely small and may be neglected unless the road bed should be deeply impregnated with salt. Even though the third-rail be covered with snow it is found that the leakage is too small to constitute a noticeable item of expense.

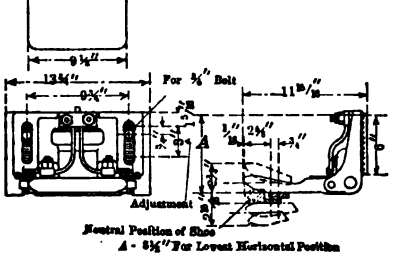

FIG. 116.—Shoe for standard and inverted rail.

**326. Third-rail shoes** (Par. 327) are of two general types: those acquiring their pressure by gravity and those actuated by means of springs. The unprotected overrunning third rail was first used in conjunction with gravity shoes, and in many installations this form of shoe is still in operation. Where rails are protected it is necessary to provide a form of shoe which will operate

Digitized by Google

in the limited space between rail and protection, and such shoes are hinged and actuated by springs in order to provide the necessary pressure.

**327. Current capacity of third-rail shoes** is much in excess of that of any form of overhead current collector, especially in regard to current capacity at high speeds. Tests have been made which indicate that electricity may be collected at the rate of 2,000 amp. from a single shoe at a speed of 35 miles per hr., and 500 amperes at a speed of 70 miles per hr. Owing to the considerable wearing surface of a cast-iron shoe its life may be taken as exceeding 25,000 miles.

**328. Conductivity of the third rail** depends upon its composition, and it is sometimes the practice to roll third rails of special composition in order to increase their conductivity. The specific resistance of steel has been found to be proportional to the per cent. of manganese and carbon which it contains. Of these two elements manganese is the most objectionable, and the standard track rail contains from 0.40 to 0.50 per cent. carbon and as high as 0.70 per cent. manganese, which gives it a specific resistance ranging from ten to twelve times that of pure copper. For samples of special construction see Par. **329**.

**329. Composition of special third rails**

| Material | Manhattan railway | New York subway | Albany and Hudson |
|---|---|---|---|
| | Per cent. | Per cent. | Per cent. |
| Carbon | 0.073 | 0.10 | 0.090 |
| Manganese | 0.340 | 0.60 | 0.440 |
| Sulphur | 0.073 | 0.05 | 0.08 |
| Phosphorus | 0.069 | 0.10 | 0.088 |
| Ratio of resistance compared to copper | 7.7 | 8.0 | 7.25 |

**330. Suggested third-rail composition specification**

Carbon not to exceed ..... 0.12 per cent.
Manganese not to exceed ..... 0.40 per cent.
Sulphur not to exceed ..... 0.05 per cent.
Phosphorus not to exceed ..... 0.10 per cent.

The specific resistance of a third-rail of composition given above will be approximately 14 microhms per centimeter cube* at 20 deg. cent. (68 deg. fahr.) or seven and three-quarters times that of commercial copper.

Including bonds, the table given in Par. **331** is representative of third-rail rolled according to these specifications for special rail giving 14 microhms per centimeter cube and for a track rail a composition giving 20 microhms per centimeter cube.*

**331. Resistance of rails including bonds**

| Weight of rail lb. per yd. | 40 | 50 | 60 | 70 | 80 | 90 | 100 | 110 |
|---|---|---|---|---|---|---|---|---|
| Third-rail resistance ohms per mile | 0.093 | 0.074 | 0.062 | 0.053 | 0.046 | 0.042 | 0.038 | 0.034 |
| Two track rails, resistance ohms per mile | 0.066 | 0.053 | 0.044 | 0.038 | 0.033 | 0.033 | 0.027 | 0.024 |

This table is based upon the use of 9-in. bonds having a carrying capacity equal to one-half that of the rail.

**332. Third-rail maintenance** is a very small item, as tests have shown the rail to wear an extremely small amount, even in very heavy service. Tests taken show that the passage of 2,000,000 third-rail shoes resulted in wearing away 0.006 in. of special soft rail. The maintenance of a third-rail includes such items of expense as maintaining the bonding, alignment,

* Meaning cube whose side = 1 cm.

Digitized by Google

and insulators in good condition together with the upkeep of jumpers and the cables. This expense has been found in practice to be very small and the low maintenance charge of third-rails together with the possibility which such a system offers for handling unlimited current values at any speed constitute the strongest arguments in favor of its adoption.

**333. Protection of third rail against sleet and snow** is affected directly by the various forms of protected third rail, and it has been found that especially the underrunning type can operate in snow entirely surrounding the third rail without difficulty, owing to the fact that the under contact surface of the rail is self cleaning. With the various forms of exposed overrunning rail it has been found that the accumulation of sleet may be prevented by the use of calcium chloride mixed with water in the proportion of 1 lb. to 5 gal. and sprayed upon the rail at intervals of not more than 2 hr. during the continuance of the storm.

**334. Underground trolley or conduit systems** are in use only in the very largest cities owing to the enormous expense of their installation. Such systems consist in the location of two third-rails or conductors placed in a conduit located between the track rails, contact being established by means of a plough extending through a slot opening of the conduit. As the plough carries both the positive and negative contacts, there is no track return and hence the conductivity of the track as a return feeder is lost.

Underground trolley systems are installed in city streets where the congestion of travel is sufficiently heavy to warrant the large expense and where the use of overhead wires is objectionable. As conduit systems are essentially double-trolley systems, the feeder network is double that required for an overhead trolley with track return. Both conductor rails are controlled by separate feeders and are divided into sections as previously indicated for city trolley systems. Each section, with its feeders, is controlled by double-throw switches so that it may be made either positive or negative at will. With this arrangement of double-throw switches it becomes possible to throw all temporarily grounded sections on a bus of the same polarity and thus prevent possible short-circuits due to simultaneous grounding of a positive and a negative conduit conductor.

**335. Double-trolley systems** are installed to a very limited extent in city streets in order to prevent any liability to electrolysis possible with the single-trolley track-return system (Par. **453**). Such systems call for double collectors and double-trolley construction, which becomes complicated and expensive to maintain in city streets. One trolley is positive and the other negative, so that the track is not utilized for return and hence need not be bonded.

**336. Three-phase double-trolley systems** or double third-rail systems are sometimes used in conjunction with three-phase induction motor equipments requiring three conductors, in which case the track acts as the third leg of the triangle. Such systems usually carry several thousand volts upon the trolley wires, employ the catenary overhead construction, and are as yet in very limited use.

**337. Three-wire systems** comprise two overhead trolleys having a potential difference of 1,200 volts between them and 600 volts each to ground. In this case the car equipment consists of two separate 600-volt motor equipments including control, connection being established with the track as a neutral. Such systems can therefore operate either as 600-volt from either or both trolleys, or as a straight 1,200-volt system trolley-to-trolley with the track acting as a neutral and carrying practically no current. Where there is no restriction placed upon the voltage drop in track return, such systems suffer in comparative first cost with the single-trolley system.

**338. Track return.** It is almost the universal custom in electric railway systems to utilise one or both rails of the tracks as a return circuit to the generating station. It was early found that the ground itself or even adjacent bodies of water constituted a return circuit of such high resistance as to be of little practical use, hence the necessity for a carefully bonded track-return circuit, reinforced by feeders where necessary. Data on conductivity and the resistance of standard rails is given in Par. **328** and **331**.

**339. Rail bonding** (Par. **340** to **354**) consists in establishing contact, rail to rail, in order to utilise to the fullest extent the conductivity of the rail as a

Digitized by Google

return circuit or as a third-rail. The contact resistance of fish plates is so great as to amount practically to an open circuit, hence the need of a bonded joint of good conductivity. The question of bonding has largely resolved itself into the mechanical problem of maintaining a low resistance contact that will withstand the constant pounding and extreme changes in temperature to which the joint is subjected under operating conditions.

**340. Types of bonds** may be listed as follows: *a*, expanded-terminal bonds (Par. **341**); *b*, soldered, brazed or welded bonds (Par. **342**); *c*, amalgam bonds (Par. **350**); *d*, cast welding (Par. **352**); *e*, electric welding (Par. **354**); *f*, thermit welding (Par. **353**).

**341. Expanded-terminal bonds** comprise all those which depend upon expanding a soft copper core into contact with the rail through a hole in the web or flange. The size of hole in the rail varies with the capacity and type of bond used, ranging from ¼ of an in. to 1 in. in diameter. There are two general types of expanded terminal bonds.

The **steel-core bond** comprises a soft steel centre inserted in a copper head and so designed that when placed in the rail and pressure applied, the expansion of the steel core centre will force the copper head into close contact with the rail. This type of bond has been largely superseded by the all-copper bond.

The second type of expanded-terminal bond comprises two solid copper heads or terminals into which is forged a laminated copper conductor joining the two. When the bond is in place and pressure applied, the soft copper head is expanded into close contact with the rail.

Bonds of the expanded-terminal type are designed for use either beneath the fish plate or under the flange of the rail, or are made of sufficient length to span the fish plate. Where the conductor joining the terminals is of considerable length as in cross bonding, it is sometimes made of solid copper wire, but a stranded or laminated conductor is absolutely necessary where the bond is short and must conform to rail deflection at the joint.

**342. Soldered bonds** have been introduced successfully in some cases. These comprise a laminated copper conductor terminating in two solid heads joined to the rail by soldering, brazing or welding. The bond is attached to the head of the rail on the outside, or to the flange of the rail. In either case it is exposed to view, which facilitates inspection and renewals but also renders the bond liable to theft. It is difficult to obtain a contact by soldering that will withstand constant vibration, but brazed and welded bonds appear to be freer from this objection. Where good contact can be secured the accessibility and cheapness of this method of bonding recommends it.

**343. Comparison of soldered and expanded-terminal bonds.** Both the expanded terminal and soldered bonds are universally used for bonding the track and third-rail of city and interurban electric-railway systems. While the soldered bond is cheaper and has many qualities recommending its adoption, its use on T-rails laid on surface ties is open to the objection that it is relatively easy of removal which renders it liable to theft. Hence the expanded terminal bond, placed beneath the fish plate is preferable when the rail is exposed.

**344. The selection of bonding** for a given road depends both upon current capacity and contact resistance desired, and is determined by the class of service involved.

**345. The contact resistance of a single 9-in. 4/0 bond** of the expanded-terminal type in good condition, is approximately 0.00003 ohms. Hence the relative resistance of bonded joints and track itself is approximately as given in Par. **346**.

**346. Comparison of track resistance with bond resistance.**

| | |
|---|---|
| 1 Mile 70-lb. track (2 rails) at 19 microhms per centimeter cube* | = 0.0361 ohms |
| Single bonding 176 joints at 0.000015 ohms (2 rails) | = 0.0026 ohms |
| Total per mile of bonded track | = 0.0387 ohms |

It is evident that the joint resistance of a well-bonded rail is relatively low compared with the total resistance of the rail itself, but the propor-

* Meaning cube whose side = 1 cm.

Digitized by Google

tion holds only when the bonding is installed and maintained in first class condition.

**347. Double bonding** is resorted to in many instances in order to insure a path of good conductivity in case of failure of a single bond. Where double bonding is not required to provide additional current capacity in order to keep temperature rise within reasonable limits, it is better engineering to install a single bond of sufficient capacity from a temperature rise standpoint and maintain this bonding in good condition. Double bonding is open to the objection that one of the two bonds may give imperfect contact and be practically useless, and such a method of installation usually results in the operation of the road with practically single bonding throughout.

**348. Single bonding for suburban roads** where the service is infrequent and current demands do not momentarily exceed 1,000 amp., is to be recommended provided rails are frequently cross bonded and all bonded joints are regularly inspected and maintained in their original good condition.

**349. The heating of bonds** will determine the size and number of bonds to be used on roads over which there is a large volume of traffic, and where the moving units demand a large kilowatt input, such as trains hauled by locomotives, etc. Following are given values of temperature rise at different current strengths:

| Current amperes | 500 | 1,000 | 1,500 | 2,000 | 2,500 |
|---|---|---|---|---|---|
| Temperature rise deg. cent. | 10 | 35 | 78 | 135 | 210 |

This table of heating constants applies only to bonding exposed to the air and not covered by fish plate, in the latter case the heating will be somewhat increased. The values given in the table apply only to bonds maintaining good contact with the rail. As one of the integral rails composing the track return may become useless owing to failure of a single bond, each rail must be bonded with the prospect of carrying the full return current. The heating of the bond varies approximately proportional with the square of the current value and extremes in temperature are to be avoided owing to the unequal expansion of copper and rail. It is therefore desirable that the greatest conservatism be used in selecting the bonds for a given service. This holds especially true where soldered bonds are concerned, as too high a temperature will melt the connection between rail and bond. Brazed and electrically welded bonds will, of course, withstand a larger current value and higher temperature without danger of falling off.

**350. Amalgam bonds** have been used with some success, the most modern comprising a spiral spring approximately 1 in. in diameter containing a soft amalgam, the whole being designed to be placed between the thoroughly cleaned fish plate and rail, and held in place by the bolts extending between them. This type of bonding is easy of application and is useful where a concealed bond is desired.

**351. Welded joints** in general give the greatest satisfaction where it becomes necessary to bond the rail to its full current-carrying capacity as when the bond is called upon to carry a very high value of current. Welding is obtained by three methods: Cast (Par. 352), electric (Par. 354), and thermit (Par. 353).

All forms of welding are necessarily somewhat expensive, and are not well adapted to the requirements of suburban roads, using T rails laid on ties in the open, because of the inability of such joints to allow for rail expansion.

**352. Cast welding** is secured by pouring the metal in a mould surrounding the rail joint, thoroughly cleaned for the purpose. Such joints will have no expansion, are somewhat likely to crack, and are best suited for use in city streets where the track is held rigidly in place by the pavement.

**353. Thermit welding** is accomplished in very much the same manner except that a relatively small amount of metal is required. This process is not as yet in very general use.

**354. Electric welding** at the rail joint is perhaps best secured by welding a steel strap to each rail, the joint not being continuous between strap and rail but maintained at one or two points of contact. Electric welding has proved very satisfactory in the past, and gives good satisfaction where great current-carrying capacity is desired.

## SUBSTATIONS

**364. Synchronous converters.** The use of the synchronous or rotary converter for converting three-phase alternating-current to 600 volts direct-current is almost universal both for a supply frequency of 25 cycles and 60 cycles (Sec. 9). The location and capacity of such stations depends upon the character of the service and local considerations, but the type of apparatus used is similar whether the substations be located in the city to supply many small-car units, or on interurban lines to supply perhaps but one or two high-speed cars of trains of several such cars. Synchronous converters are designed to operate both three-phase and six-phase depending upon the capacity and the frequency of supply.

**365. Field of application of the compound converter.** The use of the compound synchronous converter with series field is restricted more especially to those systems in which the station output is very fluctuating such as would be experienced in substations feeding suburban and interurban railway systems, or city systems in which heavy trains accelerate at a rapid rate. The compound winding of converters is generally adjusted for flat compounding at 600 volts throughout the range in load, and this is best secured in conjunction with inductive coils placed in series with the transformer secondaries. Artificial inductive reactance is introduced in compound converter substations both in order to secure flat potential on the direct-current side on all loads and unity power-factor on the alternating-current side at all loads.

**366. The plain shunt-wound converter** has a restricted field in substations supplying city service lines where the individual units are small and where a single substation feeds a large number of such units, thus producing a uniform load curve with small momentary fluctuations.

**367. Starting of synchronous converters** is accomplished by one of three methods which are as follows: first, direct-current starting through rheostat (Par. **368**); second, alternating-current starting by induction motor (Par. **369**); third, alternating-current starting from transformer taps (Par. **370**).

**368. Starting synchronous converters from the direct-current side** occasions no disturbance in the primary distributing system and recourse is had to this method of starting more especially when 60-cycle converters are fed from a primary distribution system which also carries a lighting load. This method of starting is open to the objection that synchronizing is required, which may sometimes be difficult owing to the possible fluctuations in the direct-current voltage supply. In extreme cases the delay from this cause may be considerable. See Sec. 9.

**369. Starting synchronous converters with an induction motor.** Starting is sometimes effected through the medium of an induction motor having its armature mounted upon an extension of the converter shaft. This method of starting while free from the delays caused in direct-current starting due to possible variations in direct-current potential, nevertheless requires synchronizing of the converter. Owing to the perfecting of methods of starting converters directly from transformer taps, the introduction of an induction motor for starting purposes becomes a needless expense and is moreover a slower method of starting than the method of Par. **370**. See Sec. 9.

**370. Starting synchronous converters from the alternating-current side with a reduced potential** obtained from transformer taps is the recognised method of starting in universal use, and in 25-cycle systems starting may be affected by this means without drawing more than full-load current from the primary. The advantages of alternating-current starting are cheapness of installation and a minimum amount of time required to throw the converter into service, no synchronizing being necessary. See Sec. 9.

**371. Equipment of synchronous-converter substation** is as follows: a, Incoming and outgoing primary feeders provided with disconnecting switches and lightning arresters, b, high-tension bus bars with automatic oil switches controlling same; c, current transformers in the primary-conductor circuit, feeding ammeters and relays for operating switches; d, step-down transformers either of the air-blast or oil-cooled type; e, inductive coils connected in the transformer secondary circuit, extending to the alternating-

current side of the converters; f, synchronous converters (see Sec. 9); g, direct-current outgoing feeders; h, switchboard panels controlling both the alternating-current and direct-current side of the converter as well as both alternating-current and direct-current incoming and outgoing feeders.

**372. Ratio of conversion of synchronous converters** varies somewhat with the construction of the machine, being in general as follows: three-phase converters 370 volts alternating-current to 600 volts direct-current; six-phase converters, 430 volts alternating-current to 600 volts direct-current. Machines having long pole arcs have a somewhat higher ratio of conversion than those of shorter pole arcs. In order to provide for the differences in types of machines and also for the varying drops in the primary distribution system to which rotary converter substations are connected, it is customary to provide five primary taps of 2.5 per cent. each in the step-down transformers. One of these taps is 2.5 per cent. above the receiving potential in order to take care of the high ratio of conversion of longer pole-arc converters.

**373. Substation voltages.** A typical step-down transformer (Par. 374) will have primary and secondary ratios as follows: primary voltages 19,600—19,100—18,600—18,150—17,700—17,200 secondary voltage 370. Such a transformer would be adapted to operate a three-phase 25-cycle rotary converter from a "Y"-connected 33,000-volt transmission line.

Standard primary substation voltages are 11,000 volts, 19,100 volts, 33,000 volts, 66,000 volts. It is customary to use **delta transformer connections** for both 11,000 and 19,000 volts and "Y"-transformer connections with grounded neutral for 33,000 volts and higher. Many substations now operating at 19,100 volts delta are doing so temporarily pending a change to 33,000 volts "Y" for which higher potential the transformers are insulated.

**374. Step-down transformers are of several types,** as follows: A. B. or air-blast transformers, O. C. or oil-cooled transformers, W. C. or water-cooled transformers, oil transformers self-cooled, F. O. or forced-oil transformers.

Any or all of these several types of step-down transformers can be built three-phase or single-phase, in which latter case three transformers are required for either "Y" or delta connection with each converter.

**375. Comparison of transformer cooling methods. Air-blast transformers** when used call for the construction of an air chamber over which they are placed and from which they receive air at a pressure of from ½ oz. to 1 oz. Air is supplied by a duplicate motor-driven fan feeding into the air chamber. This type of transformer is very generally used up to and including potentials of 33,000 volts. For higher potentials and for small transformer units oil is resorted to for cooling by a variety of means.

The design of the small self-cooled (oil) transformer is especially adapted to the smaller sizes, owing to its cheapness. For larger sizes it becomes necessary to cool the oil either by means of a cooling coil placed in the transformer and through which water is circulated, or by providing means of circulating the oil itself through an outside pipe coil, in order to reduce its temperature. In general the air-blast type of transformer is preferred for potentials not exceeding 33,000 volts on account of its freedom from fire risk in case of a short circuit or "burn out." For very small single-converter units or those having connection to the higher primary potentials, some form of oil-cooled transformer is to be preferred.

**376. The general arrangement of apparatus** in substations is somewhat similar in all cases, as such buildings are usually designed for the purpose. In general the wiring scheme consists in providing the shortest and most direct path from the incoming primary lines to the outgoing direct-current feeders, and the interior-wiring scheme is carried out with the object in view of preventing any crossing of circuits or doubling back upon themselves.

**377. Duplicate apparatus** in a substation may or may not be installed, depending upon local requirements. The manufacture of synchronous converters, transformers, and general substation apparatus, has been so far perfected that failures in such apparatus are very infrequent. It is, therefore, quite customary to install substations containing but a single converter and set of transformers, although it is always good engineering to provide duplicate converter, transformers, switchboard, etc., throughout. This practice is

Digitized by Google

largely influenced by local requirements of absolute continuity of service, and also by the development of the so-called portable substation, which is now furnished in units as large as 500 kw.

**378. Portable substations,** so-called comprise a synchronous converter, step-down transformer, and switchboard apparatus, mounted in a box car and intended to be moved from place to place as occasion demands, thus serving as a reserve to be used in case of failure, or overload of any substation in the system. A compact arrangement of the apparatus involved has been

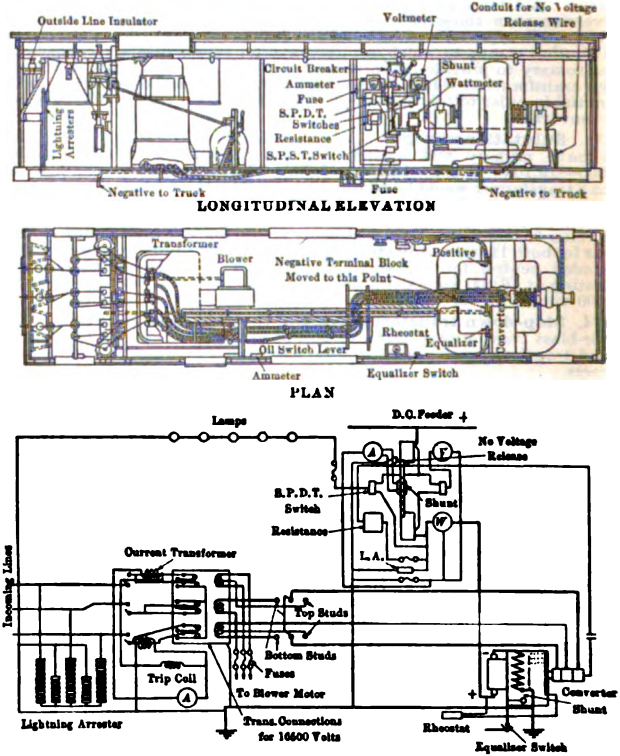

FIG. 119.—Synchronous converter portable substation.

perfected, so that portable units of 500 kw. capacity can be constructed. The complement of apparatus is identical with that in the standard sub-station, and the arrangement provides sufficient room for the operator. As such substations are not intended for any fixed location, they are not equipped for both incoming and outgoing primary lines, but are designed to be connected to an unbroken primary circuit. The converters may be compound-wound and provided with equalising switch, so that a portable substation may serve as an auxiliary to a stationary substation in case of extreme sustained overload.

**379. Alternating-current substations** designed for use with alternating-current railway motor equipments are generally designed for operation without attendant (Par. **285** to **288**). Such substations comprise a

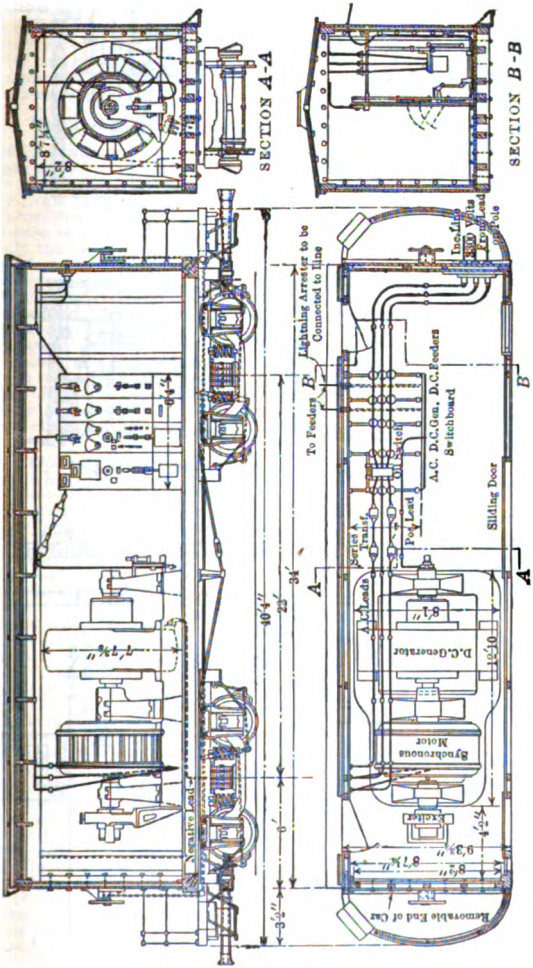

**Fig. 120.—Motor-generator portable substation.**

small fireproof building containing step-down transformers, generally in duplicate, together with the necessary switchboard apparatus. Both primary and secondary transformer circuits are provided with automatic

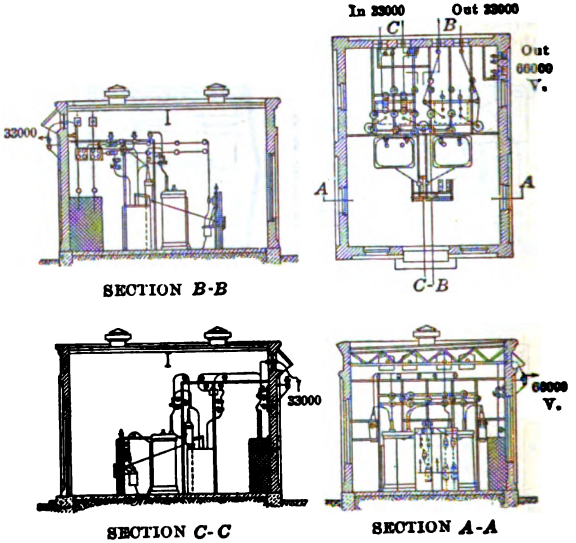

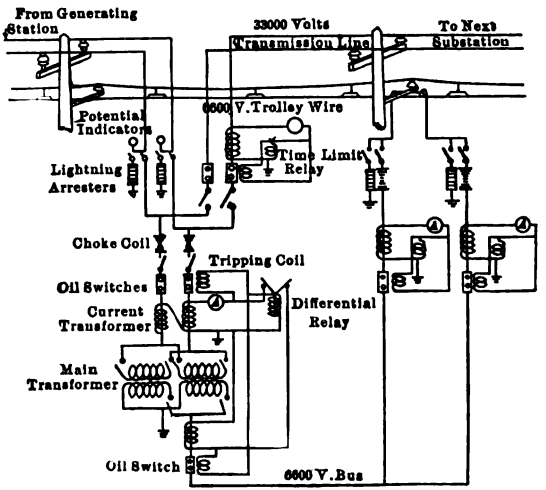

FIG. 121.—Transformer substation.

Digitized by Google

oil switches designed to open on short-circuit or extreme overload only These automatic switches serve merely as a safety device to protect the transformers from burn out. As such substations have no operator and are subject to violent fluctuations in load greatly exceeding the average, it is necessary that all protective devices be limited in their function in order to guard against short-circuit and not overload.

In order to facilitate the location of faults, alternating-current transformer substations are commonly supplied with both voltmeter and ammeter besides being equipped with lightning arresters upon both the high-tension and low-tension incoming and outgoing feeders. Step-down transformers are of the self-cooling oil type.

## AUTOMATICALLY OPERATED TRACK SWITCHES

**380. Advantages of automatic track switches.** The practice of turning switches with switch bars from the front platform of cars has been made practically impossible by the addition of the vestibule and fender, and many roads have undertaken to install electrically operated switches. Thus the inconvenience and waste of time occasioned by requiring a motorman or conductor to get off the car and turn switches, or employing a switch tender. Usually the hand-operated switches are held in place by a block of rubber or piece of steel to prevent splitting the switch as often happens in case of double-truck cars, and these small blocks frequently require considerable manipulation before they are taken out and the switch turned. An electrically operated switch is turned at will by the motorman running over an insulated section of the trolley with power on, or left on its original position by coasting over this section. Perhaps the simplest manner by which automatic track switching may be accomplished is by placing two solenoids between the tracks at the switch and connecting their cores to the switch-points. By energizing either of these solenoids the switch will be turned in one way or the other, and it remains to place two insulated sections in the trolley wire whereby a car can cause current through one or the other, or neither.

**381. Operation of automatic track switch.** The following are the ways in which the switch may be operated: a, a motorman desiring to go in the direction, "A" (Fig. 122), may find the switch set for track, "A," in which case he may either coast over both insulated sections or traverse, under power, that section which will not disturb the switch and coast over the other, or if the sections are in proper sequence he can run over both with power on; b, if the switch is set against him, the motorman must select the insulated section which will turn the switch, and traverse it with power on. If it is the last section he can run over both sections with power on; c, likewise, if he wishes to run in the direction, "B," but if the sections are arranged for all the combinations mentioned above for the direction "A," there will be one less combination by which the switch can be operated by the cars going in the direction, "B."

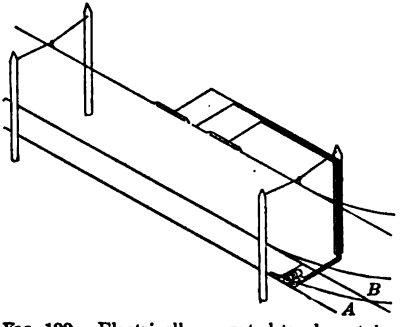

FIG. 122.—Electrically operated track switch.

If the switch is on a down grade for approaching cars the arrangement of sections before the switch points proves satisfactory, since the car can coast over both sections if necessary. If, however, the approach to the switch is on a considerable up grade, it would be difficult to coast very far at the speed permissible on the grade. Hence one insulated section is sometimes placed in the trolley beyond the switch, in which case a car will run over the first

Digitized by Google

section with power on, setting the switch for track, "A," and then reset it for track, "B," by running over the second section with power on. Cars for track, "B," will coast over the first section.

**381A. For Bibliography on electric traction, see Par. 475.**

# RAILWAY SIGNALING

**BY AZEL AMES, S.B.**

*Engineer, Kerite Insulated Wire and Cable Co. Associate, American Institute of Electrical Engineers*

## GENERAL

**382. Introduction.** The development of this art has been and is so rapid that space does not permit either its historical treatment nor consideration of details of design of apparatus or circuits. Little relating to working data or costs is given in this discussion as these change almost from day to day, but only such material as will assist the otherwise well-qualified electrical engineer who may have to do with signaling, to understand some of the principles and practices involved (for further details see Bibliography, Par. **427** to **429**).

**383. The salient features of present-day signaling** practice are the recognition of the electric track circuit as the only adequate means of signal control, the rapid increase in the use of alternating-current apparatus, and the attention being given to automatic train control.

Interlocking is treated at some length in subsequent paragraphs, because of the lack of information thereon in the publications commonly read by electric railway men, and the increasing electrification of steam roads having yards or junctions requiring its use.

**384. Railway signaling may be defined** as the art of regulating railway train movements by means of the indications displayed by visual signals of fixed location placed along the roadway. Its practice requires a knowledge of railway operating methods and rules, of train acceleration, running conditions and braking (Par. **194**) and a thorough understanding of the relations of track to traffic. Its function is to prevent loss of life or property from collision or derailment and to save time and money by minimising congestion and assuring the use of trackage to maximum capacity. Its problems include the proper layout and subdivision of tracks to handle an existing or assumed traffic with the greatest safety and least delay; the determination of the extent to which visual signal indications shall supersede written communication in the regulation of train movements; the design, construction and installation of the necessary signal apparatus; the training of engine and train crews in the understanding and observance of signals; and the organization and training of the necessary personnel for the maintenance and operation of the various installations.

**385. Capitulation of railway operation.** The tracks of a railroad bear two distinct relations to the trains or cars running thereon, they serve as channels of traffic and they also serve as structures for carrying rolling loads on flanged wheels. In order to define the relations of train movements to each other and to the definite channels of traffic provided by the main tracks and sidings of a railway, rules are established, special instructions issued and time-tables containing train schedules are prepared. These written instructions are supplemented by train orders, communicated from the train despatcher by telegraph or telephone. As the density and particularly the speed of traffic increase to a point where either danger or delay result from the multiplicity of train orders required, it becomes necessary to supply the needed directions for train movement by means less cumbersome and less liable to error. The means usually employed comprise the visual indications of fixed signals (Par. **387** and **388**).

The conditions of the track as a structure, namely, whether the rails are intact and the switches so set that a continuous path for wheels is provided over a given route, can hardly be indicated by rules or written orders but may be readily denoted by signal indications.

**386. Classification of railway signaling.** Isolated signals are sometimes used to protect particular points such as curves, stations or switches where the view is poor. Train-order signals at stations indicate to trains whether or not there are orders to be delivered. Aside from these two types

Digitized by Google

of installation, signalling naturally divides itself into two classes, namely *interlocking* (Par. 404 to 420) and *block signalling* (Par. 421 to 426).

## TYPES OF FIXED SIGNALS

**387. Targets and lamp signals.** In American practice, targets of various forms are generally used to show the positions of switches except where the latter are operated from interlocking plants. The signals generally used in interlocking practice, as well as for train-order signals and block signals, are of the **semaphore** type, in which an arm, composed of a casting on which are mounted colored glasses called roundels and a wooden blade, is pivoted about a horizontal axis so that it may be moved either manually or by power, from a horizontal position to an inclined or vertical position in order to indicate the various conditions affecting the movement of trains. All fixed signals, in addition to their day indications, are provided at night with lights of prescribed colors. With semaphore signals, one light is provided for each signal arm and is so placed that as the arm moves to its various positions, the different colored glasses will move in front of the lamp to show red, yellow, green, white or purple light as desired. For block signaling, signals of the enclosed-disc type are used to some extent, although the semaphore affords more distinctive indications.

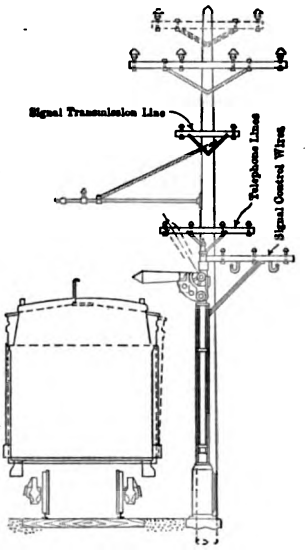

FIG. 123.—Standard location of signal (right of track).

"Light signals," consisting of electric lamps placed behind suitably colored lenses and so shaded as to permit their colors to be distinguished by day, have been introduced to some extent on electric railways, and have been recently developed to considerable efficiency.

The American Electric Railway Association's Committee on block signals has recommended as the preferred type of signals for electric roads, a semaphore moving in the upper left-hand quadrant as viewed from an approaching train; the arm in the horizontal position indicating "Stop;" in the inclined position, 45 deg. upward, indicating "Caution;" and pointing vertically upward, indicating "Proceed." It is considered that less interference with the view of signals by pole lines adjacent to the track will thus result than if the steam railroad practice of displaying the blade to the right of the mast, as seen from an approaching train, is followed. This is based on the American practice of locating signals to the right of the track which they govern (Fig. 123).

**388. The usual type of automatic signal is the electric-motor semaphore.** The arm comprising the blade and the casting carrying the colored glass roundels is pivoted near the top of the post, the shaft to which it is connected carrying a crank or arm connected to the "up and down" rod placed inside of the tubular iron signal post. The lower end of this rod is connected to the mechanism proper which consists of an electric motor and gearing whereby the motor transmits motion to the up and down rod. A device called a "slot" which comprises a magnet and latch is so arranged that if the magnet is energized the motion of the motor is transmitted to the signal arm, but if the magnet is de-energized, mechanically disconnects the motor from the up and down rod allowing the signal to go to the stop position by gravity. Signal mechanisms of the "top-post" type have the motor mounted adjacent to the semaphore-arm shaft at the top of the post.

Digitized by Google

The "slot" mechanism is generally provided with two windings in multiple, one of low resistance being in series with the motor while the latter is clearing the signal. A circuit controller actuated by the signal arm when the latter has moved to the clear position, opens the circuit of the motor and low resistance winding, leaving the high-resistance coil energized in order to hold the latch carried by its armature. This latch, by connecting the driving and driven members of the "slot," holds the signal in the clear position. The high resistance of the holding coil reduces the current required for holding the signal clear, to a fraction of that required to clear the arm using the motor and the low-resistance coil in series with it. Motor-driven signal mechanisms are of many types and are designed for either upper-quadrant or lower-quadrant movement of the arm; for operating in three positions; or for operating, by selection, one of two or three arms on a post. Motor-driven signal mechanisms are used for operating either black or interlocking signals with direct or alternating current at from 10 to 110 volts.

## TROLLEY-OPERATED SIGNAL SYSTEMS

**389. Operation and reliability of various systems.** On many electric railways the volume of traffic is not sufficient to warrant the expense of employing signalmen to operate manual or controlled-manual block signals. Hence signal systems have been developed which are partly manual and partly automatic. In such systems the manual operations are performed by the motormen or conductors of cars or trains, and the automatic operations are performed by the action of the trolley upon circuit controllers, actuated by the passage of the trolley wheel. A very large variety of signal installations of this character have been made, varying from exceedingly simple ones to those involving a greater complication of apparatus and circuits than are necessary in complete automatic blocking. Many of them are very crude and of decided limitations both as to safety and the extent to which they facilitate traffic. Many of them depend upon step-by-step devices which count the number of cars that enter a block and count them out at the other end of the block. A number of these systems have been quite highly developed as regards their apparatus. The relays and magnets as a rule require no separate source of energy for their operation but use the trolley current. None of them can be considered as offering a degree of safety or reliability approaching systems employing the track circuit, which is the only means so far known in signaling whereby a train is *continuously* active in maintaining its own protection (Par. **392**).

**390. Relative value.** By strict obedience to the prescribed rules for their observance, without which no signal system is of value, trolley-operated signals afford a very considerable degree of protection and facility to traffic. Their relatively low cost makes them available where other systems could not be installed on account of the expense involved.

**391. Tendency toward abandonment.** The development of the light signal to a point where its day indication can be observed at distances sufficient for stopping high-speed cars, enables it to be substituted for the electric-motor semaphore, resulting in a material reduction in the cost of automatic block-signal systems employing the continuous track circuit. The additional apparatus and line wires which it has been found necessary to add to the trolley-operated signal systems to make them furnish the same information as that given by track-circuit signal has, on the other hand, tended to increase their cost. The costs of the two systems are thus rapidly approaching each other, and the tendency toward the adoption of track-circuit signaling for electric railways is increasing to such an extent that the latter bids fair to supersede the trolley-operated signal at no distant date.

## THE TRACK CIRCUIT

**392. "A track circuit may be defined** as a metallic path for an electric current formed primarily by both rails of a pre-determined length of track, the terminating rails of which are electrically separated from adjacent rails; a source of electric energy for maintaining a difference of potential between the rails; and one or more devices (relays) so connected in the circuit as to respond to variations in the potential difference between the rails produced by train action upon them" (J. P. Coleman). This invention, than which none other has contributed more toward safety and despatch in railway transportation, is to-day the only medium recognized as fundamentally safe by experts in railway signaling, whereby a train or any vehicle thereof

Digitized by Google

may retain continuous and direct control of a signal while occupying any portion of the track protected by the signal.

**393. The function of the closed track circuit** is to maintain a relay normally in an energized state; the influence of the train upon the rails is to de-energise this relay by shunting or short-circuiting the generator, a process as effectively accomplished by a single car as by a train of considerable length. On account of the low insulation resistance between the rails, due to the conductivity of the ties and ballast, track circuits are susceptible to influence from excessive leakage of current from rail to rail. This leakage may approach, in its effect, the value of current conducted by the wheels and axles of a train. Obviously a failure of the source of energy or a break in the circuit, whether in the rails themselves or in the wires connecting the battery

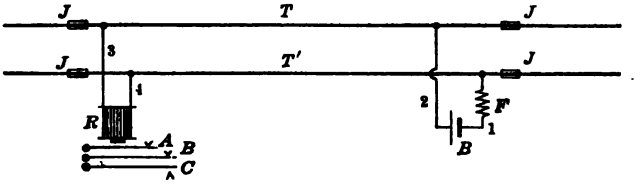

FIG. 124.—Track-circuit.

B, Source of energy, as two gravity-battery cells in multiple, or one storage-battery cell with series resistance F to limit current output when rails are short-circuited by wheels and axles of a car, or a transformer, 2 to 8 volts where alternating current is used. J, Insulated rail joint. T T', The track rails included within the block, adjacent rails being bonded. R, Relay, normally energized by current from B. A B, Contacts carried by armature of relay R and closed when R is energised. C, Contact carried by armature of relay R and closed when armature falls by gravity upon R being de-energised. The path of current is from B through wire 1, resistance F (if used) track rail T', wire 4, magnet coils of relay R, wire 3, track rail T, wire 2 to B. The distributed leakage of current between track rails T and T', through the ties and ballast, is in multiple with relay R.

or the relay to the rails, produce the same effect upon the relay as if a train were running or standing on the rails. The contacts carried by the armature of the track relay (Fig. 124), which are closed only when the relay is energized, are included in the circuits which control the signals themselves. These circuits must be closed in order that the signals may indicate "proceed." Thus the track circuit conforms to the principle demanded by sound practice, namely, that the signals shall invariably display the "stop" indication when their operating or controlling energies cease to be active from any cause.

**394. Requisite performance of the electrical equipment.** The source of energy supplying current to a track circuit should do so at the least e.m.f. that is practicable. The current capacity should not be excessively great nor yet too limited. When a train is so far advanced within the block from the relay end as to constitute a somewhat imperfect shunt upon the relay, stray currents sometimes find a path through it from adjacent rails through damp or defective rail insulations. Relays should not be sufficiently sensitive to respond to these currents. In excessively long blocks and where the likelihood of such occurrences exist, one of the remedies is to locate a relay at each end of the section and supply current to the centre of the circuit, so that as the shunting effect of the train recedes from one relay it approaches the other. Naturally the resort to this device entails additional cost and complication, for the operating circuit of the signal is carried through the entire block for control by both relays.

**395. Low e.m.f. impressed upon track circuits is advantageous** for two reasons: first, to minimise the break-down effect of the e.m.f. upon rail joints of defective insulation or upon damp ties and ballast and other parts that afford a normal leakage of current from rail to rail in wet weather; second, to reduce to a minimum the energy normally discharged through

Digitized by Google

the road-bed and relay when the track section is unoccupied, as well as to avoid extravagant discharge through the train axles when the section is occupied. Where the common gravity battery is the source of energy, the general custom on steam roads, its internal resistance is sufficient and no external resistance need be provided. On account of the variation in internal resistance with gravity batteries, however, it is more general in present steam railroad practice to use storage batteries with a fixed resistance in series therewith.

**396. Track relays.** In common steam-railroad practice relays of from 4 to 9 ohms resistance are employed on track circuits varying in length from about 60 ft. as a minimum, to about 6,000 ft. as a maximum. A certain minimum air-gap between the relay armature and its pole pieces must exist in order to prevent undesirable effects from residual magnetism. As this air-gap is increased when the armature falls away under the action of gravity, to permit the contacts carried by it to open, it is evident that more current through the relay will be required to lift the armature than to hold it in position against the pole pieces, once it has been raised. The usual 4-ohm track relay requires about 70-mil amperes through its coils to pick up the armature; it will drop away when the relay is shunted sufficiently to reduce this current flow to about 35 mil-amperes.

While much included in the foregoing paragraphs is only applicable to direct-current track circuits for steam roads, it may be considered important as indicating the principles upon which the track circuit has been developed. These principles should be thoroughly understood by the electrical engineer as a preparation to the consideration of track circuits for electric railways (Par. **397**).

## TRACK CIRCUITS FOR ELECTRIC RAILWAYS

**397. Effect of bonding.** Wherever, as is the case in most electric railways, adjacent rails of the track are bonded together to form the best possible conductor for the return *propulsion* current, it is obviously impracticable to divide these rails into sections electrically separated from each other by insulated joints, as is done where track circuits are used for signaling on steam railroads, unless means can be provided for the return of the propulsion current without affecting the action of the track-circuit relays. In case the track is laid upon a metallic structure one rail can be bonded to the structure. Other considerations may render one rail of each track sufficient for the return of the propulsion current. One of the rails may therefore be left electrically continuous to serve as a return for the propulsion current, while the other is cut into sections of proper length for the control of the signals. It is evident, if generators and relays are connected across the rails at opposite ends of each track section, that in the event of the conductance of the power rail becoming reduced as a result of defective bonding, the return current would divide so that a sufficient amount of it might flow through the signal relays to energize them even when a considerable shunting effect was produced upon them by a train in the block; furthermore, the drop in potential, due to the return of power current over the considerable length of rail included within the limits of the block, might be sufficient to energize the track relay illicitly.

**398. To prevent improper operation of track relays** by differences of potential between the track rails produced by the propulsion current itself, the track relays for electric roads are designed to be immune to the effects of the propulsion current. This may be accomplished either by protecting them against excessive flow of current with series resistance and, in some cases, providing a shunt path around the relay for the propulsion current, or by so designing them that they will respond only to the action of alternating current. Where alternating current is used for propulsion, the relays are made to respond only to an alternating current of a different frequency than that used for propulsion.

**399. Field of single-rail track-circuit system.** Whenever, as in yards or terminals, the number of tracks that can be bonded together is sufficient to afford an adequate return for the propulsion current, one rail of each track being assigned to signaling, the single rail track circuit is used for the return of the propulsion current. Fig. 126 shows a single-rail track circuit as installed at an interlocking plant, with a desirable arrangement of the apparatus.

**401. Two-rail track-circuit system.** Where it is not practicable to give up one of the track rails for signaling purposes, the conditions existing in the single-rail track circuit not only apply, but means must also be provided whereby both rails are electrically continuous for the return of the propulsion current, but are electrically separated from adjacent rails at the ends of each track section in so far as the signaling track-circuit current is concerned. This is accomplished through the means of **impedance bonds** which consist of a few turns of heavy copper wound about and insulated from a laminated-iron core. The connections of impedance bonds to the rails is so made that the traction current has no magnetic effect on the bond, provided an equal amount of current is flowing in each of the rails. If, however, more current is flowing in one rail than in the other, there will be a tendency to saturate the iron core and thereby reduce the impedance of the bond. This effect, which is called "unbalancing," is limited by introducing an air-gap into the magnetic circuit, the bonds ordinarily being designed to stand 20 per cent. unbalancing without a decrease of more than 10 per cent. in impedance. The size of the bond to be installed is dependent upon the amount of current it will be obliged to carry, the impedance for which it must be wound (this being more or less dependent upon the length of the track circuit) and the amount of unbalancing to be cared for. Where good traction bonding can be maintained, unbalancing can be assumed less, hence a smaller size of bond can be employed.

**402. Energy supply for signal system.** Power for the operation of the track circuits and signals on an electric railroad may be taken from transformers connected directly to the propulsion-power transmission system. More frequently a signal-power line is provided to furnish this current at a reduced voltage, the necessary apparatus being located in the substations. For the track circuits, the potentials of the transformer secondaries range from 2 to 8 volts, and for the operation of the signals and line circuits generally from 55 to 110 volts. At the present time no power interlocking plants are in use employing alternating current, hence it is customary to provide motor-generator sets supplying direct current for charging the storage batteries at these plants. For any installation it is necessary to construct a power diagram. The current consumption of the track circuits, relays, alternating-current signal motors, indicators, lights, etc., will vary in each installation and will be affected to some extent by the volume of traffic which governs the number of switch and signal movements per day. The energy consumption data for each piece of apparatus is furnished by the maker.

**403. Track-circuit constants.** The data in Par. 400 shows the impedance in ohms per 1,000 ft. of track and the power-factor of steel rail of various weights and lengths for frequencies of 24 and 60 cycles and with various types of bonding. In all electric-railway practice the current-carrying capacity of the bonds provided would be assumed equal to that of the rail itself. The data given for the other types of bonds apply to single-rail circuits for electric roads or to steam-railroad conditions.

## INTERLOCKING

**404. Definition and field of application.** Interlocking plants are assemblages of switches, switch-operating and switch-locking devices, and signals so interconnected that their movements must succeed one another in a predetermined order. They are used at crossings or junctions of one line with another, at drawbridges, at cross-overs, or in yards where the number of switches or the frequency of their movement is so great that hand operation would not be sufficiently rapid nor safe. At railroad crossings or drawbridges, signals are frequently interlocked with derailing devices, this protection being required by the laws of several states provided trains are permitted to pass over without stopping.

**405. Classification.** Interlocking plants are either mechanical or power-operated. In those of the former type, pipes or wires connect the switches, locks, signals, or other operated units with the levers that operate them. In the latter type, pneumatic cylinders or electric motors are connected to suitable "lock and switch movements" or signal mechanisms. Electric circuits controlled by the levers in the interlocking machine regulate the operation of these switch and signal mechanisms.

Digitized by Google

**406. Mechanical processes involved in interlocking.** In all interlocking machines the desired sequence of operations is secured by means of the dogs, bars, or tappets which constitute the mechanical locking. These parts are so interrelated that if any lever in the machine is reversed (that is, moved from its normal position), the act of the signalman in unlatching this lever will cause parts of the locking so to operate that no other lever in the frame can be moved which would allow a train movement conflicting with the train movement controlled by the first lever. The mechanical locking between the levers of the machine also provides for the movement of the levers in proper sequence when the route for a train is being set up, by assuring that the switches must first be properly set and must then be locked in the proper position before the signal governing the route can be cleared.

**407. Prevention of switch operation while train is passing.** Long bars of steel, called **detector bars**, are held by clips along the outside of the head of the rail at switches. They are of a length greater than the maximum distances between any of the adjacent wheels of a train, and are so mounted that they must move upward above the level of the top of the rail before the switch may be unlocked. They generally are mechanically connected to and operated simultaneously with the lock plungers which pass through holes or notches in the lock rods of switches to lock them in proper position. This method of protection may prove unsatisfactory owing to the increasing width of rail heads, and, especially on electric roads, the relatively narrow wheel treads of which may fail to engage the top of the detector bar while the vehicle is passing over it. Electric track circuits controlling electric locks mounted on the levers of the interlocking machine itself, are becoming quite generally used as a substitute for detector bars in the prevention of switch movement while trains are passing.

FIG. 125.—Typical interlocking plan and locking sheet.

**408. Arrangement of mechanical interlocking plant.** The plan of a single-track line crossing a double-track line is shown in Fig. 125. There is a siding switch on the single line, located so near the double-track line that it is necessary to include it in the interlocking. Derails are shown on all tracks.

Digitized by Google

Those on the double-track, which is assumed to be a steam road, are placed 500 ft. from the crossing, except the "back-up" derails which are about 300 ft. from the crossing. On the single-track interurban line the derails would be located in accordance with legal requirements or the necessities of the locality. The derail in the siding is placed at fouling distance from the main track. The single switch and each of the derails is locked with a facing-point lock and provided with a detector bar. At the crossing itself a detector bar might also be used to prevent the clearing of signals for a movement on one line while an engine or a detached car was standing on the crossing.

The "home" signals, governing through movement, and the "dwarf" signals, governing reverse movement and the movement from the siding, are located about 50 ft. from the points of the derails. One home signal in the single-track line has two arms: the upper governing the through or high-speed movement, while the lower governs the low-speed diverging movement on to the siding. Distant signals, used to regulate the approach to the home signals, are placed from 1,500 to 4,000 ft. in rear thereof.

The mechanical interlocking machine has a 24-lever frame, the assignment of the various levers being shown in a table. A locking sheet is also given, in which a circle drawn around any lever number indicates it to be in the reversed position. Levers, the numbers of which are not within a circle, are in their normal position.

**409. Power interlocking.** In mechanical interlocking (Par. 408) the rigidity and mechanical continuity of the connections between any switch, lock, or signal, and the lever that must be thrown in order to move it, is depended upon to accomplish the desired motion of the unit. It is assumed, in other words, if the lever operating a facing-point lock on a switch is moved through its full stroke, that the lock is also moved its full stroke. It is further assumed that the movement of the lock lever may be depended upon to release the mechanical locking in the interlocking machine and permit the proper lever to be moved that will clear the desired signal and permit a train to pass over the switch, which is locked by the facing-point lock previously mentioned.

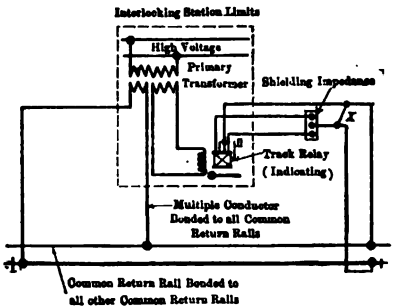

FIG. 126.—Single-rail track circuit at an interlocking plant.

**410. Return indication.** In power-operated interlocking machines where the only physical connections between the operated units and the levers in the machine consists of insulated conductors which carry small currents, there is no direct assurance, when a switch lever is operated, that the switch itself has moved at all. To insure that it is moved properly and will be locked in a position corresponding to that of the lever, all power-interlocking systems provide for what is called a return indication. When the lever in the interlocking machine is moved to cause a switch or signal to be thrown, it cannot at first be moved through its complete stroke nor through sufficient length of stroke to release the mechanical locking between itself and conflicting levers. The lever can only be moved far enough to close the circuit which will cause the desired motion of the switch that is to be operated.

The switch mechanism itself must complete the throwing of the switch, must completely lock it in the proper position, and must then close contacts that will cause current to flow back to the lever in the tower and energize a magnet to release a dog, which has heretofore limited the motion of the lever. After this dog has been released the operator is permitted to complete the stroke of the lever, which will in turn release the mechanical locking between

Digitized by Google

the switch lever and others in the frame, allowing movement of the latter to be made in proper sequence.

**411. The Electric-Pneumatic Interlocking System** of the Union Switch and Signal Company. This system is so named because compressed air is employed to shift the switches and signals, while electricity is used to control or direct the admission and discharge of pressure to and from the cylinders by which the shifting is performed. The system is comprised of the following elements: an air compressor (preferably in duplicate for reserve) which, especially in terminal station plants, is often used for many other duties; a main air pipe extending throughout the interlocking system with branch pipes connecting it with each switch and signal to be operated; a double-acting cylinder at each switch which, through a motion plate, operates and mechanically locks the switch in its two positions by movement of the piston; a slide valve for each switch cylinder used to direct the pressure to either side of the piston in order to effect the movement of the latter (Par. 412); a single-acting cylinder, operating the signal (Par. 414); a source of energy (Par. 415).

**412. Arrangement and operation of the switch-cylinder slide valve** (Par. 411). There are two miniature cylinders employed for shifting the slide valve; two pin valves, operated by electromagnets, control the movement of the pistons in these cylinders. Mounted over the slide valve is a third small cylinder, also under the control of a magnet and pin valve. The piston of this small cylinder engages with and locks the slide-valve against movement save when the magnet is energized and the pin-valve is actuated to permit the pressure to withdraw the lock.

By energising and de-energising the magnets in proper sequence, the slide valve is unlocked, shifted, and again locked by the operating and indicating strokes of the lever. During this process each movement of the valve is accompanied by a corresponding unlocking, shifting, and relocking of the switch through the resulting operation of the switch enforced by the piston of its own cylinder. The three magnets are directly connected with contacts that are actuated by one of the levers in the interlocking machine, a separate wire being used for each magnet.

**413. Indicating system** (Par. 411). In the latest development of this system, a circuit controller is employed which is actuated by each switch movement. When the switch is in one of its extreme positions and locked there, this controller allows a current *of given polarity* to traverse two wires which connect it with a polarized relay in the tower. Conversely, when the switch is moved to and locked in its opposite position, a current of the *reverse polarity* is sent through the relay. During transit of the switch, and, in fact, when the switch is in any position and unlocked, the controller establishes a shunt or short circuit between these two wires. This short circuit renders the apparatus immune, at such times, to the effects of any stray current which might energise the relay. The circuit controller or pole changer, the relay in the tower, and the two wires joining them substitute the fundamental elements of the indication system of this type of power interlocking.

The polarized relay frees one or the other of two electric locks which, previous to this action, has been arresting the *complete* movement of the switch lever in the tower. This incomplete movement of the lever from full "normal" or full "reverse" involves about two-thirds of its total movement. After the partial movement has been made, the *complete* lever movement can be consummated only in the event of one of the two locks which previously restricted the lever's movements becoming energized. The energisation of this lock can occur only when the indicating relay has shifted its armature in response to a reversal of current in the two indicating wires. Such reversal is only possible when the switch has fully moved and become locked in response to the incomplete lever movement. After the lever has been released, its movement may be completed. Following the processes involved in a final execution of the lever stroke, the mechanical interlocking between switch and signal levers permits the shifting of the proper signal lever for train movements over the switch. The current supply to each and every signal leading over the switch is carried through other contacts of the indicating relay, so that unless the relay is energized in the proper polarity and the lever and the switch correspond precisely in position, no signal whatever can be given over that switch. Conversely, should a signal be properly

Digitized by Google

cleared for train movement over a switch, by reason of switch and lever corresponding in position, any interference causing a partial or full reversal of either lever or switch would immediately cause the signal to move to the "stop" position. This, the most necessary feature of modern power interlocking practice, gives protection against careless, ignorant, or malicious shifting of a switch by improper means from the position to which it was properly moved by the lever.

**414. A single-acting cylinder operates the signal** (Par. 411), the signal being held at and returned to the stop position by gravity. Compressed air is admitted to and discharged from this cylinder by means of a pin valve, and the latter is operated by an electromagnet. This pin valve and electromagnet are identical in design with those used to shift the piston in the slide-valve cylinder of the switch mechanism. When energized, this magnet causes the pressure to depress the piston, thereby clearing the signal. When the magnet is de-energized, the air escapes from the cylinder and the signals move to the "stop" position by gravity. Failure of the signal so to move, from any cause such as the accumulations of sleet and ice in unusual quantities upon its bearings and other exposed parts, prevents the signal lever from being restored to normal. This incomplete lever stroke prevents the mechanical release of all levers operating switches which lie within the route governed by the signal.

To restore a signal to normal in regular operation the signal lever is moved partly toward normal, where the lock arrests its further movement until the latter becomes energized. This energization cannot occur until the signal, in response to the partial return of the lever, assumes the stop position and closes the circuit.

**415. The source of electric energy** (Par. 411) for supplying the current required for the operation of the pin-valves and locks of the system, consists usually of a storage battery of 7 cells in duplicate. This battery has a low ampere-hour capacity and may be charged from any local lighting or power circuit. If direct-current service is obtainable, a resistance is connected in series in order to obtain the desired charging voltage. Charging may be accomplished from an alternating-current line by use of a converter (Sec. 9), a motor-generator set, or a rectifier (Sec. 6). Magnets of 400 ohms resistance will operate pin valves controlling air at 100 lb. pressure from a 12-volt battery with a margin of 50 per cent. drop in voltage. Alternating-current magnets may be substituted for direct-current magnets in the operation of pin valves, and the system operated without batteries. Cylinders of areas and strokes appropriate for the work to be done, are used in various arrangements of switches and frogs.

The electrical energy required by this system is small, a constant current rate of 5 amp. at 12 volts being sufficient for a large terminal plant.

**416. Electric interlocking system of the Union Switch & Signal Co.** In this system of interlocking, the machine for the control of the switches and signals is very similar to that used in the electropneumatic system. The switches and signals are driven in this case, instead of by compressed air, by electric motors or solenoid magnets working through suitable gears and cams. For the control and indication of a signal, the circuit is similar to that used in connection with the electropneumatic interlocking (Par. 411), except that instead of a magnet actuating a pin valve, there is a relay or other electromagnetic device controlling either an electric motor or a solenoid and suitable holding magnet at the signal. The function of the motor or solenoid is to move the signal arm from the "stop" to the "clear" position. When the arm comes into the "clear" position it is cut out of the circuit automatically, and the holding coil is energized in order to maintain the signal in the clear position so long as the circuit is complete. When the circuit is opened the signal moves to the "stop" position through the action of gravity. The signal-indication circuit is in all respects the same as in electropneumatic interlocking.

For the movement of a switch, current is supplied by a stroke of the lever, to an electromagnetic controlling device at the switch. Here the controlling device consists essentially of an electrically operated circuit controller so arranged that with the lever in one position the controlling device will establish a circuit to operate the switch motor in one direction; whereas, with the lever in the other position, the connections will be reversed, so that the motor will run in the opposite direction. At the end of the stroke of the

Digitized by Google

switch in either direction, a circuit controller is actuated in such a manner as to cut the motor out of circuit, and partly establish connections for the operation of the switch in the opposite direction when the proper lever movement is subsequently made.

The switch-indication circuit is in all respects the same as in the electropneumatic system. A polarized relay controlled by a pole-changer at the switch is used. The pole-changer is so arranged that in any position except the extreme ends of stroke, when the switch is locked, the wires feeding the polarized indication relay are short-circuited and disconnected from the source of energy.

For the operation of the units in this system, direct current at a potential of 110 volts is used. This is supplied to the switches and signals through heavy mains running from the storage battery in the tower. Current from these mains is fed to the motors through the electrically operated circuit controllers as already explained. These controllers are energized by current from the same battery at the same potential. The resistance of the various pieces of apparatus is such, however, that the current flowing in these control circuits is very small. Consequently the wires from the interlocking-machine levers to the units need never be of larger size than is required for mechanical strength. For the indication circuits, the potential is cut down by resistances, one at each switch or in series with each signal indication circuit, therefore the indication wires may also be small. The selection of signals and their control by the various switches in a route is accomplished through the polarized indication relays and combination contacts in the same manner as in electropneumatic interlocking. The indication magnets and the general design of the interlocking machine are the same in both systems.

**417. The electric-dynamic indication interlocking system of the General Railway Signal Co.** (see Par. **418** to **420**) was the earliest and is the most widely used system of electric interlocking. The source of power consists of a storage battery with its charging unit, which furnishes current at 110 volts for the operation of the switch and signal motors. Power-control apparatus is introduced between the battery and the interlocking machine. The interlocking machine proper is provided with levers, built generally in units so that any lever with its safety and indication magnets, accessories and housing may be removed from the frame without disturbing adjacent levers. The levers are of the sliding type which are pulled out or pushed in to operate the various units. The mechanical locking is of the vertical type, the tappet bars being moved vertically by the horizontal motion of the levers through the medium of a cam slot in each lever. Fig. 127 shows a cross-section of a unit-lever type electric interlocking machine, and Fig. 128 shows typical circuits for this interlocking system.

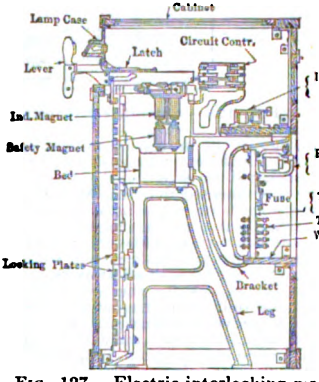

FIG. 127.—Electric interlocking machine.

Alternate levers have their handles turned upward and downward. Beside the interlocking machine, the system comprises the switch and signal mechanisms with their operating and indicating circuits and means for the prevention of unauthorized movement of any unit. Each switch or derail is thrown and locked by a switch and lock movement driven by a series-wound direct-current motor. Two wires are used for this control, one for the normal and the other for the reverse operation. These same wires are used for indicating purposes, the normal control wire being used for the reverse indication and the reverse control wire for the normal indication. The circuit is connected to the main common-return wire at each switch.

Digitized by Google

**418. Indication locking** (Par. 417). The distinctive feature of the electric-dynamic system is in its method of "indication locking," which is of the so-called dynamic type, in that the source of energy used to supply current for the operation of the switches and signals is *not* used to supply current for energising the indication magnets in the interlocking machine. In this system, whenever a switch has completed its movement and has been locked through the operation of the motor which drives it, the completion of its operation disconnects the motor from its load, permitting the former to operate as a generator under the momentum which has been acquired by the armature in operating the switch and lock. The current generated by this motor acting as a generator, is transmitted back to the interlocking machine

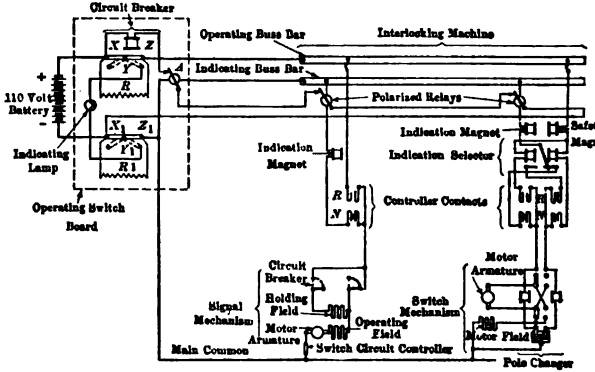

FIG. 128.—Circuits for electric interlocking system.

where it actuates the indication magnet and permits the completion of the lever stroke. In the case of signals, no return indication is necessary when a signal is operated to give the "proceed" indication. In this system, the signals are so connected that they return to the "stop" position by gravity. The counterweight, which has been raised during the operation of clearing the signal, overhauls the motor armature in being restored by gravity to its normal position; this causes the armature to generate the indication current. The indication current in this system being generated by the momentum of the motor, can only be secured after the operation of the unit driven by the motor. As the energy for the indication is developed at one end of the circuit and the indication magnet is located at the other, a cross between wires tends to prevent indication. When the momentum of the motor has sufficiently diminished, the indication current ceases. The generation of indication current serves also to retard the motor which renders unnecessary the use of buffers or other special means for stopping the movement of the apparatus without shock. Protection against the operation of the motors by foreign current is furnished by the indication circuit which forms a low-resistance path around the motor.

**419. Protection against the effect of crossed wires** (Par. 417). In this system, protection is provided for the prevention of the unauthorized movement of any switch or signal resulting from the improper application of energy to its circuit by a cross between wires. This protection is secured by cutting off current from the unit itself in the event of a cross. A small polarized relay is connected in each switch or signal circuit through which all operating and indicating currents must pass in such a direction as to maintain the relay contact closed. Conversely, currents from unauthorized sources such as crosses are compelled to pass in the opposite direction, thus opening the polarized relay. All these relay contacts are in series and control the circuit of the retaining magnet of a circuit breaker on the operating switchboard.

Digitized by Google

This circuit breaker controls the supply of current from the storage-battery to the interlocking machine. A check on the integrity of the cross-protection system is secured by having all necessary contacts and connections either on closed circuit or used in each process of operation and indication so that failure of any individual member would prevent operation and indication and would be promptly detected. A necessary feature in this system as in other electric interlockings, is the prevention of indication current from reaching any lever, while the unit normally under the control of that lever is being operated due to crossed wires from other units which may be indicating at the moment. This protection is secured by means of a safety magnet located below the indication magnet on each lever, Fig. 127. The windings of this safety magnet are included in the operating circuit of the lever, and its magnetic properties are so proportioned to those of the indication magnet, that if both were energized at the same instant, the safety magnet would overpower the indication magnet and prevent the latter from lifting its armature to trip the indication latch in the lever. Normally, the armature of the indication magnet rests upon the poles of the safety magnet. As a further safeguard, an indication selector is provided with its magnet coils in series with the safety magnet and in the control circuit. The function of this selector is to prevent possible receipt of an improper indication during the internal between the time that a lever is moved to the opposite position from that which it previously occupied, and the time the movement of the switch mechanism itself is complete.

**420. Operation in reverse direction** (Par. 417). The last portion of the stroke of the locking plunger at the switch mechanism operates the pole-changer which cuts off the operating current and puts the circuits into action for an operation in the opposite direction. The breaking of this circuit de-energizes the safety magnet, permitting the indication magnet to be energized by the current generated in the revolving motor armature. The operating circuits are so designed that the magnetic control of the pole-changer insures a correspondence in position between the lever in the machine and the operated unit outside.

## THE BLOCK SYSTEM

**421. Classification of block signaling systems.** The block system provides for the division of the railroad into lengths of track of defined limits, over which railway traffic is controlled by block signals. Block signals and block-signaling systems may be classified as follows: a (Par. 422), manual, in which the signals are operated by hand on orders or information received by telegraph or telephone; b (Par. 423), controlled manual, in which some means (generally electrical) are employed to necessitate the cooperation of the signalmen at both ends of a block in order to clear the signal admitting a train on the block; c (Par. 424), automatic, in which the signals are power-operated and are controlled by the trains themselves through the action of their wheels upon electric circuits constituted by the rails of the track. Such signals indicate the presence of a train or single car or engine in the block and also such conditions as the presence of a broken rail, an open switch or a car standing upon a siding within fouling distance of the main track.

**422. In the manual block system,** when a train has passed into any block, the signalman sets his signal to the "stop" position behind it, and notifies the signalman at the entrance to the next block of the approach of the train. This second signalman in turn consults his record to see if the signalman controlling the entrance of the third block has reported the passing of all trains out of the second into the third block which previously have been admitted to the second block. If such is the case, the signalman at the entrance of the second block will set his signal to indicate "proceed" and permit the approaching train to enter the second block. Such a system necessitates the use of very carefully prepared rules and is dependent for its safe and successful performance entirely upon the watchfulness of the signalmen and the precision with which they perform the duties prescribed for them by the rules. On single-track railroads, this system necessarily involves the protection of trains against opposing movements, and is in general supplemented by the issuance of train orders from the despatcher, which provide for the meeting of trains at other times or stations than those specified in the time-table.

Digitized by Google

**423. In the controlled-manual block system,** the levers by which the signals are operated are provided with electric locks. The solenoids of these locks must be energized to release the levers before the signals may be cleared for the passage of trains. Circuit controllers, called "block instruments," are placed in each block station and are so interconnected electrically as to require that a definite sequence of operations be performed by the signalmen at both ends of each block before the signal at the entrance of a block may be cleared. Signal bells and keys are provided for the transmission of code signals between adjacent signal stations. Adjuncts such as indicators and electric track circuits may also be installed, whereby the presence of a train in the block may effect the electric locks in such manner as to insure its own protection. The variety of apparatus and circuits necessary to afford varying degrees of protection are too diverse to be herein enumerated.

**424. The automatic block system,** which is continually coming into more extended use, has its foundation in the electric track circuit. Its cost of construction and maintenance is relatively high. Its operating cost is low as compared with any system requiring the constant presence of signalmen on duty, as would be necessary with manual or controlled-manual systems. The principles of the electric track circuit are considered at some length in Par. **392** to **403** incl.

Seldom can automatic block signals be controlled by track circuits alone. Such conditions as the existence of a number of track circuits in one block and where the position of one signal arm must be made to determine the position of another, require the use of line-wire circuits, each of which is provided with its own source of energy and one or more relays for direct control of the local signal circuits themselves. These line circuits include contacts carried on the armatures of the track-circuit relays; the latter thus indirectly control the signals through the medium of the line circuits.

The line circuits frequently pass through circuit controllers actuated by the switches in the tracks, so that the opening of any switch in the block will directly open the signal line circuit. Line circuits for the control of signals are always so designed that the source of energy is located at one extreme end of the circuit and the relay at the other extreme end of the circuit; any controlling devices are being located between these extremes. This is important in order to prevent the possibility of false "clear" indications from the supply of energy to the line relay in case crosses or grounds occur on the circuit.

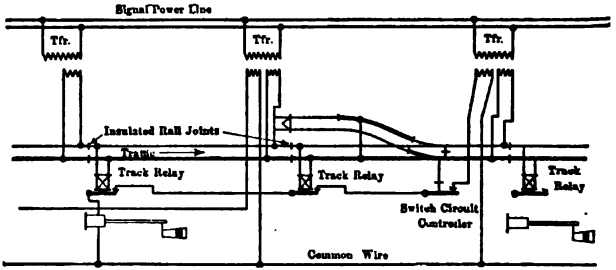

FIG. 129.—Simple field circuits. A.c. automatic block. Steam propulsion.

**425. Typical application of automatic block signalling.** Fig. 129 shows diagrammatically in simplified form, an application of line-circuit control to an automatic block signal. The track is paralleled by a power line feeding transformers which step the voltage down for the track circuits and the line circuits. The line circuit begins at one side of the transformer secondary; is carried thence through a contact operated by a circuit controller on the side track switch; thence through a contact of a track relay; next through the contact of the track relay of the other section of the block; from this point to the coils of the line relay located in the mechanism case

Digitized by Google

of the signal; and thence back over a common wire to the other side of the transformer secondary.

Fig. 129 also indicates how a portion of one of the track rails on the siding is insulated from adjacent rails and bonded to the opposite main track rail. If a train or car on the siding moves to within fouling distance of the main track, it will thus shunt the relay of the track section in which the switch is located.

**426. Automatic block signaling applied to electric railways.** Fig. 130 shows a simplified form of automatic block signal circuit for one track of a double-track railway using direct-current propulsion and two-rail alternating-current track circuits, the signals themselves being operated by direct current from batteries. Alternating-current track relays are generally of the vane, galvanometer or induction-motor type. In the first named, an aluminum sector revolves between the poles of a C-shaped laminated core, in which the winding is placed. This winding is connected across the rails of the track circuit and receives current through the rails from the transformer

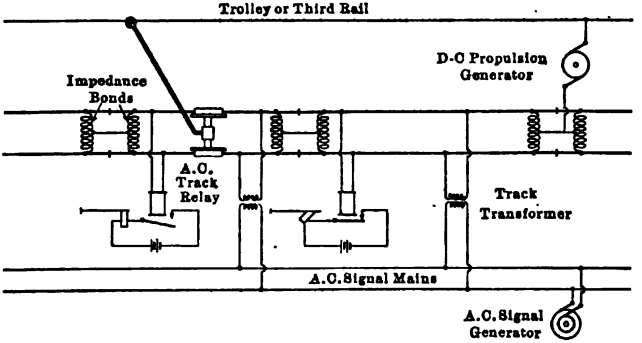

FIG. 130.—Typical circuits. Power supply for a.c. track circuits.

at the other end of the track circuit. The galvanometer type of relay has a set of fixed coils energized from a local source, and a movable coil energized from the track circuit. In the induction-motor type of relay both the track and the local windings are fixed, and the rotor is made to revolve by phase displacement in the current of the two windings. In all types the moving member carries or actuates contacts through which are controlled the circuits controlling the operation of the signals themselves.

The transformers which supply energy to the track circuit also supply energy to the local windings of motor-type track relays together with any line or secondary relays necessary in the circuits; in addition they supply energy for the operation of the signal mechanisms proper. The transformer secondary windings supplying current to the track rails are generally provided with a number of taps, so that the voltage impressed on the track may be regulated to suit the length or characteristics of the track circuit. The secondaries are naturally provided with series resistances which limit the current output when the secondary is short-circuited by the presence of a car in the block.

## BIBLIOGRAPHY—RAILWAY SIGNALING

**427. Association reports.** Comparatively few books have been written on the subject of railway signaling, most of the available data being found in periodical technical literature, in publications of engineering societies, and in the bulletins and catalogues issued by the manufacturers of signal apparatus. The last mentioned source is voluminous, as such publications are frequently issued and contain much valuable technical information.

Digitized by Google

The following associations regularly publish committee reports on signaling. Publications are listed below their names as follows:

American Electric Railway Association, 29 West 39th St., New York, N. Y. Proceedings, Standard Rules.

American Railway Engineering Association, 900 So. Michigan Ave., Chicago, Ill. Bulletins, Manual of Approved Practice. (This applies mostly to steam railroad signaling.)

Railway Signal Association, Bethlehem, Pa. Journal (Quarterly), Manual (Standard plans and specifications), Index to Signal Literature.

The rule book of the American Railway Association, containing the standard code of train rules, block-signal rules and interlocking rules, is the basis from which almost all other rule books have been developed. The School of Railway Signaling, Utica, N. Y., publishes text-books and correspondence courses of study in railway signaling.

**428. Periodicals.** The following are the principal periodicals which deal with signaling: *Electric Railway Journal*, 239 West 39th St. (weekly). *Railway Age Gazette*, Woolworth Bldg., New York, N. Y. (weekly). *Signal Engineer*, Transportation Bldg., Chicago, Ill. (monthly).

**429. Dictionaries and published bibliographies.** The most important compilation of information on signaling is the signal dictionary, second edition, 1911, *Railway Age Gazette*, Woolworth Building, New York, N. Y. By far the most complete bibliographies of signaling are the following:

Index to Signal Literature, Vol. I, October, 1910, Railway Signal Association, Bethlehem, Pa.

Bibliography on Block Signals for Electric Railways, pages 227 to 298, Proceedings of the American Electric Railway Association, 1913.

## ELECTROLYSIS OF UNDERGROUND STRUCTURES

**BY ALBERT F. GANZ**

*Professor of Electrical Engineering, Stevens Institute of Technology, Fellow, American Institute of Electrical Engineers*

### NATURE AND CAUSES

**430. General cause of electrolysis.** Electrolysis is defined as chemical decomposition by an electric current. If the anode by which an electric current enters an electrolyte consists of a metal which can combine chemically with the anions set free by the electrolytic action, then this anode will be decomposed or corroded. This electrolytic corrosion of an anode is what will be referred to as electrolysis in this discussion.

**431. Stray or vagabond currents.** Stray or vagabond currents are electric currents which have leaked from grounded electrical distribution systems and flow through earth. These stray currents in their path through earth may reach underground metallic structures, such as piping systems and the lead sheathing of cable systems.

**432. Stray currents from direct-current electric railways.** In the simplest arrangement of electric railways using the tracks as return conductors, the rails are connected to the negative terminal of the generator at the power station or substation, and the current returns to the station through the rails. Where these rails are in contact with ground, part of this current will shunt through the earth and through underground metallic structures, as is illustrated in Fig. 131. Current will leave the rails and enter the earth at distant points, and will return to the rails in the neighborhood of the power station.

**433. Electrical properties of soil.** Soil when dry has such a high resistivity that, practically, it does not conduct electric current. Under ordinary conditions, however, soils contain considerable water with various salts in solution, making them electrolytic conductors. An electric current therefore passes through soil by electrolytic conduction. The resistivity of soils varies within very wide limits, depending upon the amount of moisture and salts present. Average values lie between 10 and 1,000 ohms for one foot cube (approximately 300 to 30,000 ohms for 1 cm. cube).

Digitized by Google

**434. Distribution of potentials in rails and earth.** For the simple arrangement illustrated in Fig. 131, the distribution of potentials is shown in Fig. 132. The following assumptions are made in the development of these curves: (a) the negative bus bar is connected to the rails at the power station by an insulated cable, with no other ground connections; (b) the line extends in one direction only; (c) the load is uniformly distributed over the line; (d) a pipe of uniform resistance lies in the earth parallel to these rails; (e) the resistance between the rails and pipe is everywhere the same. With these assumptions, the current in the rails will increase uniformly from zero at the end of the line to its greatest or total load value at the power station *O*. Taking the negative bus bar and this point *O* as the datum or zero of potential, the potential of the rails is represented by the parabola *OI*. The voltage *OD* is the total rail drop. There will be a neutral point *N* in the rails at a distance 0.42 of the total length of the line from the power station where these rails are at the ground potential. Between the power station and *N*, the rails are negative with respect to ground, and current flows from ground to the rails; while from *N* to the end of the line *E*, the rails are positive with respect to ground, and current flows from the rails to the ground.

The pipe of Fig. 131 will have a potential shown by the curve *A-H* in Fig. 132. Between *O* and *N* the pipe is positive, and this, therefore, constitutes a positive region. Conversely, between *N* and *E* the pipe is negative

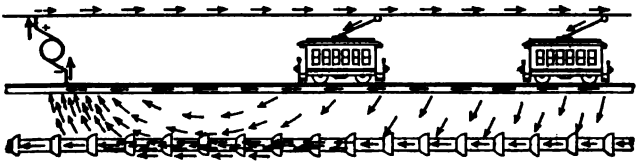

FIG. 131.—Conditions contributing to electrolysis.

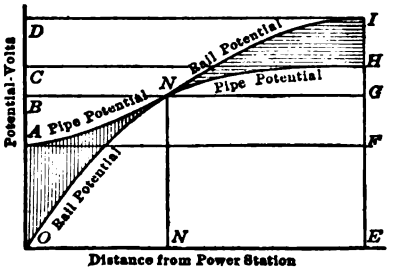

FIG. 132.—Distribution of potentials.

and this is a negative region. The current flow between pipe and rails is proportional to their potential difference. The total current flowing from rails to pipe, shown by the shaded area *N-I-H*, is equal to the total current flowing from pipe to rails, shown by the shaded area *O-A-N*. The current on the pipe will be a maximum at the neutral point *N*, and will be zero at the power station and at the end of the line. The greatest negative potential *C-D* of the pipe, with reference to the rails, will be at the end of the line; and the greatest positive potential *O-A* of the pipe will be at the power station. For the case assumed, the greatest positive potential will be twice the greatest negative potential. The total rail drop *O-D* is equal to the sum of the three voltages, the greatest positive pipe potential *O-A*, the greatest negative pipe

Digitized by Google

potential *C-D*, and the voltage drop on the pipe *A-C*. This voltage drop on the pipe is a measure of the current flowing on it, and is therefore a measure of the danger from electrolysis to which the pipe is subjected. If no current flows on the pipe there will be no voltage drop on it, and the pipe potential curve *A-N-H* will coincide with the horizontal line *B-G*. The positive and negative potentials of the pipe referred to the rails will however be increased, which shows quite clearly that the magnitude of the voltage between pipe and rails is not a measure of the danger from electrolysis.

Where there are rail networks and underground piping networks, the potential distribution curves are correspondingly altered, but follow the general trend of those given in Fig. 132.

**435. Where electrolysis occurs.** Wherever electric current leaves a metal to flow to soil, corrosion from electrolysis is produced. In positive regions stray currents generally flow from underground structures to rails and corrode these structures by electrolysis. The greatest density of current leaving will generally occur where the positive potential is highest, namely, in the neighborhood of the power station; here the destruction by electrolysis is usually most severe. Underground structures may also be destroyed by electrolysis in regions where they are negative to the rails, and far away from any return feeder connections, because of currents shunting from one set of underground conductors to an adjacent set. A case frequently met in practice is where underground gas or water service pipes cross lead cable sheaths to which they are positive, and where current flows from the service pipes to the cable sheaths, causing rapid destruction of the pipes by electrolysis even though they are negative to adjacent trolley rails. If there are one or more high-resistance joints in a pipe line carrying stray electric current, then current will shunt around these joints and produce corrosion on the positive side of the joint and frequently for many pipe lengths on the positive side of the joint.

**436. Nature of corrosion of cast iron by electrolysis.** When cast iron is corroded by electrolysis, the oxides of iron mixed with graphite usually remain in place, leaving the outward appearance of the pipe unchanged. This material resulting from electrolysis of cast iron usually has the consistency of hard graphite and possesses little mechanical strength. The oxide of iron together with the surrounding soil frequently prevent noticeable leakage of gas or water, even when corrosion has extended entirely through the metal of the pipe. In such cases a physical examination with a test hammer is required to establish definitely whether the pipe has been damaged by electrolysis. Current generally leaves iron pipes for soil from localized areas, resulting in localized corrosion of the metal. In the case of cast iron corroded by electrolysis, the graphitic residue can usually be dug out with a knife, exposing pits in the pipe.

**437. Nature of corrosion of wrought iron and steel by electrolysis.** Where electric current leaves a wrought-iron or steel pipe for soil, the oxide of iron resulting from electrolysis is diffused through the soil. The action is also generally localized, resulting in pits which eventually go entirely through the wall of the pipe.

**438. Relative danger from electrolysis to cast-iron and wrought-iron or steel pipes.** For a given current leaving an iron pipe for soil, there is practically no difference in the rate of corrosion by electrolysis among cast iron, wrought iron and steel. The electrical resistivity of cast iron is, however, about ten times as great as that of wrought iron or steel, and the usual lead joints in cast-iron pipes have a resistance which is many times greater than the screw-coupling joints usual with wrought-iron and steel pipes. For these reasons a given voltage drop through earth will, in general, cause a much smaller current to flow on a cast-iron pipe than on a wrought-iron or steel pipe, thus practically making cast-iron pipes much less subject to electrolysis than wrought-iron or steel pipes with screw-coupling joints. With ordinary conditions of soil, and with current densities of less than 5 amp. per sq. ft. (about 5 milliamperes per sq. cm.), as ordinarily found with stray railway currents leaving underground piping for surrounding soil, iron is oxidized by electrolysis at the rate of approximately 20 lb. (9 kg.) per year for every ampere leaving the pipe. Under some conditions, particularly with very small current densities, this corrosion may be considerably greater, while with larger current densities than the above this

Digitized by Google

corrosion may be considerably less than the theoretical rate. The amount of corrosion produced by electrolysis is independent of the applied voltage, except in so far as this voltage determines the amount of current flowing.

**439. Corrosion of lead and tin.** Where electric current leaves lead or lead alloyed with a small percentage of tin to flow to surrounding soil, the metal is oxidized by the electrolytic action, forming white or yellow salts. The rate of oxidation of lead by electrolysis under ordinary conditions is equal to approximately 74 lb. (34 kg.) for every ampere leaving the lead in one year. Where lead-sheathed cables are drawn in clay conduits, stray current may flow from the cable sheaths to water in the conduit or to the damp conduit itself. In such cases pittings are usually produced at the lower surfaces of the cable sheaths. Owing to the thin walls usual with lead cable sheaths, together with the high electrochemical equivalent of lead, such cable sheaths are damaged by electrolysis far more easily than are iron pipes.

## ELECTROLYSIS SURVEYS

**440. Nature of survey.** The principal measurements generally made in an electrolysis survey of an underground pipe or cable system are as follows: a, voltage measurements between the pipes or cable sheaths and the rails (Par. 441); b, voltage measurements between the pipes or cable sheaths and other underground metallic structures (Par. 441); c, measurements of current flowing on the pipes or cable sheaths (Par. 442). In order to be able to completely judge the electrolytic condition of an underground metallic system and to be able to decide upon remedial measures, it is necessary in addition to make measurements of rail drop and of the resistivity of the soil in various parts of the system.

**441. Potential survey.** To make a potential survey, potential differences between the underground structures and rails are measured at a number of points along every street where these structures and electric railway tracks are located. With lead cable sheaths contact is made directly on these sheaths in manholes. With underground pipes contact may be made by means of service pipes, hydrants or drip connections. The connections used for the potential measurements may be tested for continuity by means of an ammeter momentarily connected between the contacts with a dry cell in series if necessary. Where there are a number of underground metallic structures which may be affected by electrolysis, it is desirable to make simultaneous measurements of potential difference between the rails and each of these structures, and from these results to compute the potential differences between each pair of structures.

**442. Current survey.** To determine the current on a pipe or cable sheath, the drop between two points on a continuous length of pipe or sheath is measured by means of a millivoltmeter. From tables of pipe and cable sheath resistances, as given on the following pages, the strength of current may be computed by Ohm's law. For convenience the currents corresponding to one millivolt drop in a 1-ft. length of pipe or cable sheath are also given in the tables. This figure for current, divided by the distance in feet between the millivoltmeter contacts, and multiplied by the reading in millivolts, is the actual value of the current flowing. Where great accuracy is required, the resistance of a pipe or cable sheath should be measured instead of computed from its dimensions. In the case of lead cable sheaths, the drop measurements can usually be made in manholes where the cables are exposed. In the case of iron pipes, the millivoltmeter leads must be connected directly to the metal of the pipe on which current is to be measured; and no joint must be included between the two contacts. Service pipe connections cannot be used for such current determinations. Temporary contacts are conveniently made by means of a sharpened piece of steel rod, fastened in a wooden handle, with connecting leads soldered to the rod inside of the handle. For permanent connections which can be used at any time for measuring drop on the pipe without again exposing the pipe, rubber-insulated wires may be soldered to brass plugs and these screwed into the pipe; the wires are then brought to the street surface, preferably inside of the curb, and the free ends left in drip or service boxes. It should be noted that small potential differences, such as 0.1 millivolt or less, may be caused by local galvanic or thermal action, and care should therefore be taken that such observations do not lead to erroneous conclusions.

Current measurements on pipes or cable sheaths are frequently made at two or more stations simultaneously in order to determine whether there is a gain or a loss of current between the stations. This is the most reliable method of determining localities where current is leaving the structure and where corrosion is probably taking place.

**446. Instruments.** Millivoltmeters for measuring drop on pipes or cable sheaths should have as low a millivolt range and as high a resistance as practicable. Moving-coil permanent-magnet instruments of the Weston type having zero in the centre of the scale are the most suitable for this work. The millivoltmeter can be conveniently combined in one instrument with a voltmeter for the potential measurements. These instruments may be obtained with resistances of 600 ohms per volt and even higher where necessary. Convenient ranges for such a combination instrument are .5, 50 and 500 millivolts, and 5 and 50 volts. Ordinary shunts adjusted for 50 millivolts drop can also be used with this instrument. Convenient ranges for such shunts are 5, 50 and 500 amperes. Recording instruments having the same ranges as above noted can also be used for obtaining 24-hr. records, by means of which the characteristic variations of a potential difference or of a current may be obtained. Such recording instruments with 1-hr. clocks are also useful for recording potential differences and current in cases where, due to infrequent service, it is necessary to take readings for periods of from ½ hr. to 1 hr.

**447. Measurement of earth potential.** It is possible to trace the path of stray current through earth by measuring potential differences between points in the earth. When iron rods are used as electrodes for making contact with earth an error may be introduced, where the voltage measured is small, due to a possible difference in the polarisation voltages at the two electrodes. This polarisation voltage may be eliminated by using a non-polarizable electrode, developed by Dr. Haber. With this electrode electrolytic contact is made with soil by means of a zinc sulphate solution contained in a porous cup; the potential lead is connected to a zinc rod dipping in the solution. With this electrode the contact resistance is very high, so that a zero method and not an indicating voltmeter should be used for the potential measurement. This makes the method very troublesome in ordinary electrolysis testing, where the voltages to be measured generally fluctuate constantly. For this reason this electrode is useful only in very special cases. For description of the non-polarizable electrode see the paper by Haber and Goldschmidt listed in the bibliography.

**448. Measurement of earth current.** It is often desirable also to measure directly the flow of stray current through earth. This can be done by means of the Haber earth ammeter, which consists of a wooden frame supporting two copper sheets insulated from each other by a plate of mica or glass. Insulated copper wires connect the two copper sheets with an ammeter. To use the frame, the two copper plates are coated with a paste made of copper sulphate and a 20 per cent. sulphuric-acid solution for the purpose of equalizing polarisation voltages. A wetted piece of parchment paper is then laid over the paste, and the remainder of the frame is filled with soil. If the frame be buried in the earth with its plane normal to the direction of the current flow, the ammeter will indicate the current which is intercepted by the buried frame. This earth ammeter is well suited for measuring current flow between a pipe and earth. For this purpose the frame is buried in the earth near and parallel to the pipe. By using a recording instrument in connection with the earth ammeter, the characteristic variations of the current leaving a pipe can also be determined, and in this way the identity of the current can often be established. For description of the earth ammeter see the paper by Haber and Goldschmidt listed in the bibliography.

**449. Physical examination.** From a study of the results of a general electrolysis survey, it is possible to determine in what regions current is leaving an underground system. In the case of underground pipes, excavations should then be made where current is leaving, and the exposed pipe should be tested with a hammer for effects of electrolytic corrosion.

## PREVENTION OF ELECTROLYSIS

**450. General description of different methods.** The only method which will entirely prevent electrolysis from stray railway currents is the use

Digitized by Google

of a completely insulated return circuit, as obtained with a double-trolley system (Par. 451 and 452). The methods which have been tried for minimizing electrolysis from stray railway currents may be divided into three classes: a, the **insulation method** (Par. 453 to 455), which is intended to increase the resistance of the path of the current through earth; b, the **drainage method** (Par. 456 to 458), which essays to remove the current harmlessly from structures by metallic connections or bonds between these structures and the railway return circuit; and c, the **return-feeder method** (Par. 458 to 460) which aims to reduce the voltage drop in the grounded rails.

**451. Brief description of double-trolley systems and where used** (Par. 452). Double-trolley railways (Par. 335) may be provided with positive and negative overhead trolley wires insulated from ground, as used for example in Washington, D. C., Cincinnati and Havana; with positive and negative conductors in underground conduits insulated from ground, as used on the surface lines on Manhattan Island and in Washington, D. C.; or with separate insulated third and fourth rails for the positive and negative conductors, as used on the Metropolitan District Railway in London.

**452. Objections to double-trolley systems** (Par. 451). The principal objection to the underground double-trolley system is the very high cost of installation, which makes this method practicable only in densely populated districts. The principal objections to the double-overhead-trolley system are the high cost of installation and the complication resulting from two overhead trolley wires, especially at crossings and where several lines meet and are on common tracks.

**453. Insulation of rails.** Where a road operates on a private right-of-way, the rails can often be practically insulated from ground, and the escape of current from the rails substantially prevented. For surface or subway lines this can be accomplished by placing the rails on wooden ties above ground and using broken stone for ballast. For lines operating on elevated structures substantial insulation may be secured by fastening the rails on wooden ties and keeping them out of metallic contact with the structure.

**454. Insulation of pipes.** Attempts have been made to insulate pipes from earth by paints, dips and insulating coverings. Practical experience as well as a large number of tests have however shown that no dip or paint will permanently protect a pipe against electrolysis in wet soil. The first difficulty is so to apply the paint that an absolutely perfect coating is formed. It is also necessary to prevent mechanical damage to the coating. Where imperfections exist or develop, aggravated trouble may result. Experience further shows that even where paints or dips are apparently intact, electrolytic action is not always prevented, and, in fact, very serious electrolytic pittings have been found under apparently good coatings. It has been found that in most cases the coatings applied have either been completely destroyed by the effects of the wet soil and the electric currents, or defects in the coating have developed, causing concentrated corrosion at such defective spots. The destruction of paints in wet soil where subjected to an electric current is probably due to a trace of moisture finding its way through the coating, giving rise to the flow of a feeble current and resulting in a very slight amount of electrolysis. The gases and other products of electrolysis then form blisters and finally rupture the coating. Pipes in positive districts covered with imperfect insulating coatings are in greater danger from electrolysis than bare pipes. Coating pipes in negative districts with insulating coverings does some good in reducing the amount of stray current which reaches the pipes. Where it is attempted to apply a heated material like pitch or asphaltum to a cold pipe, it is impossible to completely cover the pipe. The only kind of insulating covering which appears to afford certain protection is a layer of at least 1 or 2 in. of a material like coal-tar pitch or asphaltum, of such a grade that it is not brittle and so will not crack, but yet is hard enough to remain in place. The best way to apply such a layer is to surround the pipe with a wooden box, to support the pipe upon creosoted blocks of wood or upon blocks of glass, and then to fill the space between the box and pipe with the molten material. The cost of carrying out such an installation is however prohibitive except in a few special cases, such as service pipes in very bad localities, or in the case of some very important individual pipe lines of small size. Embedding a pipe in cement or concrete, even if this is several inches in thickness, will not protect a pipe from electrolysis, because damp concrete is an electrolytic conductor like soil.

Digitized by Google

**455. Insulating joints in pipes or cable sheaths.** Current flow on pipes or cable sheaths can be practically prevented by using a sufficient number of insulating joints. A pipe line laid entirely with insulating joints has a comparatively high resistance and cannot pick up current in an extensive negative area and discharge it in a restricted positive area, which is generally the cause of the most serious electrolytic danger. It is sometimes possible to use comparatively few insulating joints to break up the electrical continuity of a pipe line, and so to protect the line from electrolysis. Such joints, however, must be installed only after careful tests have shown that the current is not likely to shunt through earth around them and thus incur a condition worse than the previous one. This effect depends largely upon the potential gradient through earth, and also upon the electrical resistivity of the soil.

For wrought-iron or steel pipes of small size, the Macallen, the Hammon and the Dresser insulating joints are largely used. For large sizes, a flanged insulating joint as shown in Fig. 133 is often used. For gas or oil pipes, red fibre has been found a satisfactory insulating material, while for water pipes,

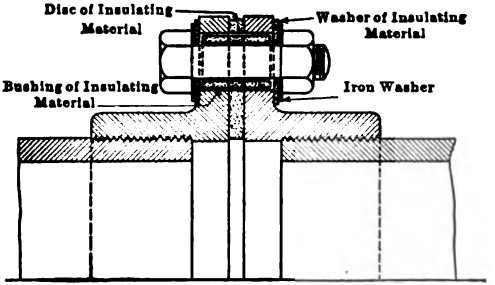

FIG. 133.—Insulating pipe coupling.

soft sheet rubber is preferred. Where such flanged insulating joints are to be used in cast-iron mains, the flanges may be cast as part of the pipe. For water mains various forms of insulating joints employing white pine wood for the insulating material have also been successfully used. A simple form of this joint for cast-iron water mains with bell and spigot joints, is made by placing a short wooden ring between the inside of the bell and the end of the spigot to prevent metallic contact between the pipe lengths, and then calking the joint with wooden staves of clear white-pine wood shaped to fit the curvature of the pipe. The spigot end of the pipe should have the bead removed or be cast without a bead. Any leaks that develop are stopped with white-pine wedges. These joints have been found satisfactory for pressures up to about 75 lb. per sq. in. (5.27 kg. per sq. cm.). Higher pressures sometimes cause moderate leakage through the pores of the wood; this has been overcome by dipping the inner ends of the staves in red lead. The staves may also be reinforced by an iron band clamped around the spigot end of the pipe. Cement joints in cast-iron pipes as ordinarily made do not produce metallic connection between the adjoining pipes and may practically be classed with insulating joints. Metallic contact may be positively prevented by inserting a ring of any cheap insulating material between the end of the spigot and the interior of the bell.

**456. Drainage method.** Since stray currents cause damage only where they leave metallic structures and flow to surrounding soil, attempts are sometimes made to remove the current harmlessly by connecting or bonding these structures, by metallic conductors, to the rails or to the negative return circuit or directly to the negative bus bar. This is known as the drainage method. The lead sheaths of underground cables form continuous and uniform metallic conductors, and it is possible to protect such cable sheaths against electrolysis by bonding them to the railway return circuit. Through such bond connections however only enough current should be drained from

Digitized by Google

the cable sheaths to render them at the same potential or slightly negative with respect to neighboring structures. The effectiveness of bonding as a protective measure depends upon the uniformity of the conductor to be protected. The method is therefore not generally applicable to underground piping systems, because these do not form continuous electrical conductors, but are more or less discontinuous networks. While lead-calked joints usually have a relatively low resistance, they frequently develop such high resistances as to make them practically insulating joints, due undoubtedly to the formation of oxide coatings.

**457. Possible dangers from drainage connections.** Drainage connections to underground metallic structures have the objection of paralleling the trolley rails by a low-resistance grounded conductor, thereby greatly increasing the total stray current through earth and on underground structures. Such drainage connections will generally result in greatly increasing the stray current flowing on the structure, giving rise to the danger of current shunting across high-resistance joints or shunting from one section of the system to an adjoining section. Also, where such connections are applied to a gas or water piping system, large stray currents are often caused to flow through buildings by way of the service pipes. These stray currents cause a serious danger from possible fires as well as from possible gas poisoning or gas explosions. Another serious objection is that such drainage connections make the structure negative in potential to all other underground structures, thereby setting up a tendency for current to flow from such other structures to the bonded structure. A piping or cable system which is bonded to the railway return circuit, thereby becomes a source of danger to all other structures which are not so connected, and this danger increases as the negative potential is increased.

Drainage connections to underground structures should never be used until the railway return circuit has been sufficiently improved, so that only small amounts of stray current are made to flow over such connections. With the construction of electric railways common in America, drainage connections to underground cable sheaths are generally necessary to protect the thin-walled lead cable sheaths against stray-current electrolysis. In the case of piping systems such drainage connections are however not to be used except in special cases, and then only as a final measure to remove small remaining currents.

**458. Reverse-current switches for drainage connections.** Cases arise where the polarity of underground structures reverses at times with reference to the railway return circuit. Consequently, where these structures are provided with metallic connection to the railway return circuit, current would be made to flow to these structures when these are negative in potential. To prevent this, automatic reverse-current switches are used in series with the drainage connection. The action of these switches is to keep this circuit open while the structures are of negative potential, and closed while they are of positive potential. Such reverse-current switches are frequently used in connection with drainage connections from telephone cables.

**459. Insulated return feeder system.** Since the drop in potential in grounded rails is the cause of the flow of stray current through the earth, the escape of stray currents will be reduced in the proportion that the drop in the rails is reduced. It is therefore desirable to use heavy rails of high electrical conductivity, and to maintain these rails perfectly bonded, so that they form continuous low-resistance conductors. The next important consideration is to limit the distance from the supply station to which this station delivers direct-current power, so that current is not returned through an excessive length of track; this is usually accomplished by the use of a number of distributed substations. Finally, the current should be removed from the rails by means of insulated return feeders connected to the rails. These feeders draw current from the rail at such points as are necessary to avoid both an excessive potential gradient in the tracks and through earth and an excessive total voltage drop in the tracks. Where it is necessary to bring current back from a distant point in the tracks, it is sometimes more economical to employ a negative booster in series with a return feeder of small cross-section, than to make this feeder of cross-section large enough to drain the required current from the tracks at the distant point. It may also be necessary to install resistances in short feeders. With such insulated track return feeders, part of the voltage drop is removed from the rails and is transferred to the insu-

Digitized by Google

lated return feeders, from which current cannot leak to ground. With this arrangement of insulated return feeders, the rails may be utilised as return conductors to the extent that the potential gradients and total track drops do not exceed safe limiting values.

A diagrammatic sketch of an insulated track return feeder system proportioned for equal drop is shown in Fig. 134. In this illustration it is assumed that the negative bus bar is at zero potential, and that the return-feeder

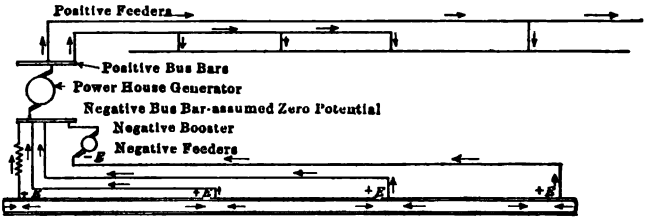

FIG. 134.—Insulated track-return feeder system.

connection points on the rails are maintained at a potential of $E$ volts with reference to the negative bus bar. Where a number of lines extend in different directions, the same arrangement of insulated return feeders must be applied to each of the lines. It should be observed that in this system the negative bus bar must not be connected to any ground contacts nor to the tracks in the neighborhood of the power station, except through suitable resistances; under these conditions the negative bus bar is said to be in-

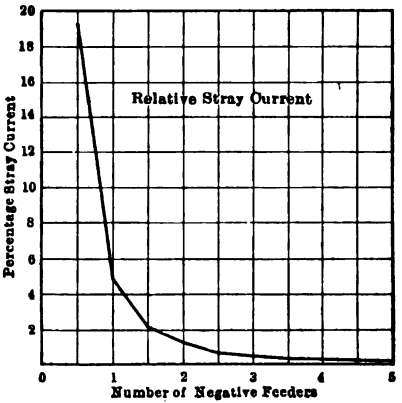

FIG. 135.

sulated. The possibilities of reducing stray currents by means of properly proportioned insulated return feeders as illustrated in Fig. 134 was clearly shown in a paper by Mr. George I. Rhodes (see bibliography). The diagram in Fig. 135 is reproduced from this paper. This shows the relative leakage currents with negative bus bar insulated and with various numbers of insulated return feeders proportioned for equal drop and connected to symmetrical points in the track. The points halfway between integral abscissas in Fig. 135, correspond to a connection between the negative bus bar and the

Digitized by Google

rails at the power station, with a resistance in the connection proportioned to maintain this point in the rails at the same potential as the other return-feeder connection points. The unit of leakage current is assumed as the amount which flows when the negative bus bar is grounded through a negligible resistance, the rails being connected to the negative bus bar only at the power station. In practice each return feeder would actually be connected to a number of points in the rails in the immediate neighborhood of the connection points shown.

**460. Examples of installations of insulated return feeder systems.** Such systems are in almost universal use in Germany and in Great Britain, and have given most satisfactory results. In America a considerable number of such systems have also been installed, the most prominent reported example being on the subway system of the Interborough Rapid Transit Company in New York City. Description of insulated return feeder systems installed in Springfield, Ohio, and in St. Louis, Mo., are given in Bureau of Standards Technologic Papers No. 27 and No. 32.

**461. Advantages of the insulated return feeder system.** This system is intended to relieve the tracks of current by insulated conductors, and thus tends to prevent the escape of current into earth. With a properly laid out return feeder system and properly bonded tracks, it is possible and practicable to reduce stray currents through earth and therefore stray currents on underground piping and cable systems to any desired minimum values and such currents may be made so small as to be negligible. This system, therefore, removes the cause of the trouble in that it minimises the escape of current into earth.

## ELECTROLYSIS FROM GROUNDED ELECTRICAL DISTRIBUTION SYSTEMS

**462. Grounded neutrals in three-wire direct-current systems.** Direct-current electric-lighting systems in which the distribution is on the Edison three-wire plan, having the neutral conductor grounded, are, in American practice, provided with such large neutral conductors of copper that only negligible stray currents are produced from such systems. This grounding of the neutral is intended to serve only as a safety measure, and is not for the purpose of using the earth to carry current.

## ELECTROLYSIS FROM ALTERNATING CURRENTS

**463. Damage relative to direct-current electrolysis.** A large number of laboratory tests have been made to determine whether electrolysis is produced when an alternating current flows between a metal and an electrolyte, as for example between a pipe and surrounding soil. These indicate that slight electrolytic corrosion may be produced; this effect is generally less than 1 per cent. of that which would be produced by a corresponding direct current. With alternating current, however, electrolytic corrosion is produced at both electrodes, while with direct current, electrolytic corrosion occurs only at the positive electrode.

**464. Grounded transformer secondaries.** The secondaries of transformers are frequently grounded, for the purpose of preventing a high and dangerous voltage from existing between the secondary circuit and ground. Such ground connections however do not produce flow of current to ground, and such grounding of transformer secondaries therefore does not cause danger from electrolysis.

## ELECTROLYSIS IN CONCRETE

**465. General effects.** Concrete when damp is an electrolytic conductor having a resistivity of the same order as damp soil. When iron is embedded in damp concrete and an electric current flows from the iron to the concrete, the iron may be oxidised by the electrolytic action. The oxides of iron formed occupy more space than the original iron, with the result that an outward pressure is produced which in time may crack the concrete. An exhaustive investigation of the effect of electrolysis on iron embedded in concrete has been made at the Bureau of Standards in Washington, and the results of this investigation are published in Technologic Paper No. 18 of the Bureau of Standards. This investigation appears to show that when no chlorides are present, the iron is practically passive at temperatures below 45 deg. cent.

Digitized by Google

but becomes active at higher temperatures. With large current densities, the heating effect of the current will destroy the passivity of the iron. When chlorides, even in very small amounts, are present, however, the iron is active at all current densities. These investigations also show that when current flows from the concrete to iron a softening of the concrete is produced close to the iron, which eventually destroys the bond between the two.

**466. Reinforced-concrete structures.** In order that a reinforced-concrete structure may be damaged by electrolysis, it is necessary that an electric current flow between the reinforcing steel and the surrounding concrete. Such current may be leakage current from a direct-current lighting system, or stray railway current brought into the building by means of service pipes. The conditions required for producing electrolysis of steel embedded in concrete are such, however, that this can result only in extreme cases; for example, where a direct contact is established between the reinforcing steel and one side of a direct-current lighting system, or where stray railway current of sufficient magnitude is brought by way of service pipes into contact with the reinforcing steel. It is therefore a safe precaution to install insulating joints in all pipes which lead to reinforced concrete structures from earth. It has been proposed to protect reinforced-concrete by making the reinforcing steel continuous throughout, and connecting it to the negative terminal of a low-voltage generator. While this would prevent corrosion of the steel, it might result, however, in greater danger, on account of the possible destruction of the bond between the reinforcing steel and the concrete.

**467. Structural foundations.** Where steel foundations are embedded in concrete, it is important to guard against stray electric current reaching the steel from external sources and then flowing from the steel to the concrete, because corrosion of the foundation steel and cracking of the concrete may result.

## MUNICIPAL AND STATE REGULATIONS

**468. General.** Municipal and state regulations, designed to minimize the escape of electric currents from electric railways using a grounded return circuit, generally attempt to limit the total allowable voltage drop and the allowable potential gradient in the grounded return circuit or grounded rails. Additional requirements limiting the total allowable current escaping from the system are included in some regulations. A few brief references to regulations which are at present in force, are given in Par. **469** to **472**.

**469. British Board of Trade regulations.** The two most important of these regulations are Regulations No. 7 and No. 8. The former limits the allowable difference of potential between any two points in the uninsulated return circuit to 7 volts, and requires that continuous records be kept by the railway company, of the difference of potential between certain points on the uninsulated return circuit. Regulation No. 8 limits the allowable current density in the rails to 9 amp. per sq. in. of cross-section (1.4 amperes per sq. cm.), which with ordinary steel is equivalent to an allowable potential gradient of approximately 0.8 volt per 1,000 ft. (0.305 km.) of rail.

**470. German electrolysis regulations.** In Germany a joint committee, representing the German Society of Gas and Water Engineers, the Society of German Electrical Engineers, and the Society of German Street Railway and Little Railway Managers, adopted in 1910 regulations for the protection of underground structures against electrolysis. The track network is divided into an inner district and an outer or suburban district. In interurban lines the parts near villages are designated as suburban districts. The potential difference between any two points on the track must not exceed 2.5 volts under average load conditions in the inner district, and on a bordering belt 2 km. (6,562 ft.) wide; outside this zone in the suburban districts, the voltage drop must not exceed 1 volt per kilometer (3,281 ft.).

**471. American municipal ordinances.** A number of American cities have enacted ordinances designed to prevent damage by electrolysis. In 1912 the City of Chicago enacted an electrolysis ordinance, the most important feature of which is the voltage requirement, limiting the permissible difference of potential between any two points on the uninsulated return circuit to 12 volts, and limiting the potential gradient in the rails within 1-mile radius of the City Hall to 1 volt per 1,000 ft. (0.305 km.), and outside of this 1-mile radius to 1 volt in 700 ft. (0.213 km.). In 1913 the City of Chicago enacted

Digitized by Google

what is known as the Unification Ordinance, which also contains clauses relating to electrolysis. These divide the city into three zones, and prescribe different voltage limitations for each zone. The Board of Supervising Engineers is, however, authorized to modify these voltage requirements as may be deemed advisable. The above ordinances although not entirely in accord are both in effect in Chicago.

In a number of cities in Ohio electrolysis ordinances have been enacted in which the most important features are track voltage requirements. In these ordinances the average potential difference during any 10 consecutive minutes between any two points 1,000 ft. (0.305 km.) apart on the uninsulated return circuit must not exceed 1 volt, and the average potential difference during any 10 consecutive minutes between any two points more than 1,000 ft. (0.305 km.) apart on the uninsulated return circuit within the limits of the municipality must not exceed 7 volts.

**472. Legal status of liability for electrolytic damage.** There has been considerable litigation at various times with reference to damage from electrolysis. It has been held by various courts that no one utility can claim the exclusive right to use the earth as a return circuit, and that priority of such use is of no importance to either side of the controversy.

**473. Peoria decision.** In the celebrated Peoria case which was finally decided after having been in the courts for over 10 years, the railway company was enjoined and restrained from injuring the property of the water company by electric current escaping from the rails or structures of the railway company. No particular method for preventing escape of current is prescribed in the decree, because the court in its decision states that a court does not have the power to prescribe by injunction any specific system, and that this power resides only with legislative bodies. The decree also requires the water company to co-operate with the railway company to the extent of giving the railway company access to its piping system for the purpose of measuring flow of current upon its system and of determining whether injury from electrolysis is being continued, in order that the railway company may determine whether it is complying with the terms of the decree.

# SECTION 17

## ELECTRIC COMMERCIAL VEHICLES

### GENERAL CLASSIFICATION

1. **The electric vehicle art,** although old in general comparison with other developments in the electrical industry, had shown relatively little advance prior to 1910. Coincident with its early progress, extensive exploitation with a view of financial manipulation resulted so disastrously as to reflect general discredit upon the machines themselves. This situation, together with the concurrent development of the gasoline pleasure car, diverted popular attention to this speedier type of machine.

2. **Lack of standardization.** Notwithstanding the serious setbacks experienced in the late 90's, the art showed a slow but consistent advancement during the subsequent 10 years. The record of this period of development so firmly established the economic value of these machines for highway freight movement that the past 3 years have witnessed enormous strides in the art, as regards both design and commercial application. Until quite recently, however, the development has been due to the individual efforts of those interested in production rather than to a cooperative program on the part of the manufacturers as a whole. Consequently it has not yet reached a stage where extensive standardization is possible, and it is therefore difficult to present the subject of electric vehicle engineering in the brief condensed style suitable for an engineering handbook. Attempt has been made in this section to cover merely the fundamentals of the subject, and, so far as possible, to describe the most typical or representative vehicle practices.

3. **Numerous special applications.** Because of the variety of designs produced by the present makers, it is impracticable within the compass of this work to include them all. These differences are by no means confined to chassis for the same general classes of service, but extend to a large variety of vehicles for special purposes, such as cable-pulling, hoisting, dumping, baggage trucks, tractors, fire apparatus, etc. Many of these applications being specific, and as yet more or less experimental, no attempt has been made to describe them.

4. **Treatment confined to leading commercial types.** It is particularly desired to point out that where descriptions of machines and accessories of various makes have been omitted, such omissions are in no way to be attributed to any inferiority in construction or design, but solely to the fact that the limitations of space confined the descriptions to those which have gained prominence in the industry, or whose designs embody characteristics of particular interest to the engineer.

5. **Highway power vehicles** may be divided broadly into three classes, viz., (1) those having electric propulsion, (2) those propelled by internal combustion engines, and (3) those propelled by steam; there is still another class (4) consisting of those vehicles having gas-electric or steam-electric propulsion, in which the energy of the prime mover is electrically transmitted to the axle or wheel.

6. **Each type of power vehicle has its distinct field of economic application,** that of the **electric vehicle** being found in **trans-city** and **suburban delivery,** embracing the interchange of merchandise between railway terminals and docks, stores and factories in the same city or community, and retail delivery in adjacent territories. The possibilities for the employment of this type of machine are evident when considering the general statement that from 60 per cent. to as much as 65 per cent. of highway freight tonnage movement is confined within city areas. Here the electric vehicle possesses superior advantages over other means of merchandise delivery, due to its inherent characteristics of rapid acceleration and retardation,

Digitized by Google

permitting it to maintain a high average speed, and due further to its freedom from intricate mechanism for transmitting the motor energy to the wheels, and the absence of numerous reciprocating parts.

**7. The gasoline motor vehicle** finds its best field of application in short-haul deliveries where the mileage is beyond that safely and conveniently obtained from the electric vehicle, its economic value being governed entirely by the individual characteristics of the particular business to which it is applied.

**8. Electric vehicles may again be divided into two general classes** according to the character of service, viz., (1) commercial vehicles and (2) passenger vehicles. The source of energy supply permits another classification, namely, (1) storage battery vehicles and (2) the so-called **"trackless trolley"** consisting of a motor-propelled vehicle receiving its energy from an overhead double trolley system. Under the second classification, the storage battery vehicle is by far the more important at the present time. The highway trolley vehicle has not yet come into extended use in this country, although it is employed to a limited extent abroad.

**9. Commercial electric vehicles** at the present time form by far the more important class of electric vehicles, and receive practically exclusive consideration in this section. This is because of their economic value as a means for highway freight movement.

**10. Passenger vehicles** involve no engineering features which are not very well covered by the discussion of the fundamentals of vehicle engineering and their application to commercial types.

## CHASSIS CONSTRUCTION

**11. In design,** the electric vehicle is of necessity a compromise, the selection of its component parts being governed principally by the question of economy of operation, rather than mechanical efficiency. Few standards are as yet established, machines of each make reflecting the individual ideas of the designing engineer as to what in his opinion constitutes the best practice.

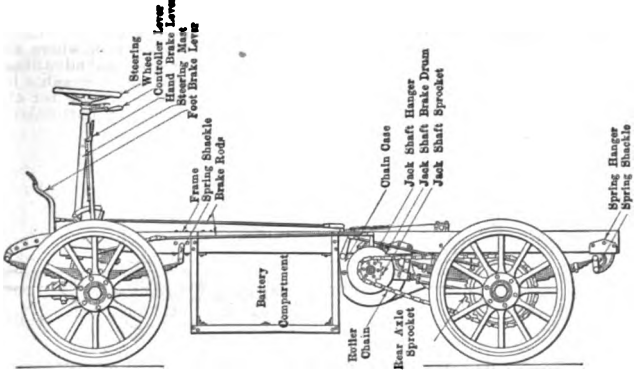

FIG. 1.—Baker chassis. Side elevation.

**12. The chassis of the various makes** differ only in peculiarities in design required by some special construction. The standard frame is rectangular, of structural or pressed steel, with lateral members for supporting the motor, battery compartment, and other equipment forming a part of the vehicle. Except in instances where the type of the drive employed requires that the axles themselves shall constitute a part of the mechanism, rigid axles are used. In the rear the ends of the axles terminate in spindles

Digitized by Google

upon which the wheels revolve, while in the front, provision is made for steering knuckles mounting the wheel spindles. Anti-friction bearings are employed throughout the construction.

**13. The leading types of chassis** are illustrated in Figs. 1, 2, and 3, showing respectively the side elevation and plan of a Baker chassis, and the side elevation of a General Motors Company (G. M. C.) chassis. Both types employ a single motor with reduction gearing and chain drive.

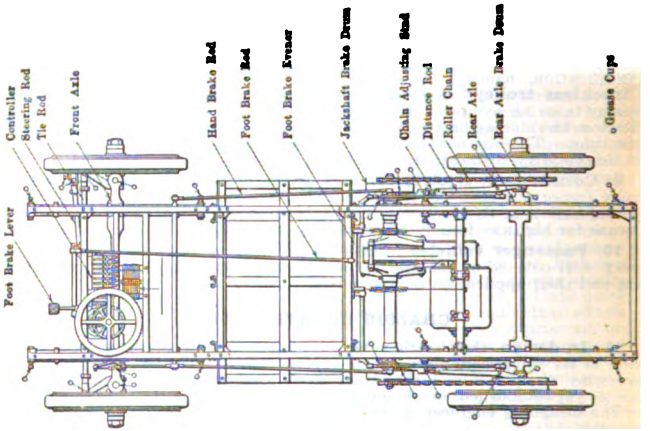

FIG. 2.—Baker chassis. Top view.

**14. The battery compartment** usually is hung beneath the chassis frame (Fig. 1). Some makers, however, adopt the top location where the battery is placed beneath the driver's seat (Fig. 3). The principal advantage of this construction lies in the fact that the batteries are easily accessible for inspection. However, the introduction of sliding battery cradles for the underslung location proves this suspension equally desirable, particularly as a lower centre of gravity is obtained.

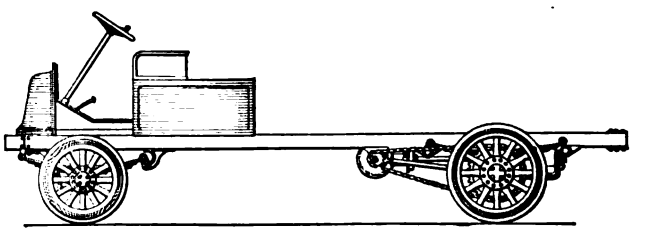

FIG. 3.—G. M. C. chassis. Side elevation.

**15. The location of the controller** varies with the different makes, some manufacturers preferring a fire-proof compartment beneath the driver's seat, while others use the location shown in Figs. 1 and 2.

**16. Chassis weights, dimensions and equipment,** according to data supplied by seven of the leading manufacturers, are given in the table in Par. **21**. This table also gives the battery equipment, number of forward speeds, turning radius and net load capacity.

Digitized by Google

**17. The chassis capacity** of an electric vehicle may be expressed as the sum of the body weight, plus the battery weight, plus the load weight at maximum speed. The **gross weight** is the sum of the chassis capacity plus the chassis weight. Variations in load, battery, and body weights are permissible so long as the gross weight moved at maximum speed does not exceed that prescribed by the manufacturers.

## VEHICLE RESISTANCE AND ENERGY CONSUMPTION

**18. The rolling resistance** of a wheel is due to the yielding or indentation of the road, which causes the wheel continually to mount a slight incline. The resistance is measured by the horizontal force necessary at the axle to lift it over the obstacle, or to roll it up the inclined surface. The rolling resistance varies with (a) the diameter of the wheel; (b) the width and composition of the tire; (c) the speed; (d) the spring suspension; (e) the nature of the road surface. This resistance varies all the way from 3 lb. per ton with true steel wheels rolling on heavy clean rail, up to 200 lb. per ton in ordinary wagon wheels through sand.

**19. Vehicle resistance.** The best authorities* give the following values or vehicle resistance:

| | |
|---|---|
| Steel-tired wheels on steel rail | 3 to 5 lb. per ton. |
| Pneumatic-tired wheels on asphalt pavement | 15 to 35 lb. per ton. |
| Solid-tired wheels | 20 to 40 lb. per ton. |
| Steel-tired wheels on average road, about | 50 lb. per ton. |

**20. Truck resistance.** In conducting tests on trucks with different makes of rubber tires, results have been secured where the total resistance has run as low as 25 lb. per ton and as high as 60. all other conditions re-

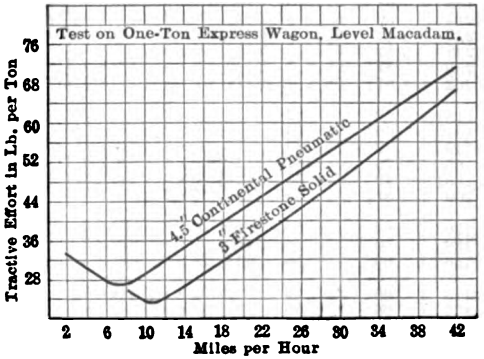

FIG. 4.—Curve showing tractive effort in pounds per ton at different speeds.

maining the same except the tire. This is due simply to a variation in the rubber compound, the low results being secured with a very high quality of rubber, whereas the high results were due to an inferior compound. (Also see Par. **24.**) The loss in transmission here amounts to approximately 3 lb. per ton, friction and windage consume 5 lb. per ton, and the remainder is due to the tires.

**22. Vehicle resistance on asphalt pavement.** The tractive effort required to haul a load of 1 ton by means of rubber tires over asphalt paving can at best only approach the low train resistance values reached in railroad work with its superior rolling surface. In Fig. 4 are given the results of tests by Churchward on solid and pneumatic rubber tires on asphalt, the solid tires calling for less tractive effort owing to the superior character of the pavement. On country roads the solid tire will demand the greater tractive

effort, owing to the superior ability of the pneumatic tire to adapt itself to surface irregularities.

**23. Critical speed for minimum effort.** It is noticeable that there is a critical speed at which the minimum tractive effort or draw-bar pull occurs, and that it varies with the type of tire used. The same effect has been observed and demonstrated in railway traction; this is attributed to wave motion in the rolling surface. In the case of the automobile it is caused by the kneading of the tires.

Digitized by Google

**24. Effect of tires on vehicle resistance.** The results of dynamometer tests conducted by F. E. Whitney* to determine the effect of different tires on vehicle resistance are shown in Fig. 5. The different tires are arbitrarily numbered from 1 to 6 for identification, the quality of the tire being recorded in the results shown by the test. It will be noted that all the curves are practically straight lines, showing that the tire loss varies directly with the load. For example, by referring to curve 3 and curve 6, at 1,250 lb. load the drag on tire No. 6 is 10.3 lb. while tire No. 3 shows a drag of 18 lb., which represents the relative efficiency of the two tires.

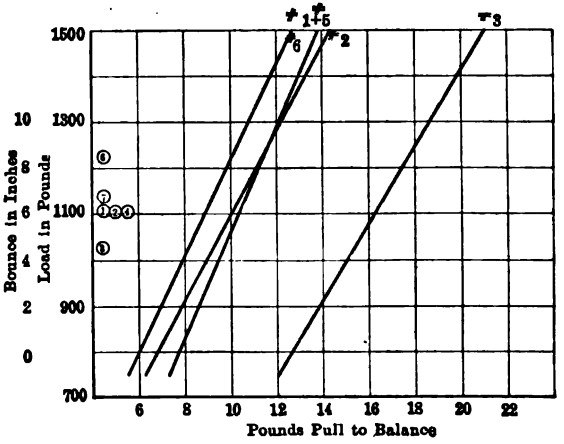

FIG. 5.—Curves showing the effect of different tires on vehicle resistance. (⊙ on diagram indicates observed result in bounce test.)

**25. Bounce test for tires.** As a direct comparison with the above method of test, the bounce in inches of each of the same tires has been plotted, as shown at the left side of Fig. 5. It will be noted that tire No. 6 shows a bounce of 8.5 in. as against 4.5 in. for tire No. 3, indicating about the same relative efficiency with the different method of test.

**26. Method of making bounce test.** The bounce test for determining relative tire efficiency is made by dropping a weight from a given height upon the tire, the rebound in inches being noted. This test is usually employed by vehicle makers because of its simplicity and the elimination of elaborate preparation.

**27. Effect of tire on vehicle efficiency and performance.** As indicating the effect on the mileage secured from one charge of the battery in an electric truck, with the two extremes of tires No. 3 and No. 6, a vehicle equipped with tire No. 6 would cover, say, 50 miles on one charge of the battery, whereas a vehicle equipped with tire No. 3, over the same route and using the same battery equipment, would be able to cover only 30 to 35 miles.

**28. Tests made with different tires** to determine the **vehicle resistance** have given the following general results:

**29. Power demand and energy consumption** of electric vehicles are governed by the gross weight, speed, grade and road surface. The curves given in Fig. 6 illustrate the relationships between the per cent. of grade and the tractive effort, and between the per cent. of grade and the energy consumption, in terms of various energy rates on level tangents. For example, curve *E* for a vehicle consuming 100 watt-hr. per ton mile on the level, would require on a 6 per cent. grade a tractive effort of 160 lb. per ton, and an energy consumption of 475 watt-hr. per ton mile.

**30. Power demand on asphalt pavement** is shown by the set of curves in Fig. 7, for various weights, speeds and grades.* The abscissas indicate the power demand on grades and the ordinates the power consumption on the level. For example: assume a vehicle weighing 10,000 lb. traveling at 10 miles per hour; a horizontal projection of the point of intersection of the lines representing this speed and weight will indicate 4,000 watts for level running, and 8,000, 16,000, and 44,000 watts for 2 per cent., 6 per cent., and 20 per cent. grades, respectively.

**31. Effect of different pavements on energy consumption.** The following relative values of energy consumption (on level tangents) for various kinds of pavements are due to Messrs. W. A. Hall and J. M. Hargrave.†

| | | | |
|---|---|---|---|
| Asphalt | 1.00–1.05 | Granite block | 2.00 |
| Macadam | 1.15 | Snow (fairly hard with grips) | 1.89 |
| Tarvia | 1.14 | Snow (fairly hard without grips) | 1.69 |
| Glazed brick | 1.34–1.36 | Hard snow and ice | 1.34 |
| Wood block | 1.07 | Snow fairly soft | 2.06 |

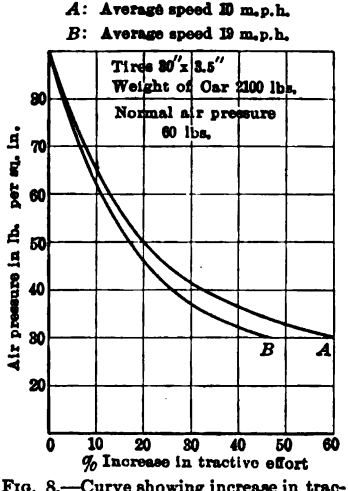

FIG. 8.—Curve showing increase in tractive effort due to deflation of tires.

**32. The effect of the tread chord of the tire on energy consumption** is very well brought out by a series of tests conducted by Alexander Churchward.‡ This effect is most noticeable, naturally, in vehicles equipped with pneumatic tires. The results of Churchward's tests are shown in Fig. 8; the different treads were obtained by deflating the tires, as indicated by the air pressure in pounds per square inch.

**33. The effect of tire resistance on energy consumption** is shown by the curve in Fig. 9, giving the relationship between tire resistance in pounds per ton, and watt-hours per ton mile, assuming the motor efficiency to be 83.5 per cent. and the transmission efficiency 90 per cent.

**34. The effect of frequent stops on energy consumption** is exhibited by the curve in Fig. 10. This curve may be used in conjunction with Fig. 7 to calculate the battery capacity required for a specific service.

## TRANSMISSION GEAR

**35. Transmission of the motor energy to the wheels** is accomplished by several methods in general use, but considerable difference of opinion exists as to what constitutes the most desirable method of motor application and the best transmission design. Without commenting upon the general

features, as illustrated in the various types hereafter described, it may be stated that simplicity of construction and design should govern the selection of transmission gear so far as is possible, without sacrificing efficiency.

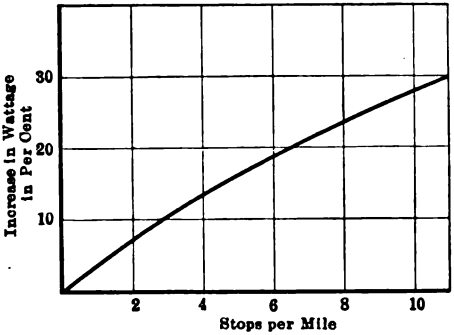

FIG. 10.—Curve showing per cent. increase of energy consumption due to stops.

**36. The essential elements of a transmission gear** comprise a means of reducing the high speed of the motor to the comparatively low speed of the propulsion or running wheels (reduction gear), and a **differential gear** which permits one wheel to turn faster than the other in propelling the vehicle in any curved path.

Digitized by Google

**37. The single-motor double-reduction chain drive,** as adopted by many manufacturers, presents the advantages of simplicity of construction, high efficiency, and practically noiseless operation. It is shown in Fig. 11.

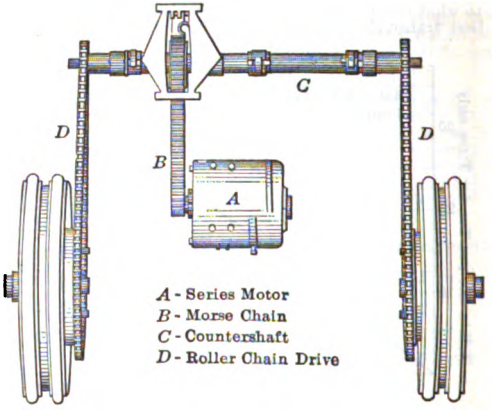

FIG. 11.—Double-reduction chain drive.

In this drive the silent chain *B* (generally of the inverted-tooth type) transmits the power from the motor pinion to the differential gear, roller chains *D* being utilized to convey the driving effort from the jack shafts to sprockets mounted on the rear wheels.

FIG. 12.—Counter-shaft assembly.

Digitized by Google

The **primary chain** *B* is enclosed in an oil-tight case, or, in some instances, protected from dust merely by an extension of the battery compartment. The former construction is preferable, as the life of the chain is increased by the better means afforded for lubrication.

**The counter-shaft** is usually assembled in such a manner as to permit its installation or removal as a complete unit. The differential gear is mounted on the differential housing. Adjustment of the silent chain is accomplished by a radius rod with an adjusting screw. For the roller chains, similar distance rods are employed. The armature shaft, jack shaft, and wheels are all equipped with anti-friction bearings. For counter-shaft assembly, see Fig. 12.

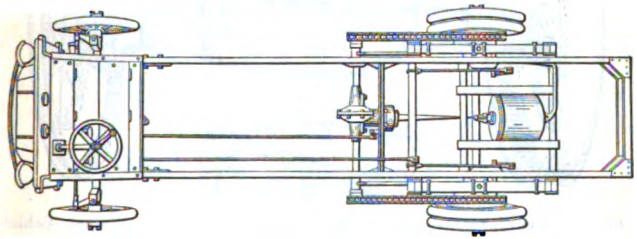

FIG. 13.—Top view of chassis showing drive assembly. (General Motors Company.)

**38. The floating shaft and chain drive** employs a flexible spring-steel blade for transmission from the motor to the counter-shaft. This shaft has a cross-section that permits torsional displacement or yielding under stress. The counter-shaft is of the floating type with bevel driving gear and pinion reduction. The power is transmitted from the counter-shaft sprockets by roller chains to the rear wheels. The motor is suspended in positive alignment with the chassis frame, with entire weight on frame members and supported at diametrical points. See Fig. 13.

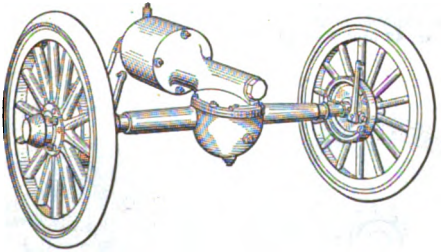

FIG. 14.—Rear axle assembly, spiral gear drive. (Commercial Truck Company.)

**39. The spiral gear drive** (Fig. 14) has the advantages of clean-cut appearance and compactness, few parts, good lubricating facilities, mechanical efficiency, and extremely quiet operation. Through a worm and gear drive the power is transmitted from the motor to the wheels by a single reduction, making an extremely simple mechanism.

The rear wheels are mounted on roller bearings entirely independent of the driving mechanism, and are driven by floating shafts engaging the outer ends of the wheel hubs. The inner ends of these shafts are squared into the hubs of bevel differential gears. The whole mechanism is immersed in oil, and gives noiseless operation. The rear axle unit consists of motor, gear

Digitized by Google

casing, axle housing, and rear wheels with gear and driving shafts. This permits the ready removal of the complete power equipment.

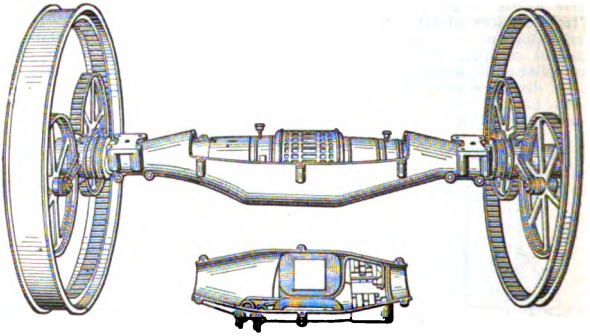

FIG. 15.—Rear axle assembly. Motor cover removed. (Walker Vehicle Company.)

**40. In the balance drive,** the motor, differential, and transmission members are all embodied as parts of the rear axle and wheel assembly (see Fig. 15). The power is transmitted through drive shafts to floating pinions within each wheel, thence through intermediate spur gears housed within disc wheels which mesh with internal gear rings, forming the interior of the wheel rims. The drive pinions and shafts have no bearing except the teeth of the idler gears, between which the pinions float in a balanced manner. The mechanical efficiency is high when all parts are retained in proper alignment.

**41. The wheel-drive systems** embodying constructions in which a motor drives each wheel separately, and forms a more or less self-contained unit therewith, is capable of good mechanical efficiency. Such systems are described in Par. **42** and Par. **43**.

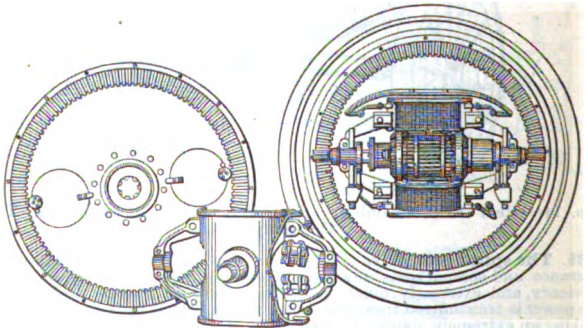

FIG. 16.—Wheel assembly, couple gear.

**42. The couple-gear drive,** shown in Fig. 16, employs a motor mounted in a fixed horisontal position within the wheel itself, the axle stubs on which the wheel turns being integral with the motor castings. The armature shaft makes a slight angle with the plane of the wheel, permitting the bevel

Digitized by Google

pinions mounted on each end of the armature shaft to mesh with their respective halves of a "double" cog-rack near the periphery of the disc wheel. Thrust stresses arising from one bevel set are balanced by the other. A small number of parts make up the complete assembly. The arrangement lends itself to **four-wheel drive and steering**, features often required in special applications, where turning space is limited.

**43. Other wheel systems** which obviate the use of bevel gears and embody the double spur-gear reduction are shown in Fig. 17 and Fig. 18.

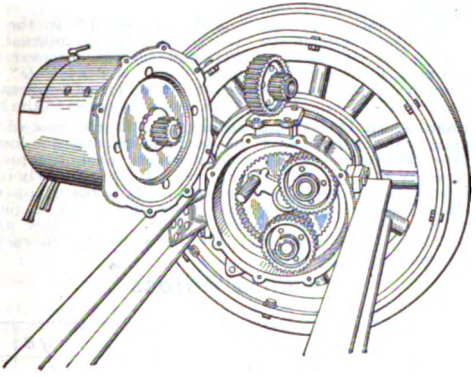

FIG. 17.—Concentric gear drive. (Commercial Truck Company.)

In the former, showing the **spur concentric form of gear**, the gear cases are mounted between two axle members, the extension of the case forming the axle spindle. The motor is bolted to the inner side of the gear case in a fixed position. The armature pinion engages spur gears which are carried

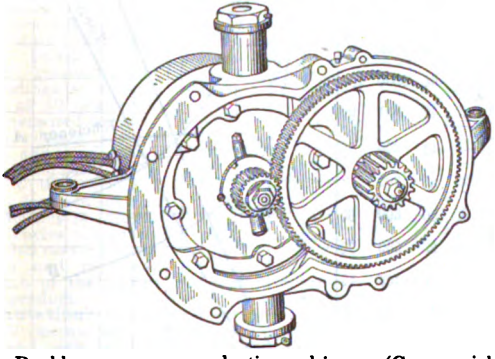

FIG. 18.—Double spur-gear reduction drive. (Commercial Truck Company.)

by studs integral with the driving shaft. The driving shaft passes through the axle spindle and connects with the outer end of the wheel hub through a square form in the hub cap.

The drive illustrated in Fig. 18 is employed with forged steel axles, which

Digitized by Google

are made in two parts and separated by a spacer, thus forming the equivalent of a deep I-beam section. The axle forgings are enlarged, and are bored out and bushed to receive trunnions, which are a part of the motor casing, thus forming a knuckle construction for steering. The motor casings are bored to receive the motors, which slip freely into the casings up to a shoulder. The casings are split part way around and provided with a clamping bolt for holding the motor in position. The mountings are alike in front and rear. At the front, the two casings are connected to the steering gear. At the rear, the casings are secured in a fixed relation to the axle, the rear wheels being rigidly mounted.

Fig. 18 shows motor and casing ready to assemble in the axle. The pinion which projects through the case meshes with the internal gear bolted to the wheel. The outwardly projecting flange extends over the outside of the wheel gear, forming a grease-tight joint. A heavy "*D*" washer and crown nut hold the wheel on the axle and provide for adjustment of bearing. The internal gear is cut from forged steel, and is fastened to the hub casting.

**44. Transmission losses and efficiency.** In the case of truck resistances ranging from 25 lb. to 60 lb. per ton, and transmission losses of 3 lb. per ton (Par. 21), any possible improvements over the present transmission efficiency of approximately 85 per cent. are relatively insignificant, in regard both to increased performance and decreased operating cost. For example: a vehicle having a truck resistance of 25 lb. per ton, and capable of 50 miles on one battery charge, would show an increased mileage of only 0.7 per cent. were the transmission efficiency increased from 85 per cent. to 90 per cent.

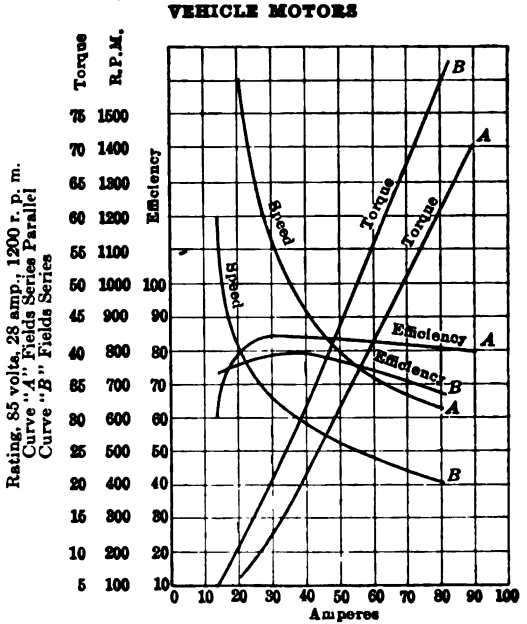

FIG. 19.—Characteristic curves of speed, torque and efficiency. (Make A.)

Digitized by Google

**45. Design.** In order to meet the requirements of automobile manufacturers. vehicle motors are made in a number of different sizes, each of which can be supplied in several electrical ratings. The features of design follow closely after railway motor practice, since the conditions of vehicle service are very severe. Special attention is given to commutation, insulation, efficiency and reliability. These motors are all of the series-wound type.

**46. Special torque characteristic.** It is of paramount importance that the storage battery should be protected, and all motors are designed with this object in view. The current-torque curve has the property that doubling the current will approximately quadruple the torque, with reference to any given point on the curve.

**During starting and acceleration** an electric vehicle requires about five times the normal running torque. Again, the average **maximum grade** encountered in cities is about 7.6 per cent., to climb which also requires about five times normal torque.

**47. General motor characteristics.** The characteristic curves of torque, speed, current and output, for vehicle motors, are shown in Fig. 19 and Fig. 20, being representative of the products of two leading manufacturers.

**48. Performance specification.** The manufacturer (*B*) of the motor whose characteristics are shown in Fig. 20 gives the following performance specification:

**Rating:** The normal full-load rating of each motor is based on the specified voltage and amperes. Where series field coils are arranged for series and parallel connection, the rating is given with field coils connected in parallel.

**Speed:** The rated speed is based upon the speed of the motor at the end of the specified full-load temperature run. Speeds of individual motors may vary 5 per cent. above or below the speed shown on the specified curve. Approximate speeds for loads other than full or rated load are also shown on the specified curve.

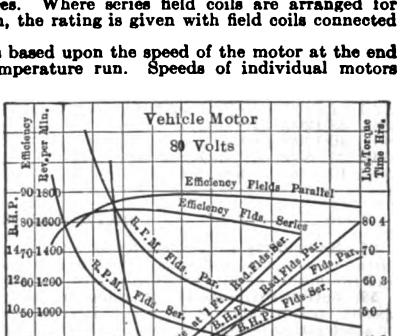

FIG. 20.—Characteristic curves of speed, torque and efficiency. (Make B.)

**Efficiency:** The efficiencies shown on the specified curve are to be calculated from $I^2R$ losses in the armature and field windings, based on the measured resistance of these windings at a temperature of 50 deg. cent. and the measured core-loss and friction-losses, including brush and bearing friction and windage. These losses are to be determined separately for each load at which efficiency is desired. The efficiencies shown on the specified curve are approximate and represent the average of the manufactured product.

**Commutation:** Each motor will operate at rated full load with no sparking or burning of the brushes, and without blackening of the commutator. It will commutate any load encountered in normal operation without injurious sparking.

**Temperature:** After a continuous run (for four hours) at the specified voltage and current, no part of the windings will exceed a temperature of 50 deg. cent. above the surrounding air. Test to be made on stand with motor covers removed. Temperatures are to be measured by thermometer and rises specified are based on a room temperature of 25 deg. cent. For

Digitized by Google

room temperatures other than 25 deg. cent., corrections should be made according to the Standardization Rules of the A. I. E. E.

**49. The commercial ratings of vehicle motors** are based upon the point of maximum efficiency, as shown in efficiency curves in Fig. 19 and Fig. 20. The standard sizes, weights, and speeds for motors of make (*A*) are given in Par. **51**, showing motor ratings, speeds, and weights.

**50. Choice of number of motors.** Applications of one, two, or four motors are dependent upon the type of transmission employed. The **single-motor** application is generally favored because of its high efficiency, light weight and simplicity of control. The **two-motor** application shows slightly better performance when the stops per mile are frequent, due to the elimination of running resistance in the first notches of the controller, but it is doubtful whether this advantage offsets the extra weight and care necessitated by the additional motor.

The **four-motor four-wheel** drive is peculiarly adapted to vehicles of large capacity, and for operating where a heavy tractive effort is essential, such as hauling trailers, or under poor road conditions.

**51. Table of Commercial Ratings**

## CONTROLLERS

**52. Reliability** in a controller is scarcely less important than the same virtue in a motor, and each should be selected with reference to the other and the nature of the service to which the vehicle will be applied.

**53. Series resistance.** In adapting the motor characteristics to the specific performance of a vehicle, it is necessary that during the starting or accelerating period the resulting current not only shall be reduced to the safe commutating capacity of the motor, but also to a value which will not produce an abnormal voltage drop in the battery nor increase the initial torque beyond a point required to start the vehicle without slipping the wheels. This is usually accomplished by introducing an external resistance when operating on the starting or accelerating points of the controller (see Fig. 21); this resistance is cut out in successive steps as the controller handle is advanced to the full-speed position.

**54. Starting and running points.** The relationships among speed, torque and current of a series motor are shown in Fig. 21 and Fig. 22.

**Typical method of control.** The usual method of controlling the torque and speed of the motor is shown in the wiring development on Fig. 21, the successive steps of acceleration being controlled as indicated for points 1, 2, 3 and 4, for forward movement of controller; thus,

Point 1: Resistance in circuit to control torque.

Point 2: Resistance out out; torque thereby increased through increased current flow.

Point 3: Torque increased through increased armature flow (shunted fields).

Point 4: Speed increased by paralleling fields, and cutting out all resistance.

Digitized by Google

**55. Economical running points.** Since it is apparent that the controlling factor in starting and accelerating is the torque, while for running the controlling factor is the speed, combined with torque for hill climbing, it would appear that the economical operating points on the controller are as follows: point 1 and point 2 for starting and acceleration; point 4 for running on level; point 3 for running on hills.

In pleasure vehicles the speed and the torque are similarly controlled, except that the manipulation of the fields, armature, and external resistance is planned to produce a smoother operation, which is required when personal comfort is a factor (see wiring development in Fig. 22).

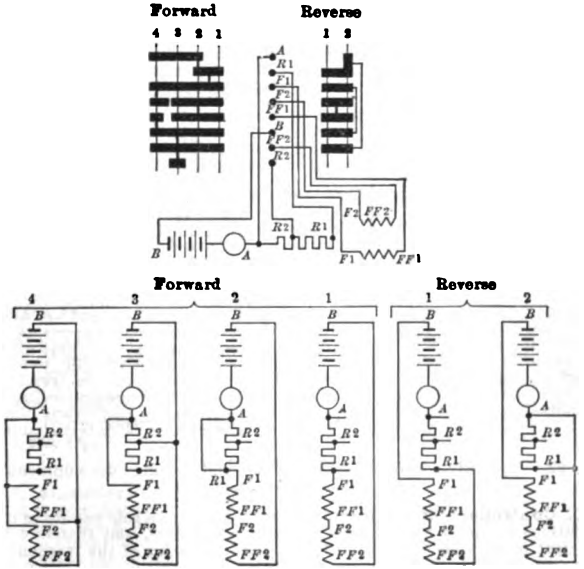

FIG. 21.—Controller connections and wiring development for commercial vehicles. (General Vehicle Company.)

**56. Single-motor control** is effected, in the standard arrangement, by means of series-parallel commutation of the field coils and the use of series resistance for starting and intermediate steps. At starting the fields are all in series, with all resistance in circuit.

**57. Two-motor control** is usually effected by series-parallel commutation of the motors, with series resistance for starting and intermediate steps. At starting the motors are in series, with all resistance in circuit.

**58. The continuous-torque principle** in two-motor control is an advantageous feature, because it insures smooth acceleration in changing from series to parallel connection of motors. The same principle is equally advantageous in single-motor control in passing from series to parallel connection of field coils (Fig. 21). Otherwise there is a sudden drop in torque, or jerk in acceleration, in making these changes.

Digitized by Google

**59. Controllers for passenger vehicles** customarily have a large number of points, relatively, in order to permit slow operation in cities where the traffic is congested, and higher speed over park and country roads.

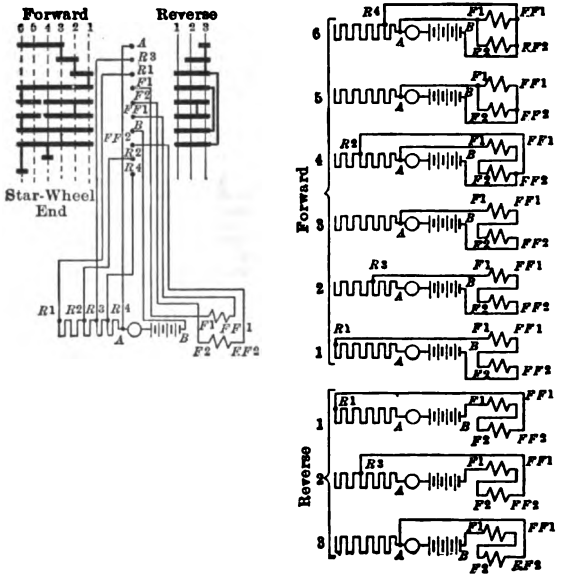

FIG. 22.—Typical controller connections and wiring development for passenger vehicles.

**60. Controllers for commercial trucks** do not as a rule require as many gradations of speed as passenger or pleasure vehicles, and therefore have sufficient points only to safeguard the chain or gearing of the transmission.

**61. Typical controller connections** are shown in Fig. 21 and Fig. 22, for two different systems of control. Fig. 21 represents a single-motor truck equipment, and Fig. 22 a single-motor passenger or pleasure equipment.

## BATTERIES

**62. Storage battery characteristics** are covered as a whole in Sec. 20, including batteries for vehicle service. The following brief instructions relate exclusively to storage batteries in vehicle service, of the lead-lead or the nickel-iron types, and are intended merely to supplement the treatment given in Sec. 20.

**63. Battery discharge in commercial vehicle service** takes place in practically all cases at varying rates, and is accompanied by periods of rest. The total elapsed time of discharge is ordinarily 8 hrs. or more. The reduction in capacity due to high discharge rates largely disappears when the high rates are merely intermittent. Therefore the normal discharge rate will be available for the full period specified by the manufacturers, provided the total elapsed time during which discharge occurs is not in excess of the period prescribed.

Digitized by Google

**64. Intermediate or "boosting" charges.** Should it be desired to take advantage of any idle time of the vehicle for boosting charges, the rate for such charges may be determined by the following formulas:

**(a) Rate for lead batteries:***

$$\text{Rate} = \frac{\text{ampere-hours discharged from battery}}{1 + (\text{time in hours available for boosting})} \quad (1)$$

NOTE. See temperature limitations in Section 20.

Ninety per cent. of any total number of ampere-hours which may be charged into the battery in this manner can be added to the rated ampere-hour capacity to obtain the available ampere-hours during operation. For example: a battery of 150 amp-hr. rated capacity, if totally discharged, may be boosted for 1 hr. at 75 amp., or 75 amp-hr. returned; 90 per cent. of this added to the original capacity would give 217 amp-hr. as the total capacity during operation.

**(b) Rate for alkaline batteries:**

For 5 minutes at 5 times normal rate
For 15 minutes at 4 times normal rate
For 30 minutes at 3 times normal rate
For 60 minutes at 2 times normal rate (2)

**65. Precautions to be observed in applying boosting charges.** The charging rates given in Par. 64 for alkaline batteries may be used under average conditions. However, the rate must not be such as to cause excessive heating, and its determination should be governed in each case by experience. Frothing is an indication that the charging has been carried too far (if the solution is at the proper height), and the boosting should be discontinued.

**66. Battery renewals in vehicle service** must be reckoned as much a part of the necessary operating expense as renewals of tires, bearings, chains or any other part of the equipment. The interval between periodic renewals is not at all a measure of the general efficiency of the battery, because the service in one case may be much more severe than in another. Economy and efficiency of vehicle operation, expressed in terms of dollars and cents, should govern the choice of a battery, assuming always that it is sufficiently standardized so that renewal parts can be obtained as desired.

## INSTRUMENTS

**67. Ammeters** are covered, as a whole, in Sec. 3. This instrument is being largely displaced by the ampere-hour meter, for the reason that, while indicating the discharge flow from the battery, the information is of little value in operating. The switchboard meters at the garage are sufficient for determining the current-flow on charge.

**68. Voltmeters** are covered, as a whole, in Sec. 3. The ampere-hour meter has also displaced the voltmeter, as well as the ammeter, for the reason that the voltmeter does not indicate the condition of discharge of the battery (while running the vehicle) without the aid of a somewhat confusing mental calculation. The switchboard voltmeter, of course, is essential for determining the battery voltage while charging. **Low-reading portable voltmeters** are desirable for testing the condition of the individual cells of the battery, and are generally used in public garages and the larger private installations.

**69. Ampere-hour meters** are described, as a whole, in Sec. 3. This type of instrument is coming into general use in electric vehicles because it gives visual indication of the condition of charge of the battery, both while operating the vehicle and while charging. In Fig. 23 is shown a diagram of connections for the ampere-hour meter, with a differential shunt which compensates for the efficiency losses in the battery by retarding the reverse movement of the meter while charging.

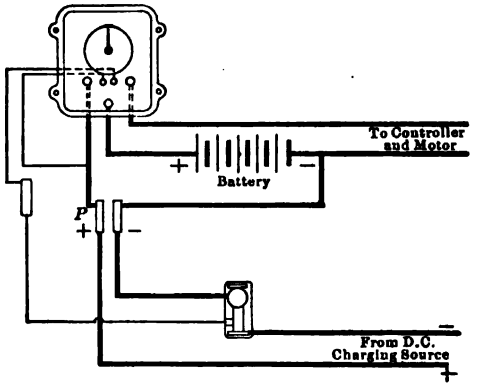

FIG. 23.—Ampere-hour meter connections.

**70. Stop-charge devices** are usually one of three types, viz., (1) those operating in connection with the ampere-hour meter, (2) time switches operated by clock mechanism, (3) underload circuit-breakers. In the first type the recording hand of the ampere-hour meter makes contact at 0, or at the full-charge point of the battery, and closes a trip-coil circuit operating the breaker. In employing time switches, the condition of the charge of the battery is first determined, and the period required for its full charge calculated upon the basis of the average ampere input; the clock mechanism is then set to operate a trip-coil breaker at the proper moment. The underload circuit-breaker, or no-voltage release, depends for its operation upon the magnetic field strength of coils in the battery-charging circuit; through the rise in battery voltage and consequent decrease in current flow, the magnetic field gradually weakens to a point insufficient to overcome the gravity release, or spring pull, which trips the breaker. The last-named device (3) is not generally recommended, because accidental interruptions of the supply circuit would operate it, possibly before the battery is fully charged.

## GARAGE EQUIPMENT

**71. Direct-current switchboards for private garages,** wherein few cars are housed and where service of suitable voltage is readily obtainable, consist of a simple charging panel for mounting switches, measuring instruments and protective devices, such as are ordinarily employed in general switchboard construction (see Fig. 24 and Fig. 26). Hand rheostat regulation is used for controlling the current flow to the battery.

**72. Direct-current switchboards for public garages** and large private installations housing a number of vehicles are naturally more elaborate than those described in the last preceding paragraph, because of the necessity for a local distribution system to accommodate a number of vehicles which may be on charge simultaneously. Typical switchboard arrangements and wiring connections are shown in Figs. 25 and 27.

**73. Rheostats for battery charging** are specially designed to meet the various conditions required by the number and type of cells employed in the battery to be charged. Only by using the proper rheostat for a given battery, is it possible to start the charge at the correct rate and reduce the current in suitable steps to the final amount required, as the charging progresses. The table given in Par. 74 shows the essential data on battery charging rheostats for circuits up to 115 volts maximum, for both lead and alkaline cells.

**77. Charging from alternating-current sources** necessarily involves a conversion from alternating to direct current. Four types of conversion apparatus are available, according to the needs of the case, as follows: (1) Synchronous polyphase converters, requiring two-phase or three-phase supply, are not available in standard ratings except for relatively large

Digitized by Google

outputs (see Sec. 9), suitable only for very large battery installations. (2) Motor-generator sets, for either single-phase or polyphase supply, are available in all sizes and numerous types, at almost any desired voltage (see Sec. 7 and Sec. 8). (3) Single-phase synchronous converters, in small ratings, are

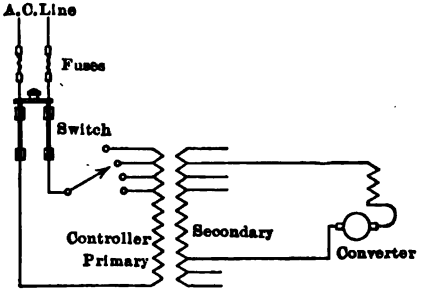

FIG. 28.—Diagram of connections when starting.

manufactured specially for battery-charging work (see Par. 80). (4) Mercury arc rectifiers are especially adapted to battery charging and are supplied in standard types for that purpose (see Par. 83 and also Sec. 6).

**78. Synchronous polyphase converters** (Sec. 9), because of their high efficiency, are desirable in the larger installations, but require more intelligent care in operation than a simple motor-generator set. The choice between these two types is governed not only by the foregoing consideration, but also by relative reliability and the comparative annual costs.

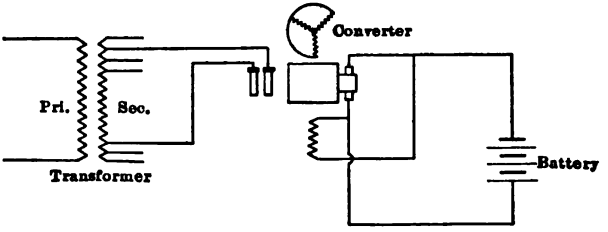

FIG. 29.—Diagram of connections when running.

**79. Motor-generator sets** may be divided into two classes, those with shunt generator windings and those with compound windings. The former are applicable only in the smaller installations where the charging load is substantially constant. The second (compound) type should be employed where the charging load is subject to fluctuations, as in the larger garages.

**80. Single-phase converters**, designed particularly for use in garages for charging individual vehicle batteries, are constructed with direct-current ratings from 16 amp. to 70 amp., as shown in the table in Par. 81. The con-

Digitized by Google

nections for starting, as a single-phase commutator motor, are shown in Fig. 28; the normal running connections are shown in Fig. 29.

**Voltage control** on the direct-current side is effected solely by changes in the value of the alternating-current voltage impressed on the slip-rings. Taps in the secondary of the transformer are provided for different numbers of cells, these taps being tagged, not for voltage, but arbitrarily, as $S_1$, $S_2$, etc. A table of the proper connections for the number of cells under charge is provided by the manufacturer.

**81. Table of Standard Ratings of 60-cycle Single-phase Synchronous Converters**

(Wagner Electric Mfg. Co.)

| Normal charging capacity in amperes | Number of cells for which taps are provided | Possible voltage variations on d.c. side | | Direct current fuse capacities | Capacities in h.p. as motor |
|---|---|---|---|---|---|
| | | Min. | Max. | | |
| 16 | 32–44 | 67– 92 | 86–119 | 35 | 1.5–1.75 |
| 16 | 46–52 | 97–109 | 124–140 | 35 | 2.25 |
| 25 | 20–30 | 42– 63 | 54– 81 | 35 | 1.5–1.75 |
| 25 | 32–36 | 67– 75 | 86– 97 | 35 | 2.25 |
| 25 | 38–48 | 80–100 | 103–130 | 35 | 2.5–3.00 |
| 35 | 18–26 | 38– 55 | 49– 70 | 45 | 2.5–3.00 |
| 35 | 28–34 | 59– 72 | 76– 92 | 45 | 2.5–3.00 |
| 35 | 36–42 | 76– 88 | 97–113 | 45 | 3.0–3.50 |
| 50 | 18–24 | 38– 50 | 49– 65 | 60 | 2.5–3.00 |
| 50 | 26–30 | 54– 63 | 70– 81 | 60 | 3.50 |
| 50 | 32–42 | 67– 88 | 86–113 | 60 | 3.5–5.00 |
| 50 | 44–50 | 92–105 | 119–135 | 65 | 6.0–7.50 |
| 70 | 22–32 | 46– 67 | 60– 86 | 90 | 3.5–7.00 |

**82. Protective devices** form a most essential portion of the charging equipment. These consist of a reverse-current relay (controlling a main

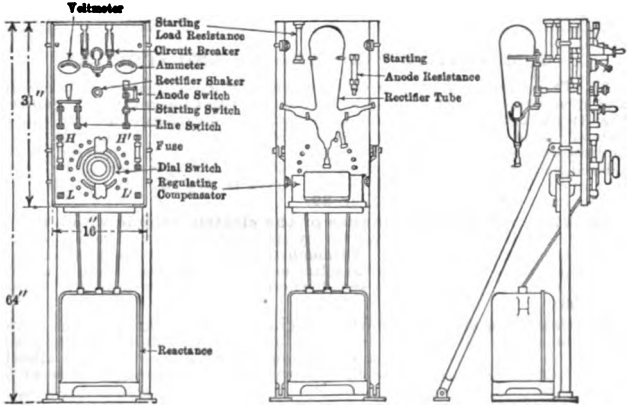

FIG. 30.—Mercury arc rectifier—front, rear and side elevations. (General Electric Company.)

Digitized by Google

circuit-breaker) to protect the generator (or converter) and battery from possible damage resulting from interruptions of the alternating-current supply, and a maximum-voltage relay which automatically opens all circuits when the battery voltage has reached a predetermined value indicating full charge.

**83. Mercury-arc rectifiers** are supplied in special types adapted to storage-battery charging. The general appearance of the equipment, including the reactance, rectifier tube, panel, switches and instruments, is shown in Fig. 30 (see also Sec. 6). These rectifiers are applicable to single-car installations where the current values required do not exceed those shown in the table in Par. **84**.

## COMPARATIVE PERFORMANCE AND ECONOMY

**85. The economy of the electric vehicle** as compared with gasoline and horse vehicles operating under similar conditions is graphically shown in Fig. 31, plotted from data obtained through investigations made by Professor Pender* of the Massachusetts Institute of Technology. It must be clearly understood that the comparison applies only when motor vehicles are considered for application within the practicable field of operation of the electric machine. The data from which the curves in Fig. 31 were plotted were drawn from the tabulation in Par. **89**.

**86. The superior performance of the electric vehicle** within its own field of application is accounted for by its inherent characteristics of rapid acceleration and retardation. Although the electric vehicle is geared to a lower maximum speed than the gasoline machine, its characteristics permit it to maintain a higher average speed where the stops per mile are frequent (Par. **88**).

**87. Cost of energy.** Improvements in the design and operation of electric vehicles within the past few years have been so numerous that, with electric energy at 3 cents per kilowatt-hour, the amount of energy expended by the storage battery in propelling a well-designed electric vehicle of five

* Pender, H. "Notes on the Cost of Motor Trucking," Electric Vehicle Association of America; 1913.

Digitized by Google

tons' capacity constitutes less than 10 per cent. of the entire operating cost of the machine. Under these conditions, the path of future development lies not so much in the direction of increased efficiency, from the viewpoint of energy consumption, as through a better coordination of the parts employed.

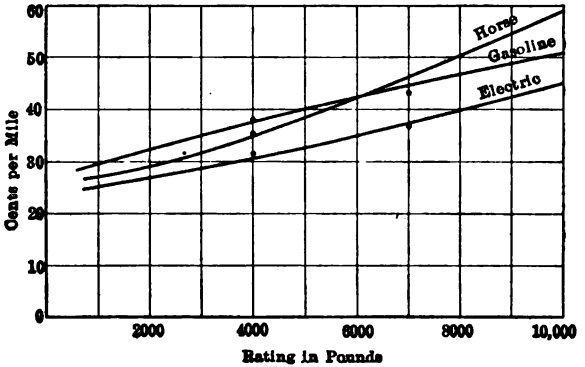

FIG. 31.—Curves of comparative cost per mile in delivery service by electric gasoline, and horse equipment.

**88. Table showing Comparative Performance of Electric and Gasoline Vehicles Operating within the Electric Zone**

| Conditions of test | Electric | Gasoline |
|---|---|---|
| Total weights (gross) | 5,230 lb. | 2,840 lb. |
| Diameter of wheels | 34 in. | 36 in. |
| Rated speed (m.p.h.) | 10 to 12 | 15 to 18 |
| No. of stops per mile | 9.47 | 9.47 |

**90. Maintenance costs.** In an extended investigation of the operating costs of gasoline and electric machines in several similar lines of business, the data collected showed that for the electric vehicle the average cost per car-mile for maintenance increased only 13.3 per cent. over a period of 4 years, while that of the gasoline car increased 363 per cent. in the same time; and, further, at the end of the 4-year period the maintenance cost for the electric vehicle was less than 50 per cent. of that of the gasoline machine (Par. 91).

**91. Table Showing Comparative Maintenance Costs per Car-mile for Electric and Gasoline Vehicles**

| | Number of machines reported | Average maintenance cost per car-mile after 7 months' operation | Average maintenance cost per car-mile after 48 months' operation |
|---|---|---|---|
| Gasoline.... | 54 | 4.0 cents | 18.5 cents |
| Electric.... | 69 | 7.5 cents | 8.5 cents |

These figures were obtained from the records of the operators themselves and include all items chargeable to the replacement of mechanical parts, storage batteries and tires.

**92. The greater economy of the electric vehicle** is accounted for by the absence of a multiplicity of wearing parts, and the lower operating speed of the machine itself. To compete successfully with horses, a power truck is not required to run at touring car speeds. The average speed of a 3-ton horse-drawn truck is about 2.5 miles per hour, and the average mileage not over 12 miles to 15 miles per day. Therefore, a 3-ton motor truck operating at 7.5 miles per hour will not only compete very successfully with a horse-drawn vehicle, but its maintenance cost will be low.

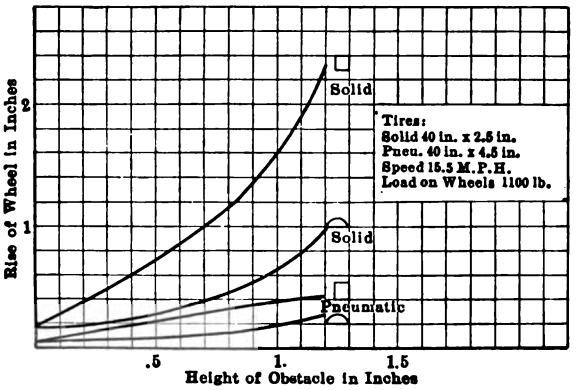

FIG. 32.—Graphs showing vertical lift of axle caused by different shaped obstacles.

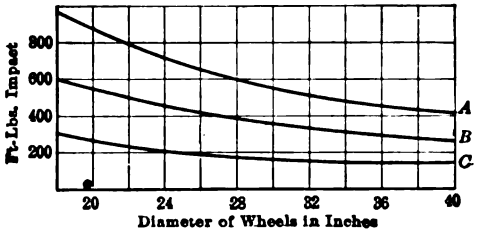
**93. The relation of speed to maintenance costs.** As the speed of a vehicle progressively increases, the force of impact on tires, wheels, axles and springs caused by rough road surface also increases, and very rapidly. This effect is very well shown in Fig. 32 and Fig. 33, plotted from results of tests made by Welles and Michelin.* It is obvious from these results that

* Report of Standardization Committee, Electric Vehicle Association of America, October 7, 1912.

Digitized by Google

the cost of vehicle maintenance will increase as the average service speed increases, because of the greater shocks and stresses to which the entire vehicle is subjected.



*A:* Ft-lb. Impact at 1000 lb. per Wheel Lift of 3 in.
*B:* Ft-lb. Impact at 1000 lb. per Wheel Lift of 2 in.
*C:* Ft-lb. Impact at 1000 lb. per Wheel Lift of 1 in.

FIG. 33.—Curve showing foot-pounds impact for different wheel diameter and axle lifts.

**94. The selection of the best type of vehicle** adapted to a specific service is governed by the individual characteristics of the service under consideration. The factors affecting the number, size, and operation of the machines required are:

(1) The total work performance expressed in units of delivery, namely, in "tons," "ton miles," "packages," "barrels," or whatever the nature of the merchandise dictates.
(2) The weight of these units.
(3) The relation of the time required for loading, unloading, traveling and delays, to the total time available.
(4) The average speed of travel permissible. (This is affected by traffic, road surface conditions and grades.)
(5) The mileage requirements.
(6) For electric vehicles, the energy consumption in kilowatt-hours.
(7) The frequency of stops.
(8) The cost of the service as compared with other means of accomplishment.

**95. The number of vehicles required for a given service** in light delivery work may be calculated by the use of the following formula:

$$\frac{PT}{M} = N \qquad (3)$$

where $P$ = number of packages; $T$ = average delivery time in minutes per package, including running time of vehicle; $M$ = available time in minutes in delivery zone; $N$ = number of machines.

**96. For heavy trucking service the number of vehicles required** may be expressed as

$$\frac{\text{ton-miles} + (\text{tons} \times \text{empty miles})}{\begin{pmatrix}\text{average}\\ \text{speed}\\ \text{(m.p.h.)}\end{pmatrix} \times \begin{pmatrix}\text{average}\\ \text{load}\\ \text{(tons)}\end{pmatrix} \times \begin{pmatrix}\text{available}\\ \text{run'g time}\\ \text{(hours)}\end{pmatrix}} = \text{number of machines} \qquad (4)$$

**97. The numerical values of these performance factors** are determined only through observation, and differ not only with each installation but with the type of vehicle employed. In Fig. 34 are shown the relative values of the time elements in horse vehicle operation as observed by Pro-

Digitized by Google

fessor Pender,* and in commercial electric vehicle applications in similar service as observed by the author. It is noticeable that the relative time values for loading and unloading do not vary in proportion to the amount of merchandise handled. This is accredited to the tendency of the machine to "speed up" the men.

## ELECTRIC SHIP PROPULSION

### SHIP RESISTANCE

**1. General law of ship resistance.** The frictional resistance of any well-designed ship is roughly proportional to the square of the speed. Consequently at half speed the frictional resistance will be only one-quarter of the frictional resistance at full speed. Since the power required to propel a ship is proportional to the product of the frictional resistance and the speed, it follows that the power delivered from the propeller is proportional to the cube of the speed. Thus at half speed the output from the propeller is only one-eighth of the output at full speed. This relation is not exact but is nevertheless widely employed for approximate calculations. For large, high-speed vessels, such, for instance, as the "Mauretania" and the "Lusitania," the power required for driving the ship increases, at high speeds, even more rapidly than as the cube of the speed, as the result of decreasing propeller efficiency. For ships operated at widely varying speeds, it has thus been a consideration of much importance that the economy of the engine should be fairly high over a wide range not only of loads but of speeds.

**2. Fundamental data on ship resistance.** By analysis of the published data of a large number of modern ships of a wide variety of speeds, displacements and types, the results in the following table have been obtained for the frictional resistance reduced to the common reference basis of a speed of 20 knots (1 knot is a speed of 1 nautical mile per hour.* One nautical mile = 6,080 ft. = 1,850 meters).

**3. Table of Approximate Values for the Frictional Resistance of Ships**

| Displacement in (2,240-lb.) tons | Frictional resistance in lb. per ton, at a reference speed of 20 knots |
|---|---|
| 500 | 42 |
| 1,000 | 34 |
| 2,000 | 26 |
| 4,000 | 18 |
| 8,000 | 12 |
| 16,000 | 9 |
| 32,000 | 7 |

It will be seen from the values in the above table that, for a given speed, the frictional resistance per ton gradually decreases with increasing size of ship and attains a very low value in large ships.

**4. Estimation of the thrust horse-power required.** The power delivered from the propeller, is termed the thrust horse-power. Consider the case of a 4,000-ton ship when proceeding at a speed of 22 knots. From the table in Par. 3, the frictional resistance at a speed of 20 knots is given as 18 lb. per ton. For a speed of 22 knots, the frictional resistance of the ship will be:

$$4{,}000 \times \left(\frac{22}{20}\right)^2 \times 18 = 87{,}400 \text{ lb.}$$

$$\text{Output from propeller} = \frac{87{,}400 \times 22 \times 6{,}080}{60 \times 33{,}000} = 5{,}900 \text{ thrust h.p.}$$

Again, for a 24,000-ton ship proceeding at a speed of 14 knots:

* Although the term "knot" is a unit of velocity, as strictly defined, it is often loosely employed as unit of length, or the equivalent of one nautical mile (see Webster's "International Dictionary," 1913).

Digitized by Google

$$\text{Frictional resistance} = 24{,}000 \times \left(\frac{14}{20}\right)^2 \times 8 = 94{,}000 \text{ lb.}$$

$$\text{Output from propeller} = \frac{94{,}000 \times 14 \times 6{,}080}{60 \times 33{,}000} = 4{,}040 \text{ thrust h.p.}$$

Of course in actual service, these values will vary tremendously with wind, wave, tide, condition of ship's bottom, disposition of cargo, arrangement of superstructure and other varying conditions. Furthermore the values given correspond with normal designs of average vessels. It is to be observed, however, that reasonable extremes in type of vessel do not occasion great departures from representative values of the frictional resistance.

**5. Ship momentum.** When increasing the speed of a ship, power must be expended in order to provide the greater momentum associated with the higher speed. This power is in addition to that required to overcome friction. Consider the acceleration of a 24,000-ton* ship from rest up to a speed of 14 knots. The formula for $E$, the energy of momentum, is:

$$E = \frac{1}{2}\frac{W}{g}V^2 \qquad (1)$$

where: $W$ = weight in pounds,
$g$ = acceleration of gravity in feet per second per second (= 32.2),
and $V$ = speed in feet per second.

In our example we have:

$$W = 24{,}000 \times 2{,}240 = 53{,}800{,}000 \text{ lb.}$$

$$V = \frac{14 \times 6080}{3600} = 23.6 \text{ ft. per second.}$$

$$E = \frac{53800000 \times 23.6^2}{2 \times 32.2}$$

$$= 467{,}000{,}000 \text{ ft-lb.}$$

[1 h.p. = 33,000 ft-lb. per minute.
∴1 h.p-hr. = 33,000 × 60 = 1,980,000 ft-lb.]

$$\therefore E = \frac{467}{1.98} = 236 \text{ h.p-hr.}$$

**6. Acceleration.** If the acceleration is accomplished in 3 min. and at the uniform rate of $\left(\frac{23.6}{3 \times 60} =\right)$ 0.131 ft. per second per second, then the output from the propeller for providing this acceleration is:

$$(60/3) \times 236 = 4{,}720 \text{ thrust h.p.}$$

We have already seen (Par. 4) that, at a speed of 14 knots, an output of 4,040 thrust h.p. is required for overcoming the frictional resistance. Consequently when accelerating the ship from rest up to a speed of 14 knots in 3 min. the output from the propeller gradually increases from 4,720 thrust h.p., at the moment the ship starts, up to 4,720 + 4,040 = 8,760 thrust h.p., at the completion of the acceleration, and then decreases to 4,040 thrust h.p., when constant speed is attained.

In practice, the acceleration is not at a uniform rate but gradually decreases as the ship gathers speed.

**7. Retardation.** It is interesting to consider the conditions attending an emergency reversal when the ship (Par. 6) is proceeding at a speed of 14 knots. In order to bring the ship to rest in 3 min. (neglecting the losses in the machinery and the resistance of the ship), the propellers must, after reversal, *impart to the water* 236 h.p-hr. of energy. It may be assumed that 30 sec. is occupied in bringing the propellers up to speed in the reverse direction and that, during this time, the ship travels: (30/3,600) × 14 × 6,080 = 710 ft.

For the remaining 2.5 min. (150 sec.) the propellers must impart to the water nearly 236 h.p-hr. (say 200 h.p-hr.) of energy. The average output from the propellers is: (60/2.5) × 200 = 4,800 thrust h.p. If the retardation is uniform, the average speed during these 150 sec. is: 23.6/2 = 11.8 ft. per second and the distance traversed is: 150 × 11.8 = 1,770 ft., the total dis-

* Throughout this section the 2,240-lb. ton will be employed.

Digitized by Google

tance traversed during the 3 min. occupied by the manœuvre is: 710+1,770 =2,480 ft.

Since the momentum increases as the square of the speed, and since, as will be seen in Par. 17, the efficiency of propellers is only of the order of 60 per cent., the bringing to rest of a 24,000-ton ship in 3 min. from a speed of 25 knots, would require an average output from the engines to the shaft, of the order of: $\left(\frac{25}{14}\right)^2 \times \frac{100}{60} \times 4{,}800 = 25{,}500$ h.p.

During such a manœuvre, the ship would cover a distance of over 4,000 ft.

Reciprocating engines are very effective for astern manœuvres, but since steam turbines are non-reversible and since it is economically impracticable to provide astern turbines with any such capacity as that of the ahead turbines, ships equipped with steam turbines are deficient in capacity for prompt astern manœuvres. The seriousness of any such deficiency is too apparent to require comment. See Par. 9.

**8. Emergency power requirements.** In the ordinary course of navigating a ship, the power required is, from time to time, far in excess of that required in a smooth sea to maintain constant speed. In a heavy sea, the ship's speed is repeatedly and abruptly decreased by impact with waves. Under such circumstances the progress of the ship is accompanied by a succession of cycles which impart to it the momentum which is absorbed by impact with the waves. Under these circumstances, not only must the output of the engines be great enough to overcome the increased frictional resistance, but also to provide, again and again, the energy of momentum corresponding to the speed of the ship. The power equipment of a ship should be estimated with due regard to whether it will navigate inland waterways or whether it is destined for ocean transportation.

**9. Backing tests (retardation); engines versus turbines.** In a paper by Capt. C. W. Dyson, U.S.N., entitled "Engineering Progress in the United States Navy" read before the Society of Naval Architects and Marine Engineers at New York on Nov. 21 and 22, 1912 (see page 184, *The Engineer*, for Feb. 14, 1913), the author states that in backing tests of the battleship "Delaware," which is equipped with two sets of triple-expansion engines, 1 min. and 52 sec. were required to bring the vessel dead in the water from a speed (ahead) of 21 knots; and that in similar tests on the battleship "Utah," which is equipped with Parsons turbines, 4 min. and 44 sec. were required to bring the vessel dead in the water from a speed (ahead) of 20 knots.

On page 492 of *Engineering* for April 10, 1908, in a description of tests on the turbine ship "Lusitania," it is stated that with the vessel proceeding at a speed of 22.8 knots, 3 min. and 55 sec. were required from the instant of signalling "full-speed astern" to bring the ship to rest. In this time, she had run a distance of three-quarters of a mile. These figures indicate the great inferiority of the turbine ships "Utah" and "Lusitania" with respect to prompt stopping, as compared with the "Delaware," equipped with reciprocating engines.

**10. Formulas for determining the power required for propulsion.** Naval architects and marine engineers employ to good purpose, in calculating the power required for ship propulsion, a large collection of coefficients and ratios which represent the results of accumulated experience. In this limited space it would be inexpedient to deal categorically with all of these coefficients and ratios.

**11. Block coefficient.** In the design of cargo boats a leading consideration relates to having a high "block coefficient," *i.e.*, a high ratio of displacement ($D$), to the weight of a block-shaped volume of water whose length, breadth and depth are equal to the ship's length ($L$), beam ($B$), and draught ($H$), respectively. The "block coefficient" of fast ocean liners and of warships, with the lines essential to speed, is only of the order of 0.6 to 0.7; but for cargo boats the carrying capacity is of such importance that designs with block coefficients of 0.8 and higher are employed, and with only moderate increase in frictional resistance per ton of displacement. Even in slow-speed cargo boats the length must be maintained in fairly high proportion to the tonnage capacity, partly in order to maintain the frictional resistance at a reasonably low value, and largely in order that the ship may be passed

Digitized by Google

through locks, and in general conform to the requirements of such service. The "**beam draught**" ratio $(B/H)$, and the "**displacement length**" ratio $D+(L/100)^3$, are also amongst the criteria employed in this connection.

**12. The admiralty formula.** Naval designers and marine engineers (especially in Great Britain), have made considerable use of the "admiralty formula," and although it dates from the period before the advent of the marine steam turbine, it is still widely used. The "admiralty formula" expresses the indicated horse-power (i.h.p), in terms of the two-thirds power of the displacement, the cube of the speed, and a factor, $C$, known as the "**admiralty displacement coefficient.**" The formula is:

$$\text{indicated horse-power} = \frac{D^{\frac{2}{3}} \times V^3}{C} \qquad (3)$$

It will be seen that the length $(L)$ of the ship does not enter directly into this formula but is embodied in $C$, the "admiralty displacement coefficient."

Other formulæ and data relating to ship resistance, and to the power required for propulsion, are given in Taylor's "Speed and Power of Ships;" John Wiley & Sons, New York, 1910, and in Chapters II and IV of Hobart's "Electric Propulsion of Ships;" D. Van Nostrand Co., New York, 1911.

## PROPELLER CHARACTERISTICS

**13. General.** The screw propeller was first employed for ship propulsion thousands of years ago by the Chinese. The steam-driven screw propeller came into wide use during the last half of the nineteenth century. The first quarter of the twentieth century will witness the extensive adoption of electrical transmission from the steam engine or oil engine to the propeller. This will permit various advantages which will be set forth in later paragraphs. At present it is desired to dwell on the very important advantage that the method will permit greater freedom in the choice of propeller speed.

**14. Propeller thrust, diameter and speed.** It will be impossible to touch upon more than the mere elements of the characteristics of propellers. In Par. 4, we briefly discussed a 24,000-ton ship for operation at a speed of 14 knots. At this speed the output required from the propeller for overcoming frictional resistance was estimated to be 4,040 thrust h.p.; now assume that 5,000 thrust h.p. will be provided. At a speed of 14 knots the corresponding thrust will be:

$$\frac{5{,}000 \times 33{,}000 \times 60}{14 \times 6{,}080} = 116{,}000 \text{ lb.}$$

It is usual in large ships to design the propellers for a **pressure** of not over **12 lb. per square inch of projected surface.** The projected surface of a propeller is the component of the area of the blades corresponding to a surface normal to the axis of the shaft. Therefore the projected area should be $116{,}000/12 = 9{,}700$ sq. in.

**The surface ratio** is the ratio of the projected area to the area of a circle whose diameter is equal to that of the tips of the propellers blades. We may assume that we shall employ a design having a surface ratio of 0.35. Consequently in the present instance we must provide a gross area of $9{,}700/(0.35 \times 144) = 192$ sq. ft. If we employ a **single propeller**, its diameter should be: $\sqrt{(4 \times 192)/\pi} = 15.6$ ft. For a peripheral speed of 6,000 ft. per minute we arrive at a rotational speed of $6{,}000/(15.6 \times \pi) = 122$ r.p.m.

For the alternative of employing **two propellers,** and again assuming a surface ratio of 0.35, a pressure of 12 lb.per square inch of projected area and a peripheral speed of 6,000 ft. per minute, we arrive at a diameter of $(0.707 \times 15.6 =)11.0$ ft. and a speed of $(1.414 \times 122 =)173$ r.p.m.

Many other considerations enter into the determination of the preferable design. The number of blades, and their shape, size and pitch, have a far-reaching influence on the result, as have also the peripheral speed and the pressure per square inch of projected area. The determination of the most favorable disposition of the propellers with reference to the hull and to one another, is another matter of much importance. The range of practicable diameters is also affected by the size of the ship and by its lines. If the propellers are to be well immersed in all weathers the permissible diameter is quite limited in ships with shallow draught.

Digitized by Google

**15. Propeller slip.** No reference has yet been made to the important consideration of the slip. The slip of the propeller is expressed as the percentage by which the speed of the ship is less than the speed corresponding to the pitch of the propeller. Let us illustrate this by the example of the 15.6-ft. propeller, which, when driven at a speed of 122 r.p.m. (Par. 14) should propel the ship at a speed of 14 knots, or $(14 \times 6{,}080)/60 = 1{,}420$ ft. per minute. At each revolution, the ship must travel a distance of $1{,}420/122 = 11.6$ ft.

Were there no slip, the propeller would be designed with a **pitch** of 11.6 ft.; in other words, the **"pitch-ratio"** (the ratio of the pitch to the diameter), would be $11.6/15.6 = 0.75$. The relations between the slip and the other characteristics of a propeller are highly complex and a knowledge of them is one of the assets of the naval designer. Such knowledge at present is in process of evolution, and forecasts of the performance of propellers, as well known, are likely to be very wide of the mark. Notwithstanding the elaborate and expensive tests on models, which often precede the construction of an important ship, great modifications in the propeller equipment are often made during her first few years of service. Assuming (for explanatory purposes) that experience has indicated that the slip will be 15 per cent. in the present case, it is seen that instead of a pitch of 11.6 ft. (corresponding to a pitch-ratio of 0.75), the propeller must be designed with a pitch of $\frac{11.6}{0.85} = 13.6$ ft., corresponding to a pitch-ratio of $(13.6/15.6 =)$ 0.87.

**16. Compromise design.** It is hardly necessary to dwell further upon the large number of factors entering into the design of propellers. The object in view is to arrive at an economic balance between good efficiency, satisfactory capacity in executing all manœuvres required of the ship and conformity with the requirements of the machinery from which it is driven. It was possible to arrive at a more satisfactory compromise among all these requirements when reciprocating engines were customarily employed, than has been the case since the advent of the steam turbine. This is for the reason that the **efficiency** of low-speed propellers is decidedly higher than that of high-speed propellers. In the case of ships of any considerable size, it would be utterly out of the question to design good propellers for speeds remotely approaching the high speeds of *efficient* steam turbines.

**17. Best speed of propellers.** It does not follow that, even with electric drive, it is desirable to adopt exceedingly low propeller-speeds. On the contrary, when due consideration is given to the efficiencies of (1) propellers, (2) electrical machinery, and (3) prime movers, and to their weights and costs, a compromise speed will usually be arrived at which involves at least a small amount of sacrifice in propeller efficiency. A consideration which frequently justifies the fitting of propellers of smaller diameters and higher speeds than are consistent with maximum efficiency, relates to ensuring as complete immersion as possible under all conditions of wind and weather and load, in order to minimise "racing."

Surprise may be occasioned by the statement that it is rare to realise **propeller efficiencies** of over 60 per cent., and that for representative modern ships of large size, the propeller efficiency is usually of the order of only 50 per cent. for turbine-driven ships, as against some 55 per cent. for ships equipped with reciprocating engines. Considering the greater flexibility resulting from the electric drive, and the gradually increasing knowledge of propeller design, it would appear that 60 per cent. should be kept in mind as a reasonable propeller efficiency for ships equipped with electric gearing, and that an improvement up to some 65 per cent. should be realized in favorable cases in the not-distant future. Allusions to propeller efficiencies of the order of 70 per cent. to 75 per cent., which are found in treatises dealing with the design of propellers, must be relegated to the category of theoretical abstractions which can be approached in tests of models, but which require the ruthless application of large allowances in order to arrive at values which can be realized in actual practice.

In a paper entitled "A Case for Electric Propulsion" read in June, 1913, before the Institution of Naval Architects, the authors, Mr. Henry A. Mavor and Mr. John Reid, stated:

"There are not 10 per cent. of the merchant vessels now afloat which would not be most efficiently propelled by screws designed to turn at revolutions not exceeding 80 per minute."

Digitized by Google

**18. Limits of propeller size and power.** It is well to call attention to the enormous power which can be delivered by a single propeller. In driving the "Mauretania" at 26 knots, an average speed at which she has made complete journeys across the Atlantic, the total thrust horse-power amounts to fully 36,000 h.p., or if equally distributed among the four propellers 9,000 h.p. per propeller. This corresponds, with her present equipment of four-bladed screws, to an output of 2,250 h.p. per blade. The propeller diameter is 15 ft., corresponding to a gross area of 176 sq. ft. The output may thus be reduced to 9,000/176 = 51 thrust h.p. per square foot of gross area. Taking the projected area, in the case of the Mauretania's latest propellers, as probably being some 40 per cent. of the gross area at the pitch circle, we have also: 51 / .40 = 127 thrust h.p. per square foot of projected area. No significance is to be attached to these large values, as they result from the employment of propellers of a speed distinctly too high to be compatible with good efficiency, and which have, furthermore, too small an area for effective manœuvring.

The turbines of the British battle cruiser "Tiger" will deliver 100,000 shaft h.p. at the vessel's maximum speed of 31 knots. Her four high-speed propellers will hardly have an efficiency of over 50 per cent., giving a thrust horse-power of some 50,000 h.p. or 12,500 h.p. per propeller.

**19. Multiple propellers.** In the early stages of the development of the marine steam turbine, engineers failed to realize that its natural speed was far in excess of speeds consistent with good propeller characteristics. Consequently vessels were equipped with propellers of such small diameters as to embody merely the necessary mechanical strength at high speeds, and the necessary area was obtained by resorting to the use of several (multiple) small propellers. In certain instances this was carried to the extreme of installing more than one propeller on a single shaft.

In 1894 on the occasion of the first trial of the historical "Turbinia" (of 45 tons displacement), she was fitted with only one shaft and a single two-bladed propeller of 30 in. diameter and 27 in. pitch. As thus fitted, the "Turbinia" was quite inoperative owing to intense cavitation. The slip was 49 per cent. She was then re-fitted with three propellers on the same or single shaft; these propellers were spaced from each other by three diameters and yielded a vessel speed of 20 knots, the propeller slip being 38 per cent. In 1896 the "Turbinia" was again re-fitted, three turbines being installed. Each of the three shafts carried three 18-in. diameter screws with a pitch of 24 in. She attained a speed of 34 knots with a turbine speed of 2,200 r.p.m. and slips of 17 per cent. on the middle shaft and 25 per cent. on the side shafts. In 1903, the "Turbinia," after having her *nine* 18-in. propellers replaced by *three* propellers of 28 in. diameter with a 28-in. pitch (there being one propeller on each shaft), was again tested, and showed about the same economy up to a speed of 17 knots, and a quite considerable increase in speed for a given steam consumption, for all speeds between 18 knots and 28 knots. Further particulars of the "Turbinia" tests may be found in a paper by Parsons, read before the Institution of Naval Architects on June 26, 1903.*

## SYSTEMS OF PROPELLER DRIVE

**20. Reciprocating steam engines.** There are three leading **advantages** possessed by the reciprocating engine for marine propulsion. These are:

(a) The natural speed of the marine type of reciprocating steam engine is of the same order as the natural (most efficient) speed of the screw propeller.

(b) The reciprocating steam engine may be designed for good economy over a wide range of speeds and loads, and for best economy at some intermediate speed and load.

(c) The reciprocating steam engine may readily be reversed and may exert great power during astern running. It is susceptible of ready control at all speeds including "dead-slow" speeds, and consequently endows the ship with excellent manœuvring ability.

The case for the reciprocating engine for marine propulsion, with special reference to the requirements of the United States Navy, has been very ably presented by Capt. C. W. Dyson, U. S. N., in a paper entitled "Engineering

*Stevens and Hobart. "Steam Turbine Engineering," Chap. XXIII, Whittaker & Co., London, 1906.

Digitized by Google

Progress in the U. S. Navy" and read before the Society of Naval Architects and Marine Engineers in November, 1912* (Par. 21).

The **disadvantages** of reciprocating steam engines relate chiefly to their great weight and bulk as compared with modern high-speed steam turbines. This disadvantage is serious where space and weight have as great significance as in a ship. But as pointed out in Par. 21, Capt. Dyson has not found any disadvantage in this respect in certain typical warships, when reciprocating engines are compared with *low-speed* marine steam turbines for direct connection to the propeller shafts. The initial cost of the reciprocating engine is relatively great when compared with the modern high-speed steam turbine. It is more impracticable to profit to so great an extent with the steam turbine, from the decreased steam consumption attending the high vacuums which are readily and economically attainable at sea. The reciprocating engine consumes far more lubricating oil than does the steam turbine, and also the wages item associated with the engine-room personnel is greater.

**21. Capt. Dyson on relative advantages of steam engines and low-speed turbines in the U. S. Navy.** The following quotations are made from Capt. Dyson's paper:† "This excessive falling-off in efficiency of propulsion under adverse conditions of wind, sea, and of ship's bottom, are characteristics of turbine-driven vessels." . . . . . "Should the duties of a vessel be such that she be required to steam for long periods and long distances at speeds much lower than her designed maximum speed, a less fuel expenditure per day will be required, and consequently a greater cruising radius will be obtained and less frequent re-coaling necessitated should reciprocating engines be fitted rather than turbines for propelling purposes. Should, however, the vessel operate from a fixed base, only doing sufficient cruising to ensure that the machinery is kept in efficient condition in readiness for forced runs to any threatened point, the value of fuel economy at low speeds becomes minimized, and, where the maximum speed of the vessel does not exceed 21 to 22 knots, either turbines or reciprocating engines may be used, the choice being dependent upon other factors than economies, which are practically equal at these speeds." . . . . . "The claim is frequently made by the turbine advocates that while the reciprocating engine, when new, is undoubtedly more economical than the turbine at small fractions of designed power, this advantage is soon lost in actual service, due to excessive wear of piston and valve rings causing large losses through heavy leakage of steam. The turbines, not being subject to such frictional wear, would, on the other hand, retain their original economy indefinitely. Practical experience with both types of engine in actual service comes very far from justifying this conclusion." . . . . . "In the cases of the main engines of the three scouts, 'Birmingham,' 'Salem' and 'Chester,' the 'Birmingham,' with reciprocating engines, has always been ready for service, while her two sisters have been repeatedly laid up at the yards for overhaul of the main turbines." . . . . . "For existing conditions nothing can be saved in the boiler-room weights or space by adopting turbines, as the same boiler power is required in the two cases. In the engine rooms, for these powers, however, the reciprocating engine has a decided advantage in both weight and space required. Thus, in the 'Delaware,' 'North Dakota' and 'Utah,' the engine-room weights and space required are as follows:

| | Delaware (reciprocating engines) | North Dakota (Curtis turbines) | Utah (Parsons turbines) |
|---|---|---|---|
| Engine-room weights, dry tons‡ | 728.0 | 731.0 | 865 |
| Engine-room weights, wet tons. | 773.0 | 786.0 | 920 |
| Engine-room, length, ft..... | 44.0 | 44.0 | 60 |
| Engine-room, total width, ft... | 50.5 | 50.5 | 51 |
| Engine-room, sq. ft., floor space. | 2,222.0 | 2,222.0 | 3,060 |

* *The Engineer*, London, Feb. 14, 1913, p. 184; Feb. 21, 1913, p. 208.

† Dyson, Capt. C. W. "Engineering Progress in the U. S. Navy;" Society of Naval Architects and Marine Engineers, Nov., 1912.

‡ "Wet and dry tons" relate to the engine-room weights with and without water in the boilers.

Digitized by Google

While the reciprocating engine has a decided advantage in the features of weight and space required, under present conditions these advantages would disappear should the necessary power to be developed be increased considerably above what is now asked for, and the advantage would rest with the turbine." . . . . . "Basing the choice between reciprocating engines and turbines for battleship propulsion under existing conditions of speed and power upon the above comparison of relative advantages of the two types, the advantage appears to rest most decidedly with the reciprocating engines."

**22. Relative economy of steam engines.** In the case of large, compound, triple-expansion and quadruple-expansion marine engines the economy falls but little behind that obtained in modern, high-speed land steam turbines for the same power, and is much better than that of steam turbines designed to operate at *speeds so low* as to permit direct connection to the propellers.

**23. Examples of steam-engine economy.** In a paper by C. Waldie Cairns* the result of 1.70 lb. of coal per indicated horse-power-hour with triple-expansion engines was given for a 36-hour trial of the 10-knot "Cairngowan" on Feb. 6, 1913. The corresponding water consumption was 15.2 lb. per indicated horse-power-hour; steam pressure, 175 lb. per square inch; vacuum, 26.8 in.; propeller speed, 61.7 r.p.m.; displacement, 9,950 tons, draft, 23 ft. 10 in.; length, 371 ft.; beam, 51 ft. See Par. **34** and **35**.

Elsewhere it has been stated on excellent authority that there are many ships which, even without superheaters, are working at 1.3 lb. and 1.4 lb. per indicated horse-power-hour (triple expansion) for all purposes.† In an editorial on p. 349 of *Shipbuilding and Shipping Record* for March 19, 1914, allusion is made to the estimate that with the combination of a reciprocating unit exhausting into a low-pressure turbine geared to a propeller shaft the water rate for large ships could be cut down to 8.5 lb. per horsepower per hour.

**24. Internal-combustion engines.** The only types of internal-combustion engine as yet developed which can come in for reasonable consideration for marine propulsion are those employing oil as fuel. The impracticability of providing space on board ship for gas producers and auxiliary plant precludes gas engines from consideration, so far as can be foreseen at present. Indeed it is the elimination of any equivalent to the steam-raising plant which is chiefly instrumental in giving the oil engine any standing as a prime-mover for ship propulsion.

**Space and weight are** factors of supreme importance on board ship, and it is the consideration that four-tenths of a ton of crude petroleum (or probably even of residue), will suffice for supplying the same number of shaft horse-power-hours to the propellers as would be supplied by burning 1 ton of coal‡ under boilers in a steam plant, that is proving so attractive to marine engineers and shipowners, even though the outlay for 0.4 ton (120 gal.)§ of crude petroleum will be much greater than for 1 ton of good coal. The advantage of the space and weight saved is of no small account, and for medium-sized and small-sized ships it should often outweigh the accompanying handicap of the increased outlay for fuel and the very great initial outlay for engines requiring the finest of workmanship in their manufacture and skilled attendance and adjustments during service. It is characteristic of oil engines as at present developed, that the weight of an engine of twice the capacity of a reference engine is, for the same speed, usually

---

* Cairns, C. W. "A Comparative Trial between the Triple-expansion Engine and Geared Turbine in Cargo Steamers." Also see *Shipbuilding and Shipping Record*, Apr. 3, 1913; p. 6.

† *Engineering*, London, July 19, 1912; p. 91.

‡ Crude petroleum is taken as having 19,000 B.t.u. per pound and coal as having 15,000 B.t.u. per pound. $0.4 \times 19{,}000/15{,}000 = 0.51$. Thus the statement in the text is based on obtaining with the oil engine only twice the efficiency from fuel to shaft, as in the steam plant. While better results are guaranteed and obtained, it is desirable at so early a stage in the development of the internal combustion engine to be conservative in estimating its performance.

§ The U. S. gallon, equal to the volume of 8.35 lb. of water or about 7.5 lb. of crude petroleum, is taken here.

Digitized by Google

*more than twice* as great as the weight of the engine of reference. Furthermore the economy is no better in the larger engine.

This state of affairs is in striking contrast with the characteristic of steam engines and steam turbines, that the greater the capacity the less the weight per horse-power and the less the steam consumption per horse-power-hour. On the other hand, *in small sizes* the economy of the steam turbine is not good, and it requires a large outlay for boilers and condensers.

**25. Limitations of the oil engine.** It appears that for installations of the order of **2,000 h.p. or less,** there should be a large field for the oil engine, notwithstanding the greater outlay for fuel. As compared with the steam turbine, the oil engine is handicapped by a considerable further outlay for lubricating oil. But taking into account the small quantity of fuel and the absence of any equivalent to the boiler plant, the advantage will usually, for less than some 1,500 to 2,000 h.p., remain with the oil engine *provided* the installation consists of several small sets, or subdivided units, with individual **electric drive** between engine and propeller. The last feature is necessary to overcome the relative unreliability of the oil engine and to enable repairs to be made without stopping the propellers.

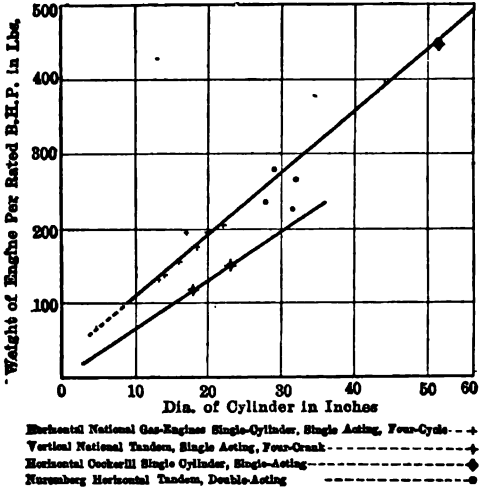

FIG. 1.—Weights of gas-engines of different dimensions.

Except for very small outputs, the oil engine is particularly ill-suited for direct connection to the propeller, for the reason that for starting and for reversing, a considerable supply of compressed air must be available. Furthermore, the efficiency of the oil engine decreases rapidly as the load decreases, and also it is satisfactory only at normal speed. Sight must not be lost of the fact that oil engines of the sizes which come into consideration for the purpose are expensive machines and much less rugged and reliable than steam turbines or steam engines. The handicap in first cost and fuel cost must be equated against the greater earning power of the ship consequent upon the space and weight saved and made available for cargo.

**26. Weight of internal combustion engines.** It is important that sight should not be lost of the relatively great weight of internal-combustion engines. Dr. Diesel has stated* that the more recent engines of his type

* Diesel, R. "The Diesel Engine and Its Industrial Importance, Particularly for Great Britain;" Proceedings Institution of Mech. Engineers, 1912.

Digitized by Google

(double-acting, two-stroke-cycle) weigh only some 110 lb. per horse-power. Mr. Dugald Clerk in the discussion of Dr. Diesel's paper gave the table of weights in Par. **28** and also the curves which appear in Fig. 1 and Fig. 2.

It is the order of magnitude of these weights, relating to four-stroke-cycle engines, which has occasioned the strong tendency to develop the larger capacities in two-stroke-cycle engines.

A single acting, four-stroke-cycle, low-speed, 800 b.h.p. Diesel engine is considerably heavier than any of the engines shown in Fig. 2, as it has a weight of some 600 lb. per brake horse-power. Retaining the same low speed,

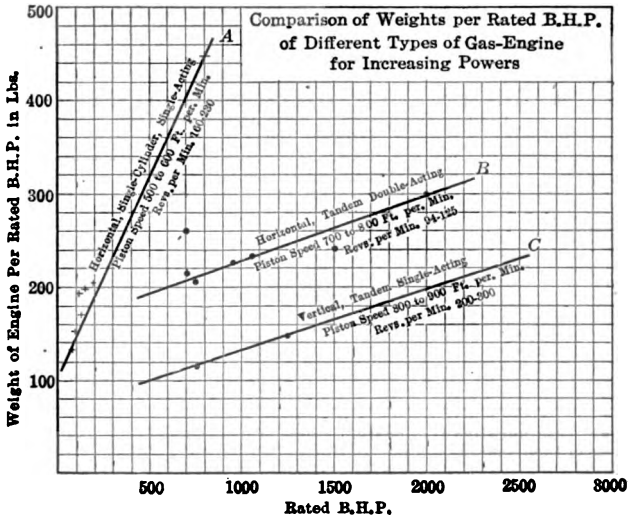

FIG. 2.—Comparison of weights per rated brake h.p. of different types of gas-engine for increasing powers.

but resorting to a double-acting two-stroke-cycle, the weight comes down to 238 lb. per brake horse-power; and in recent high-speed Diesel engines of the double-acting two-stroke-cycle type, the weight is brought down to 116 lb. per brake horse-power. The above data of weights of Diesel engines present a striking contrast to the low weights per brake horse-power which are being obtained in large steam turbines.

**27. Diesel marine engines.** The "Selandia," "Fionia" and "Jutlandia" are sister ships; each is 370 ft. long and 53 ft. beam. Each ship is fitted with two four-stroke-cycle vertical, single-acting Diesel engines and each of the two engines comprises eight cylinders and has a rated capacity of 1,250 i.h.p., or a total of 2,500 i.h.p. per ship. The speed at sea is 130 r.p.m. In a paper by Mr. I. Knudsen entitled "Results of Trials of the Diesel-engined Sea-going Vessel 'Selandia,' read on March 28, 1912, before the Institution of Naval Architects, the results of the trial trips are given. It is stated that reversal of the engines from full speed ahead to full speed astern can be carried out in 20 sec. The fuel oil is stored in the double bottom of the vessel, and sufficient storage capacity is provided for a continuous journey of about 30,000 miles. After three short trial trips the "Selandia" made a journey across the North Sea from Copenhagen to Aalborg with a cargo consisting of about 2,000 tons of cement. The fuel consumption (including all oil used for auxiliaries, but excluding that used for heating the vessel), was

Digitized by Google

0.363 lb. per indicated horse-power-hour developed by the main engines. On the basis of a calorific value of 19,000 B.t.u. per pound of fuel, this works out at (0.363 × 19,000 =) 6,900 B.t.u. per indicated horse-power-hour. The thermal equivalent of 1 h.p-hr. is 2,550 B.t.u. and therefore the thermal efficiency was 2550/6900 = 37.0 per cent.

Since no deduction was made for the fuel consumed by auxiliaries, and since the efficiency figure relates to the efficiency in actual service at sea, the result must be regarded as very good indeed. In the course of the discussion of the paper Mr. J. T. Milton stated that "the brake horse-power would be about 82 per cent. of the indicated horse-power, according to general practice. Assuming this tob e correct for the 'Selandia,' it would give a consumption of from 0.4 lb. to 0.5 lb. per brake horse-power-hour, which was about the same result as that obtained in the 'Vulcanus.'" (The Vulcanus is a Dutch oil-tank vessel of 2,500 tons displacement and equipped with a 500-h.p. Diesel engine. It was put in commission in the summer of 1911.)*

**28. Table of Weights of Large Continental Gas Engines**
Tandem Double-acting Four-stroke-cycle Type
(Dugald Clerk)

| Brake h.p. | Net weight of engine with fittings, but without fly-wheel, in tons | Same per b.h.p. in lb. |
|---|---|---|
| 630 | 66.5 | 237 |
| 700 | 81.7 | 261 |
| 750 | 68.5 | 205 |
| 800 | 85.0 | 238 |
| 950 | 95.1 | 224 |
| 1,000 | 120.0 | 269 |
| 1,060 | 109.3 | 231 |
| 1,500 | 162.3 | 243 |
| 2,000 | 266.5 | 299 |

**29. Comparative fuel costs.** Prices of fuel should be compared on the basis of their calorific contents in British thermal units (B.t.u.). Take good bituminous coal as having a calorific value of 14,300 B.t.u. per pound (or 32,000,000 B.t.u. per 2,240-lb. ton). Take oil fuel as having a calorific value of 19,000 B.t.u. per pound (or 42,500,000 B.t.u. per ton). Comparing bituminous coal at $3.00 per ton with oil fuel at $12 per ton, the former costs 9.4 cents per million B.t.u., compared with 28.2 cents per million B.t.u. for oil fuel. Since 28.2/9.4 = 3.00, the oil engine must be three times as efficient as the steam engine in order to bring the fuel cost down to the same value per brake horse-power-hour. A large modern steam engine or steam turbine should give out, in brake horse-power-hours, about 14 per cent. of the energy in the coal, under the conditions of service at sea. It is yet to be demonstrated that an oil engine can be built which will give out in brake horse-power-hour (3 × 14 =) 42 per cent. of the heat energy in the oil, under the conditions of service at sea. At the present stage of development, it would be venturesome to count on obtaining, under these conditions, an efficiency of more than (2 × 14 =) 28 per cent. Consequently, so long as the oil fuel costs more than (⅓ × $12 =) $8 per ton, as against coal at $3. per ton, the fuel cost will be greater in the case of the oil engine.

If, with producer plant, there can be developed a producer which will work satisfactorily in every way with bituminous coal, the price for fuel would be the same in the two cases. Assuming an efficiency, say, of 21 per cent., from the coal to the shaft, as against 14 per cent. for a steam plant, then the fuel cost of the gas plant would be only (14/21 =) two-thirds of that for the steam plant.

Should commercial success ultimately attend the efforts to develop an internal-combustion engine consuming coal dust in the cylinders, we should

* See page 219 of the 1912 *Proceedings* of the Institution of Mechanical Engineers, where also will be found interesting particulars of many ships equipped with Diesel engines.

Digitized by Google

finally have the result of high efficiency and cheap fuel. When supplied in the form of coal dust, 3 cents per million B.t.u. is a fair relative figure for the fuel cost. Assuming as the sea efficiency from fuel to shaft:

(a) 14 per cent. for boiler plant and steam engine or turbine,
(b) 28 per cent. for oil engine,
(c) 21 per cent. for producer plant and gas engine,
(d) 28 per cent. for coal-dust engine,

and assuming for the price of fuel per million B.t.u.:

(a) 9.4 cents for coal for the steam-engine equipment,
(b) 28.2 cents for oil for the oil-engine equipment,
(c) 9.4 cents for coal for the gas-engine equipment,
(d) 3.0 cents for coal for the coal-dust engine equipment,

then the costs per million B.t.u. given out at the shaft and per brake horse-power-hour given out at the shaft, work out as shown in Par.30.

**30. Summary of Comparative Fuel Costs for Marine Prime Movers**

| | Fuel cost per million B.t.u. at shaft, cents | B.t.u. per h.p-hr. | Fuel cost per brake h.p-hr., cents |
|---|---|---|---|
| I. Steam plant..... | 67 | 2,545 | 0.171 |
| II. Oil-engine plant..... | 101 | 2,545 | 0.257 |
| III. Gas-engine plant..... | 45 | 2,545 | 0.115 |
| IV. Coal-dust engine plant.... | 11 | 2,545 | 0.028 |

The attractively low fuel cost in the case of the coal-dust engine would be futile in marine propulsion unless attained with an engine of small weight and of low cost and upkeep.

**31. Low-speed, direct-connected turbines.** Ever since the advent of the steam turbine into engineering work on land, there has been gradual but uninterrupted progress toward the employment of ever higher speeds. This progress has been accompanied by a great decrease in weight per horse-power and a very satisfactory decrease in steam consumption per brake horse-power-hour. In marine applications the difficulties encountered at an early date with respect to propeller efficiency, and the attainment of satisfactory operating characteristics of the propeller, imposed restrictions on the speeds employed. Consequently marine steam turbines have been much more heavy and less economical than land turbines for equivalent outputs.

The steam turbines of the "Mauretania" run at a speed of 188 r.p.m. and (exclusive of condensing plant) represent a weight of about 40 lb. per shaft horse-power. The steam consumption per shaft horse-power-hour during the full-speed trials was just over 12 lb.* Each of the four main turbines delivers about 17,000 s.h.p. Land turbines for twice this output can now be built with speeds of 1,800 r.p.m. and there is thus obtained, not only an enormous reduction in the weight per horse-power, but also a very satisfactory improvement in the steam consumption per shaft horse-power-hour.

**32. Improved economy of high-speed turbines.** By using 250 deg. fahr. of superheat, the firm of Messrs. Parsons will obtain on a 750-r.p.m., 25-cycle, 25,000-kw. set which they have constructed, a steam consumption (guaranteed) of only 11 lb. per kilowatt-hour, which (allowing for an efficiency of 97 per cent. for the electric generator) is equivalent to 8.0 lb. per brake horse-power-hour from the steam turbine. High superheats can be used much more successfully in high-speed turbines, since with their relatively small diameters they are more rigid and more free from the difficulties consequent upon expansion than is the case with large, slow-speed, steam turbines. When tested with 220 deg. fahr. superheat, a pressure of 184 lb. per square inch at the boiler side of the pressure stop valve, a condenser pressure of 0.72 in., and a load of 9,000 brake-horse-power, a 40-

* See p. 463 of *Engineering* for April 4, 1913.

Digitized by Google

cycle, 1,200-r.p.m. steam turbine in the Dunston-upon-Tyne power house of the Newcastle-upon-Tyne Electric Supply Co., was ascertained by Messrs. Merz and McLellan to have a steam consumption of 8.2 lb. per brake horse-power-hour. The turbine employed in this set was of the Curtis type and was built by the A. E. G. of Berlin.

Tests made on a 10,000-kw., 25-cycle, 1,500-r.p.m. generating set, constructed by the Gen. Elec. Co. and employing turbines of the Curtis type, showed a steam consumption of 12.7 lb. per kilowatt-hour when operating at 185 lb. gauge pressure, 100 deg. fahr. of superheat and 28 in. of vacuum. When reduced to terms of the pressure, superheat and vacuum of the Parsons 25,000 kw. set the consumption works out at 10.5 lb. per kw-hr. although the Curtis set is of only 10,000 kw. capacity as against 25,000 kw. for the Parsons machine.

In the case of a 1,500-r.p.m., 30,000-kw. set constructed by the Gen. Elec. Co. for the Chicago Edison Co., the steam consumption at a load of 25,000 kw. is guaranteed not to exceed 11 lb. per kilowatt-hour when operating at 230 lb. gauge pressure, 200 deg. fahr. superheat and 1 in. absolute back pressure.

**33. High-speed, geared steam turbines.** When it was first contended by Mr. Geo. Westinghouse and Sir Chas. Parsons that thousands of horse-power could be transmitted through toothed speed-reduction gearing of the double-helical type, with a loss of only 1.5 per cent. to 2.0 per cent., engineers were very sceptical. Already, however, many ships fitted with geared turbines are in service. In an editorial on page 610 of *Engineering* for Nov. 1, 1912, appears this statement regarding the efficiency of the toothed gear transmission: "The loss in transmission is only 2 per cent. as against 8 per cent. for electrical gear and from 10 per cent. to 14 per cent. for hydraulic gear."

The U. S. collier "Neptune" is equipped with Westinghouse geared turbines, the performance of which has been discussed by Lieutenant W. W. Smith in the 1912 *Journal* of the American Society of Naval Architects. Lieut. Smith expresses the opinion, from his experience with this gearing, that it will ultimately be quite possible to transmit 15,000 to 25,000 h.p. *through a single gear*. For a vessel speed of 14 knots, the "Neptune's" propellers run at a speed of 135 r.p.m. and are driven through gearing with a ratio of 9.3 : 1. Each of the "Neptune's" two steam turbines is of some 3,000-h.p. capacity and runs at a speed of only 1,250 r.p.m. The "Neptune's" displacement is 20,000 tons.

**34. Results of Trials of Sister Ships fitted with Geared Turbines and Triple-expansion Engines**

| | Cairnross | Cairngowan |
|---|---|---|
| Type of engine | Geared turbines | Triple-expansion |
| Revs. per min. (mean of 36 hours) | 61.8 | 61.7 |
| Coal per day | 27.8 tons | 32.7 tons |
| Indicated horse-power | —— | 1,790 |
| Shaft horse-power | 1,570 | —— |
| Ratio of shaft horse-power (Cairnross) to indicated horse-power (Cairngowan). | 87.7 per cent. | —— |
| Pounds of coal per indicated horse-power-hour, all purposes | Equiv. 1.54 lb. | 1.70 lb. |
| Pounds of coal per shaft horse-power-hour, all purposes | 1.65 lb. | Equiv. 1.94 lb. |
| Pressure at steam pipe in engine room | 158 lb. | 175 lb. |
| Vacuum | 28.8 in. | 26.8 in. |

The machinery of the "Cairnross" is some 20 tons lighter than that of the "Cairngowan." See Par. **23**.

**35. Comparison of geared turbines and triple-expansion engines** The "Cairnross," a tramp steamer designed for a sea speed of 10 knots, is equipped with two steam turbines running at a speed of 1,700 r.p.m. and both geared with a ratio of 26.2 :1 to a single propeller with a speed of 65 r.p.m. The length between perpendiculars is 370 ft., and the breadth is

Digitized by Google

51 ft. On the trial run, the displacement was 9,950 tons; block coefficient, 0.779. The steamer fitted with triple-expansion engines, the "Cairngowan," is a sister ship to the "Cairnross," has practically the same dimensions, the same propeller speed, and was loaded to the same displacement as the "Cairnross" during the 36-hr. trial. The results of the trials appear in Par. 34.

**36. Alquist mechanical gearing.** A very recent development in speed-reduction gearing is the Alquist mechanical gear for large powers, incorporating the feature of flexibility to the extent necessary to overcome the grave difficulties associated with rigid mechanical gears operating at high tooth speeds.

**37. Electrical transmission for marine propulsion.** Although mechanical speed-reduction gearing is quite appropriate for ships of low power, making long journeys at a fairly constant speed, it is inferior in a number of respects to the plan of interposing electric transmission between the prime-mover and the propeller. The electrical plan provides effectively for: (1) obtaining the desired speed reduction for operating a low-speed propeller from a high-speed steam turbine; (2) dispensing with any additional turbines for astern running, since the electric motor provides the reverse ible attribute. As to the first feature, the electrical method greatly excels the mechanical method in the respect that ratio of reduction can be varied to any extent desired, thus permitting the operation of the ship economically at various speeds, while the prime-mover is preferably operated at substantially constant speed. Moreover, a greater ratio of speed-reduction is practicable with the electrical system than with mechanical gearing, and more favorable speeds can be adopted both for the steam turbine and for the propeller.

The second feature, the ability to reverse the ship by reversing the electric motors which drive the propellers, has not only the advantage of eliminating the additional turbines for astern running and thus lightening and cheapening the equipment, but there is the further advantage that in all manœuvring operations the full power of the main turbines is available, instead of the limited power of the astern turbines. Thus electrically-driven ships will be characterized by their prompt and decisive manœuvring abilities.

**38. Relative weight and efficiency of electrical gearing.** For a given speed-ratio, the interposed electrical machinery will usually be heavier and more expensive than mechanical reduction gearing, but electrical gearing permits employing a *greater* speed reduction than is practicable with mechanical gearing. Consequently, with the electric drive, the prime-mover is lighter and more efficient than when the mechanical gearing is employed, and this greater saving as regards the main prime-movers is increased by the complete elimination of the astern turbines. It must be admitted, however, that the overall efficiency of the electrical machinery is rarely above 90 per cent. to 92 per cent. as compared with 98 per cent. efficiency of the mechanical gearing. But here again it will be found that the inferiority of some 6 per cent. to 8 per cent. efficiency is fully made up by the increased economy in the steam consumption of the prime-mover, because of its higher speed, and the improved efficiency of the propeller, because of its lower speed.

**39. General conditions under which electric propulsion is best adapted.** The general tendency is in favor of mechanical gearing for small ships, of low power, making long journeys at full speed, and electrical gear for large ships, and for ships requiring different speeds on different occasions, including those ships which frequently navigate inland waterways and crowded harbors and consequently require excellent manœuvring ability.

**40. Special advantages of electrical gearing for ships operating at variable speeds.** The most important reasons for operating ships electrically relate to the introduction of certain principles which, in land central stations for the generation of electrical energy, are recognized as having fundamental commercial importance. These principles can be well illustrated by considering the case of a battleship. Such a ship must be equipped with enough propulsive machinery to provide some stipulated maximum speed. This may require an aggregate capacity, say, of 32,000 h.p. If the ship is equipped with steam turbines direct-connected to the propellers, probably there would be four turbines, each of 8,000 h.p., connected to each individual propeller. But the ship will be driven at its full speed only a small portion of the time. Its cruising speed is only some six-tenths of the

Digitized by Google

full speed, and it is at this lower speed that the ship is practically always driven. The power required to drive the ship at its cruising speed will be only of the order of 8,000 h.p. or less, as against the 32,000 h.p. aggregate capacity of the four turbines. Steam turbines become less efficient the lower the speed, and the lower the load. In this instance there would be four turbines running at only six-tenths of their full speed and only one-fourth of their full load. Under these conditions the steam consumption per horsepower-hour will be very much greater than at full speed and full load.

If the ship is arranged to be driven electrically, however, the general plan will be to employ a number of turbo-driven electric generators, of very high speed, situated in an engine room (or preferably in two independent engine rooms) located at any convenient point in the ship. These generating sets will supply energy to electric motors which in turn drive the propellers. Under this plan, while all the generators and all the motors will be required when the ship is operating at full speed, three-quarters of the generating plant can be shut down when the ship is proceeding at cruising speed; and if there are two or three motors for each propeller, it will also be possible, at cruising speed, to switch out all but one of the motors for each propeller. By this means those generating sets which are in service will be running at their economical speed, and sufficiently near their full load to be highly efficient. The plan provides complete independence between the number of prime-movers and the number of propellers; consequently the number and size of prime-movers can be determined with due regard to the best economy.

**41. Advantages of electric drive with internal-combustion engines.** While internal-combustion engines are usually of moderate speed, and while, consequently, the speed-reduction feature is of less importance, the features of operating the prime-movers at constant speed and of varying the number of prime-movers in service so that those in use shall be carrying their economical load, are equally valuable with internal-combustion engines. In fact, operation at constant speed is a factor of the very greatest importance in contributing to the success of large internal-combustion engines. There is the further important advantage that any occurrence rendering it necessary to repair a prime-mover during a voyage is usually of quite minor consequence and will not affect the progress of the voyage, since any particular engine is quite independent of any particular propeller.

In land central stations, an ensured continuity of service is obtained largely by virtue of having a number of independent generating sets. By the introduction on board ship of this feature of land practice, it becomes feasible at any time during the voyage to make such adjustments or repairs as are usually made in port on a ship having only one power unit for each propeller. It is an important advantage of the electrical method of propelling ships that it provides a great increase in flexibility in these directions over that which is otherwise practicable.

## TYPES OF VESSELS FOR DIFFERENT SERVICE

**42. Freight and tramp steamers.** Representative vessels of this class range from 250 ft. length by 42 ft. beam and 14 ft. draught for canal routes, up to some 420 ft. length by 52 ft. beam and 23 ft. draught for lake and ocean routes. The displacement ranges from some 5,000 tons for the former class, up to some 12,000 tons for the latter. The speed is of the order of some 8 to 12 knots; the power required is about 400 shaft h.p. for the smaller boats, ranging up to some 2,200 shaft h.p. for the larger.

As examples may be mentioned the "Cairngowan" (Par. **23**, **34**, and **35**), fitted with triple-expansion engines; the "Cairnross" (Par. **34** and **35**), fitted with geared turbines; the electrically propelled "Tynemount" (Par. **71** and **72**), with Diesel engines; the "Vespasian" (Par. **59**), with geared turbines; and the "Selandia" (Par. **27**), with Diesel engines.

Such boats are usually provided with a single propeller, which should preferably have a speed well below 100 r.p.m. In the largest vessels (400 ft. length) equipped with Diesel engines, two sets of engines and propellers will be customary.

**43. Cross-channel boats.** For modern cross-channel vessels for passenger transportation, speeds of the order of 20 to 23 knots are required. Their displacement is usually a matter of 1,500 to 2,500 tons and their engines should develop some 6,000 to 10,000 shaft h.p.

Digitized by Google

**44. Ocean liners.** Although each year witnesses increases in the size of ocean liners, the most recent vessels are equipped for slightly lower speeds than the 26-knot "Mauretania" and "Lusitania" of the Cunard Line. These two ships have an overall length of 790 ft., a breadth of 88 ft., a draught of 33 ft. 6 in., and a displacement of 38,000 tons. At full speed their turbines, of which there are four, develop some 68,000 shaft h.p.

The new Hamburg-American liner "Imperator" has an overall length of 920 ft. and an extreme breadth of 98 ft.; height, 100 ft. from keel to boat-deck and 246 ft. from keel to masthead; displacement, about 57,000 tons; propelled by four Parsons turbines, driving four screws of 16.5 ft. diameter, and four blades each. The total shaft output is about 62,000 h.p., corresponding to a draught of 35 ft. 6 in. and to a sea speed of some 22.5 knots; the corresponding propeller speed is 175 r.p.m. The coal bunkers have a capacity for over 8,500 tons. Full complement of passengers, 4,000; total ship's company, 1,180.

The Hamburg-American turbine liner "Vaterland" has an overall length of 905 ft. and a breadth of 100 ft.; the turbines develop 61,000 h.p. at about 180 r.p.m., corresponding to a sea speed of about 22 knots; accommodates 5,700 persons including the crew.

The Cunard liner "Aquitania" has an overall length of 901 ft.; breadth, 97 ft.; and draught, 34 ft.; depth from keel to boat-deck is 92 ft.; propelled by steam turbines driving four screws; speed, 23.5 knots—corresponding to 60,000 h.p.; displacement, 50,000 tons.

**45. Oil boats.** The largest oil-carrying vessels have capacity for 15,000 tons of oil. The "San Fraterno,"* when fully loaded with 15,700 tons of oil, has a draught of 28 ft.; length, 542 ft.; breadth, 66 ft. 6 in.; contract speed, 11½ knots (exceeded in trials); propelled by a quadruple-expansion engine; equipped for oil burning.

**46. Ore and Grain Boats.** Similar in general shape and capacity (Par. 45) are the ore carriers which transport cargoes of ore or grain between the Great Lake ports. The limitations of the depth of waterways through which they pass sometimes require a draught of less than 20 ft. On routes where such limitations do not hold, these vessels are often loaded to a draught of 24 ft. Their length is of the order of 600 ft.; beam, 58 ft; and moulded depth, 32 ft. They can accommodate a cargo of some 20,000 tons of ore or coal, or nearly half-a-million bushels of wheat, and can be loaded at the rate of 8,000 tons per hour. They are propelled at a speed of some 10.5 knots by a single screw, usually driven at about 120 r.p.m. by a triple-expansion engine of some 2,200 h.p.

**47. Tug-boats** are of course designed for towing service, mainly in sheltered waters. The three essential requirements are: (a) high speed when running free; (b) fair speed when towing; (c) high thrust or pulling effort at practically zero speed. If attention is paid first to the second requirement, the others will usually take care of themselves.

**48. Battleships.** The modern battleship has a length of from 550 to 600 ft., a breadth of some 90 ft. and a displacement of the order of 25,000 tons. A battleship is usually equipped for a maximum speed of about 21 knots; the cruising speed is about 12 to 14 knots. At maximum speed the engines are required to develop some 30,000 shaft h.p. Effectiveness in a battleship outweighs all questions of cost. Consequently a general movement is taking place toward the practice of burning oil fuel. By this plan, not only can a greater weight of fuel be stored in a given volume than with coal, but a ton of oil has a calorific value some 33 per cent. greater than a ton of coal. Consequently, with oil fuel, the radius of action is greatly increased. Furthermore, the use of oil fuel ameliorates the almost intolerable conditions in the stokehold. Every gain in economy is important, not from the standpoint of money actually to be saved, but on account of the increased radius of action on a single supply of fuel.

**49. Battle-cruisers.** Ships of this class constitute a modern development. They differ from battleships in the respect of being equipped for much higher speeds. This entails a certain sacrifice in armament and in armouring. The United States Navy has no battle-cruisers. As examples of battle-cruisers may be mentioned the following:

* *Shipbuilding and Shipping Record*, April 24, 1913, p. 149.

Digitized by Google

The German battle-cruisers "Moltke" and "Goeben." These ships have a length of 610 ft.; beam, 96.5 ft.; displacement, 23,000 tons; four propellers, driven by Parsons turbines aggregating 84,000 shaft h.p. The "Moltke" developed a speed of 28 knots, with the turbines running at 320 r.p.m.

The British battle-cruisers "Princess Royal" and "Lion" have a length of 700 ft.; beam, 88 ft. 6 in.; displacement, 26,000 tons; their turbines develop 70,000 shaft h.p. The "Princess Royal" displayed a speed of 33 knots, and the "Lion" a speed of 31 knots. The British battle-cruiser "Tiger" has 100,000 shaft h.p. (Par. **18**).

**50. Cruisers.** Prior to the advent of the battle-cruiser, the term armored cruiser was associated with a ship of somewhat less displacement than a battleship, and a speed exceeding that of a battleship by only 3 or 4 knots. This is the class of ship now termed simply "cruiser." Ships of this class are about as long as a battleship, but have considerably less beam. As typical of such armored cruisers it may be stated that their length is some 500 to 550 ft.; beam, 70 to 78 ft.; displacement, 14,000 to 18,000 tons. Their speeds are of the order of 23 to 25 knots.

**51. Light cruisers** (often designated "scouts" or "scout-cruisers"). These vessels are small cruisers having a displacement of some 2,500 to 4,000 tons and a speed of some 24 to 26 knots. They require engines of from 10,000 to 20,000 shaft h.p. As examples in the United States Navy may be cited the engine-equipped "Birmingham," and the turbine-equipped "Salem" and "Chester." These three boats are 420 ft. long; displacement, about 3,750 tons with 450 tons of coal on board; coal bunker capacity, 1,250 tons. The speed is 24 knots and the power about 16,000 i.h.p.

The "Fearless" is a typical British scout-cruiser; length, 385 ft.; beam, 41 ft. 6 in.; displacement, 3,360 tons. She has turbines of an aggregate capacity of 18,000 shaft h.p. and develops a speed of 25 knots.

**52. Colliers.** Allusion has already been made to the collier "Neptune," in Par. **33**. The electrically-equipped collier, "Jupiter" is described in Par. **69** and **70**. A sister to these two ships is the "Cyclops" which is equipped with triple expansion engines. Some of the leading data of these ships have been taken from recent publications and brought together in the following table (Par. **53**).

**53. Data of Three Colliers of the United States Navy**

| | Cyclops | Neptune | Jupiter |
|---|---|---|---|
| Type of propulsive machinery... | Triple-expansion engines | Geared turbines | Turbo-electric |
| No. of engines | 2 | 2 | 1 |
| No. of propellers | 2 | 2 | 2 |
| Speed of engines | 88 r.p.m. | 1,250 r.p.m. | 2000 r.p.m. |
| Speed of propellers | 88 r.p.m. | 135 r.p.m. | 110 r.p.m. |
| Speed reduction ratio | 1 : 1 | 9.3 : 1 | 18.1 : 1 |
| Speed of vessel | 14 knots | 14 knots | 14 knots |
| Displacement | 20,000 tons | 20,000 tons | 20,000 tons |
| Cargo capacity | 12,000 tons | 12,000 tons | 12,000 tons |
| Indicated horse-power at 14 knots | 5,600 | ..... | ..... |
| Steam consumption in lb. per shaft h.p.-hr. | 14 lb. (estimated) | ..... | 11.2 lb. (tested) |
| Weight of driving machinery.... | 280 tons | ..... | 156 tons |
| Speed during 48 hr. trial at sea.. | 14.6 knots | 13.9 knots | See Par. **70** |
| Corresponding output from engines. | 6,705 i.h.p. | ..... | for data of unofficial |
| Corresponding speed of propellers | 92 r.p.m. | ..... | 48-hour trial |
| Corresponding coal consumption for main engines only. | 1.49 lb. per i.h.p. hr. | ..... | |

**54. Torpedo-boat destroyers.** Modern boats of this class have displacements ranging from 500 to 1,800 tons, and speeds of 28 to 36 knots. They burn oil fuel in order to secure a maximum radius of action. Torpedo-boat destroyers are now usually driven by steam turbines and are fitted with from two to four propellers. Owing to the high speed of which they must

Digitized by Google

be capable, their horse-power per ton of displacement is usually much higher than for vessels of any other class. Take for instance the British torpedo-boat destroyer "Velox"; the displacement is only 440 tons, but at maximum speed of 36.6 knots (see page 70 of Hobart's "Electric Propulsion of Ships"), the vessel requires some 12,000 shaft h.p. This small boat has four propellers, and an engine capacity of about (12,000/440 =) 27 h.p. per ton of displacement, whereas scout cruisers have only some 4 h.p. per ton of displacement. Battleships are provided with only 1.0 h.p. to 1.3 h.p. of engine capacity per ton of displacement. The *cruising* speed of the "Velox" is only 11.3 knots, which requires merely some 300 h.p.

Thus a noteworthy characteristic of this class of ship is the great ratio of the power required at maximum speed to that required at cruising speed. In the case of the "Velox" this ratio is 12,000 : 300 = 40 : 1.

## ELECTRIC PROPULSION

**55. Consequences of the self-contained feature in a ship-propulsion installation.** There is one very important aspect of the proposition of driving a ship electrically, which should facilitate its introduction in marine practice. Each ship represents an independent, self-contained proposition. There is no particular need for, or advantage in, a rigid adherence to some one particular system. There are usually several alternative methods of dealing with any engineering problem and it is often difficult to determine which is the best. Generally, one can definitely discard several methods as less suitable for some particular case, but there will usually remain two or three methods between which it is difficult to choose.

In undertaking the electrification of a railway, this may well constitute a great embarrassment, since it is important to have standardisation and interchangeability of rolling stock over extensive systems. But in the case of ship propulsion, comparisons of various types of engine equipment, of propeller designs and speeds, of locations of propellers, of number of propellers, of kinds of fuel, etc., are continually being made on ships of otherwise identical characteristics. The rapid progress which is continually in evidence in marine engineering is largely a consequence of this established policy. It is easy to foresee that the application of electrical methods to ship propulsion will be more readily accomplished (so far as it is demonstrated to realize the economic advantages that are claimed for it), than has been the case with railway electrification.

The engineer's task will include determining upon a thoroughly appropriate installation in each case. It will be entirely unnecessary for him to adopt any other than the economically appropriate solution in any case, out of consideration for uniformity with the machinery employed in some other case.

Various combinations of machinery for the electric propulsion of ships have been worked out, and some of them have crystallized into "systems." But there are many sound plans and principles of proved appropriateness which have been employed in electric-power applications on land which are equally entitled to be designated as "systems" appropriate for ship propulsion. It is therefore not considered desirable to devote any space to detailed descriptions of "systems." The reader may care to refer to Chapters XIII to XVI, inclusive, of Hobart's "Electric Propulsion of Ships" for descriptions of various systems which have been proposed by Mavor, Emmet, Durtnall, Day, Hobart, and others.

**56. Turbines versus internal-combustion engines in electric propulsion.** For anything over 4,000 h.p. it would appear that for electrically-driven ships the economic advantage will be greater when the steam turbine is employed as prime-mover than when the oil engine is employed. In the first place, the cost of steam turbines is only a matter of some 20 cents per pound, as compared with some 50 cents per pound for oil engines. Furthermore, the weight per horse-power for oil engines of large output is several times the corresponding figure for steam turbines of the same output. The handicap in the matter of cost is so great that it is far from being offset by the cost of the steam-raising plant in the case of the steam turbine. Moreover, the fuel cost per brake horse-power-hour is at present much greater for oil than for coal. In electric propulsion, the very highest turbine speeds may be adopted, since in a self-contained plant such as that on board ship, the particular periodicity employed is of no consequence.

Digitized by Google

It had heretofore been usual for engineers to commit themselves to advocating either a geared-turbine drive or an electric drive. But this seems ill-advised. If the ratio of turbine speed to propeller speed is too great to be bridged economically and satisfactorily by double-helical gearing, on the one hand, or by an electric transmission on the other hand, then both should be used. For instance, for a 6,000-h.p. plant, either two 3,000-h.p. turbines could be employed or three 2,000-h.p. turbines, according to the requirements of the case. These turbines could be driven at 4,800 r.p.m., or even faster, and could supply a 60-r.p.m. propeller by first driving 600-r.p.m. generators through 8 : 1 gearing and then transmitting the power from these generators to 60-r.p.m. electric motors. This extreme case of a total speed-reduction of 80 : 1 has simply been taken to impress the viewpoint, and no special significance should be attached to the ratios selected for each of the two component speed reductions; these would be determined with due regard to the conditions in each particular case.

It should be realised that sacrifices are often made by keeping down to such a low turbine speed as 1,500 rev. per minute and that in each case the particular turbine speed should be adopted which leads to the best combination of low steam consumption and low weight and cost. But the mistake should not be made of sacrificing good characteristics in the electric generator by necessarily designing it for direct connection to the steam turbine. Similarly, for the electric motor, the design should be for a speed consistent with good electrical and mechanical characteristics and low weight and cost. If these are secured at a speed near that of the best propeller speed, then a compromise permitting the elimination of intermediate mechanical gearing may be appropriate; otherwise double-helical gearing, of 98.5 per cent. efficiency, should be interposed. As long as electric transmission constitutes one link in the chain, it is obviously a simple matter to provide a variable speed ratio and also to eliminate the astern turbines, thus securing excellent manœuvring characteristics.

Just as the steam turbine is at its best from 4,000 h.p. upward, so is the oil engine often appropriate from 1,000 or 2,000 h.p. downward, notwithstanding the high cost of oil fuel. In ships of such relatively small capacity as not to require more than from 1,000 to 2,000 h.p., the elimination of steam-raising plant is of much importance. Furthermore, with the inclusion of the feature of electric transmission, the provision of a small oil-engine installation of two or three component units ensures ample reliability. The space and weight saved, partly in consequence of the elimination of the boiler room and partly in consequence of the fact that 0.4 of a ton of oil fuel is the equivalent (as regards the shaft output of the engine), of 1.0 ton of coal in a steam plant, will provide, in cargo vessels, sufficient increase in the cargo capacity to more than offset the considerably greater outlay for fuel at present prices. The range of capacities lying between 1,000 or 2,000 h.p. on the one hand, and 4,000 h.p. on the other hand, constitutes a neutral zone where a study of the circumstances of each case will disclose some circumstance affording guidance to a correct decision.

**57. Study of electric drive for the "Mauretania."** In engineering estimates involving comparisons of alternatives, certain among which are untried, it is often necessary to discount liberally for the optimism of exploiters of systems. Making all due allowances of this kind, the following comparison is of interest and value. It is abstracted from a letter by Berger Ljungström written under date of April 12, 1912, and published at p. 536 of *Engineering* for April 19, 1912.

Ljungström has developed a turbine, both members of which revolve, and in opposite directions. This turbine is described in *Engineering* for April 12 and 19, 1912. In a 4,500-kw. turbo-generator set, the relative speed of the two parts of the turbine is 6,000 r.p.m. while the speed of the generator is only 3,000 r.p.m. Such a 4,500-kw., 6,000-r.p.m. turbo-generator weighs only 34 tons, or 11.5 lb. per horse-power. The total weight for the whole plant, with pumps, and with water in the condenser, is 65 tons, or 22 lb. per horse-power. The main dimensions are: Length, 23 ft. 7 in.; width, 6 ft. 7 in.; height, including condenser, 14 ft. 6 in. The 86-r.p.m. asynchronous motors with which Ljungström proposes to drive the propellers, would weigh 38 lb. per horse-power.

It is estimated that by installing on the "Mauretania" eight of these 4,500-kw. sets, and supplying energy from them to four motors (two motors on

Digitized by Google

each of two propeller shafts), the same vessel speed could be obtained by supplying only 45,500 shaft h.p. to the two 86-r.p.m. propellers as is now obtained by supplying 69,000 h.p. to the four 188-r.p.m. propellers which are actually fitted to the ship.

The calculations in Ljungström's comparison are given in tabular form in his letter and include cost estimates.

**58. Study of electric drive for the destroyer "Hugin."** Ljungström has also worked out estimates for an electric drive for the 348-ton Swedish destroyer "Hugin," which is now equipped with Curtis turbines of 10,400 shaft h.p., 850 r.p.m., and direct-connected to the propeller shafts. The corresponding vessel-speed is 31.2 knots. By substituting a Ljungström turbo-electric transmission, it is estimated that the propelling power would be reduced to 6,500 shaft h.p. and the coal consumption to 42 per cent. of its present value; the weight would be decreased by 75 tons and the floor space by 33 per cent. This turbo-electric alternative comprises three turbo-generators driving electric motors at 500 r.p.m. normal speed.

**59. Study of electric drive for the cargo boat "Vespasian."** Ljungström has also described an electric transmission which he proposed for the cargo boat "Vespasian." He states that "the electric motors, intended for 100 periods, are two in number and *geared* to the shaft." On p. 106 of Hobart's "The Electric Propulsion of Ships," this same plan was earlier advocated in the following words: "The disabilities of low-speed induction motors may be escaped and advantage may be taken of their good qualities by arranging that high-speed motors shall drive the propeller-shafts at low speeds through double-helical speed-reduction gearing. The pinions of two (or even more) motors could be arranged to gear with a single low-speed gear-wheel on the propeller shaft, quite analogously to the way in which two steam turbines drove the 'Vespasian's' shaft in the tests made by Parsons. Usually the 2 per cent. loss in the gearing would be largely offset by the higher efficiency of the high-speed induction motor, and the weight and cost of the gearing would be partly offset by the lesser weight and cost of high-speed as compared with low-speed induction motors. The difficulties associated with finding space in ships for large diameters are also eliminated by this plan."

**60. W. L. R. Emmet on electric propulsion.** Mr. W. L. R. Emmet has read papers on electric ship propulsion before various engineering societies. References to these papers are given in the bibliography (Par. **73**). In 1909 Mr. Emmet designed an electrical equipment for the battleship "Wyoming" and a proposal embodying these designs was made to the Government. Since that time Mr Emmet has submitted several designs to the Government relating to equipments of battleships which have been built. In the spring of 1913 Mr. Emmet submitted a design which applied to a case like that of the "Pennsylvania." The estimates as to the results of this equipment as compared with those which will be accomplished by the equipment which is being put into the battleship "Pennsylvania" are shown by the following table:

| | R.P.M. at 21 knots | H.P. required at 21 knots | Pounds of steam per hour, turbines alone, 21 knots | Pounds of steam per hour, turbines alone, 15 knots | Weight of driving machinery in tons |
|---|---|---|---|---|---|
| Turbine drive with geared cruising turbines as adopted. | 222 | 31,700 | 374,000 | 106,000 | 749 |
| Turbo-electric drive..... | 160 | 29,200 | 205,000 | 91,000 | 598 |

Mr. Emmet states* that if in 1909 his first design for a warship had been accepted by the Navy Department, the vessel produced would have been

* In a paper read on Dec. 11, 1913, before the Society of Naval Architects and Marine Engineers.

Digitized by Google

very greatly superior in respect to economy reliability, weight, simplicity, and cruising radius, to any ship now afloat.

**61. Mavor system of electric propulsion; "spinner" motor.** In a paper entitled "Electric Propulsion of Ships, with Note on Screw Propellers," read before the Institute of Engineers and Shipbuilders in Scotland, on Feb. 18, 1908, Mr. Henry A. Mavor describes an electric drive for a 17,000-brake h.p. ship with three propellers and a maximum vessel speed of 21 knots. Power would be provided by two turbo-generators from which three induction motors are driven. The motors are of a type which he designates as "spinner" motors and from which he obtains three efficient speeds.

On Dec. 7, 1909, Mr. Mavor read another paper in London (see p. 134 of Vol. 179 of *Proc.* Inst. Civil Engineers), in which he developed further plans employing the "spinner" type of motor. These studies constituted important steps in the history of ships propulsion, and the papers should be consulted.

**62. Study of electric drive for the cargo boat "Frieda."** Among other interesting projects for turbo-electric drives which have been worked out by Mr. Mavor (Par. **61**) may be mentioned one described in a paper which he read at the Portsmouth meeting of the British Association in September, 1911, and published in the *Electrician* for Sept. 8, 1911. This case related to the "Frieda," a 300-ft., single-screw vessel for the transport of bulk freights between the Gulf of Mexico and New York City. The vessel was for carrying a dead weight of 5,000 tons at a mean loaded speed of 12 knots at sea. The turbo-electric generator was to run at 3,000 r.p.m. The generator provided three-phase, 50-cycle, alternating current to a 1,900-brake. h.p. induction motor which drove the propeller at about 84 r.p.m. It was estimated that such an installation would cost less and weigh less than the normal equipment, and that the saving in coal would amount to 10 tons per day. Owing to various reasons, one of which related to the skepticism of the owners, this vessel was finally equipped with reciprocating engines instead of with the proposed turbo-electric drive.

**63. Reference to descriptions of other proposals for electric propulsion.** Various other turbo-electric drives which have been proposed for ship propulsion are described in Hobart's "Electric Propulsion of Ships," D. Van Nostrand Co., New York, 1912.

**64. Oil-electric projects for ship propulsion.** Mr. Mavor* has described several plans employing Diesel engines driving electric generators which, in turn, drive a motor or motors direct-connected to the propeller. He has also described the plans† proposed for driving a 245-ft. Canadian canal-type tank barge and employing three Diesel engines, each capable of developing 200 shaft h.p., direct-connected to alternating-current generators. It was proposed that the energy from one or all of these sets should supply one or all of three separate windings of a squirrel-cage induction motor keyed to the main propelling shaft and operating a single slow-turning screw.

## EXAMPLES OF ELECTRICALLY PROPELLED SHIPS

**65. Russian tank vessel.** In 1903 the Société Nobel Freres, of Petrograd, constructed an oil-tank ship of 1,100 tons displacement and fitted with electric transmission gear. The vessel was employed on the Volga and in the Caspian Sea. She was equipped with three Diesel engines with an aggregate capacity of about 360 h.p. direct-connected to continuous-current generators which in turn supplied energy to three motors, on the three propeller shafts, respectively. The vessel had a speed of some 7 to 8 knots. The control was arranged from the bridge.

**66. The Chicago fire boats "Graeme Stewart" and "Joseph Medill."** The electric equipments for these boats were designed in 1908 by Mr. W. L. R. Emmet and built by the General Electric Co. of Schenectady. Mr. Emmet describes these installations as follows:‡

"Each of these boats is equipped with two turbines having a capacity of about

---

† See *Electrician* for Sept. 8, 1911.

‡ In a brochure issued in 1913 by the General Electric Co.

Digitized by Google

660 h.p. each, and operating at a speed of 1,700 r.p.m. One end of the shaft of each of these turbines is connected to a large centrifugal fire pump and the other end is connected to a 200-kw. direct-current generator. The boats are propelled by twin screws and the speed and direction of each motor is controlled by manipulation of the field of the generator which drives it."

These Chicago fire boats have a length of 120 ft. and are of 28 ft. beam and 10 ft. draught. On page 389 of *Engineering* for Sept. 20, 1912, will be found scale drawings of the general arrangement of the machinery in these boats.

Mr. Emmet has made tests directed toward studying the propeller characteristics of these boats and has published the results in a paper presented in New York in November, 1911, before the Society of Naval Architects and Marine Engineers.

**67. The "Electric Arc."** In 1910 and 1911 Mr. Henry A. Mavor equipped with electric gearing a 50-ft. steel-built vessel, and subjected it to a series of tests. This boat, the "Electric Arc," was launched in February, 1911. See description in Par. **68.**

**68. The "Multiple" squirrel-cage motor.** The generator supplied three-phase current to a squirrel-cage induction motor, also of a type invented by Mr. Mavor (British Patent No. 12,917 of 1909) and to which he applies the designation of "multiple" motor. This motor drives the propeller at one or other of two speeds, in accordance with the following plan:

The stator is provided with two independent windings for two different pole numbers. At its normal speed, the generator provides periodicities which bear to one another the ratio of these two different pole numbers. By connecting the winding of higher pole number to the supply of lower periodicity an efficient running speed of low value is obtained. For higher speed and power, the winding of higher pole number is transferred to the supply of higher periodicity and the winding of lower pole number, which was idle for the lower speed and power, is connected to the supply of lower periodicity. Consequently, at full speed and power, both sources of supply and both motor windings are fully utilized, and cooperate in driving the propeller. With this "multiple" motor it is thus possible to integrate in a single motor the power from several prime movers and also to obtain two or more efficient speeds without resorting to a motor with moving contacts.

**69. The United States Collier "Jupiter."** Certain leading data of this vessel have already been given (Par. **53**) and an illustrated description appeared in an article entitled "Electrical Equipment for the Propulsion of the U. S. Collier Jupiter," by Mr. Eskil Berg at page 490 of the *General Electrical Review* for August, 1912. The "Jupiter," a vessel of 20,000 tons displacement and designed to carry about 12,000 tons of coal and oil, was built at the Mare Island Navy Yard. The contract for the equipment was awarded to the General Electric Co., in June, 1911. The machinery was designed by, and constructed under the direction of, Mr. W. L. R. Emmet. The contract price of the electrical propelling machinery was stated in the article in the *General Electrical Review*, to be $13.75 per horsepower. The turbo-electrical propelling machinery comprises a 9-stage, 2,000-r.p.m. Curtis turbine driving a 2-pole, three-phase, 2,300-volt, 33⅓-cycle, 5,500-kv-a. generator. The two 36-pole, 110-r.p.m. induction motors each have a normal rating of 2,750 h.p. The rotors are provided with three-phase windings leading to slip rings. By means of these slip rings, the rotor current, at starting, reversing and manœuvring, is carried to water-cooled resistors which are short-circuited when the ship is proceeding normally. The heat is removed from the active material of these resistors by the circulation of sea water through them.

An interesting feature of the arrangement of the machinery relates to the provision of sheet-metal ducts so connected to the air outlets from the generator and motors as to lead the heated air to the suction of the fire-room blowers, thus avoiding needless heating of the engine room.

**70. Performance of the "Jupiter."** The "Jupiter" was put in commission September 15, 1913. After a period of preliminary trials in San Francisco Bay and at sea, the ship was docked. After cleaning her bottom, a set of standardization runs and a 48-hour unofficial trial were made.

Digitized by Google

On the 48-hr. trial the ship averaged 14.78 knots. The average power delivered by the generator was 5,000 kw., corresponding to about 6,300 h.p., delivered from the electric motors to the propellers. The average revolutions of the propellers were 115. The "Cyclops" (see Par. 53) in her official 48-hour run made 14.61 knots with an average of 6,700 i.h.p. The official trials of the "Jupiter" have not yet been made. These particu-

lars are taken from Mr. Emmet's paper read on Dec. 11, 1913, before the Society of Naval Architects and Marine Engineers. The drawing in Fig. 3 shows the arrangement of the "Jupiter's" motors:

**71. The "Tynemount."** Messrs. Swan, Hunter and Wigham Richardson have built to the order of the Electric Marine Propulsion Company

Digitized by Google

of Glasgow, a canal-type tank-barge for service on the Canadian lakes and through the Welland Canal. The vessel was built for operation by the Montreal Transportation Company, and was designed and fitted under the supervision of Messrs. John Reid and Henry A. Mavor. The "Tynemount" was described, with drawings, in a paper by these gentlemen read in June, 1913, before the Institution of Naval Architects and entitled "A Case for Electric Propulsion." The power equipment consists of two four-stroke-cycle, 400-r.p.m., 6-cylinder, Diesel engines, each direct-connected to a three-phase 235-kv-a., 500-volt generator. These two generators are wound respectively with 6 and 8 poles and thus constitute sources of different periodicity, the one supplying 20 cycles per second and the other 26.6 cycles per second. An exciter is fitted on an extension of the shaft of each generator. Each exciter gives normally about 30 amp. at 100 volts and is capable of supplying a considerable overload. The propeller is driven by a "multiple" motor of the type invented by Mr. Mavor and already described (Par. 63). This motor is of the squirrel-cage induction type and is

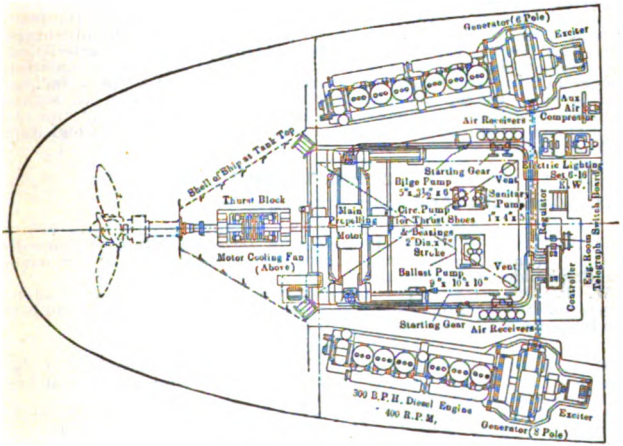

FIG. 4.—Plan of arrangement of the "Tynemount's" machinery.

provided with two stator windings for 30 and 40 poles respectively. At the vessel's normal speed the power of the two Diesel engines is integrated at this motor, the 20-cycle supply being absorbed in the 30-pole winding and the 26.6-cycle supply in the 40-pole winding. Under these conditions the synchronous speed is 80 r.p.m. Allowing for slip in the rotor of this motor the propeller speed is about 78 r.p.m. By changing the 40-pole winding to the 20-cycle generator and leaving the 30-pole winding of the motor and the 26.6-cycle generator out of circuit, the speed is lowered to 75 per cent. of full speed, *i.e.*, to some 58 r.p.m. The 26.6-cycle set may then be shut down thus leaving the 20-cycle set alone to propel the ship and consequently providing as good economy at this low speed and load as at the higher speed and load. The vessel is designed to carry about 2,400 tons dead weight of cargo, fuel, fresh water and stores on a 14-ft. mean draught in fresh water. On, p. 412 of Engineering for Sept. 27, 1912, the cost of the Tynemount is given as £30,000 ($150,000).

The dimensions of the ship and of her propeller are determined by the dimensions of the canal locks through which she must pass. The system adopted has permitted of increasing the carrying capacity to 250 tons more than would have been practicable with steam equipment. This saving is a consequence of:

Digitized by Google

(a) The absence of boilers and the consequent reduction in space and weight of machinery.

(b) The great difference in the heat value of the fuel and the efficiency with which it is used, so that the bunker capacity can be materially reduced.

The "Tynemount" is fully described and illustrated in an article published at p. 381 of *The Engineer* for Oct. 10, 1913. The plan of the arrangement of the machinery shown in Fig. 4 is reproduced from this article.

The "Tynemount" is 250 ft. long, of 42 ft. beam and has a displacement of some 3,400 tons at 14 ft. draught in fresh water. She is designed for a speed of some 8 knots.

**72. Performance of the "Tynemount."** On the 17th of September, 1913, the Tynemount made her first trip, and her performance was tested at sea over a measured mile. She was also reversed many times and it was ascertained that only some 15 to 18 sec. were required to bring the propeller from full speed ahead to full speed astern or *vice versa*. This is an interesting demonstration of the excellent capabilities of properly designed squirrel-cage induction motors for work where considerable starting and accelerating torque is required. The design of the squirrel cage comprises the feature that the slots are exceedingly deep and narrow in order to take advantage of the "Field" effect which acts to impart high resistance characteristics to the rotor at starting. The high resistance characteristics automatically merge into low resistance characteristics as the motor speed increases. Consequently, the slip and losses are low at full speed, whereas, with the ordinary construction employing high resistance rotor bars of the usual proportions, the slip and losses and heating would be undesirably high during normal running.

# SECTION 19

## ELECTROCHEMISTRY

### INTRODUCTION

**1. Definition.** Electrochemistry deals with the production of electrical energy from chemical energy (primary batteries, storage batteries) and with the reverse problem, namely, the production of chemical effects by electrical means. Only the latter problem, however, will be covered in this section.

**2. Chemical equations.** The briefest way to make a quantitative statement of an electrochemical fact is by means of a chemical equation. If the chemical equation of a certain reaction or process is given, it is possible to derive a great many conclusions from it with the aid of certain sets of constants, such as atomic weights, formation energies, the constants of the gas laws, of Faraday's law, etc. We will first give a concise summary of the different ways in which a chemical equation may be interpreted; this will involve summing up the fundamental principles of physical chemistry and electrochemistry. Interpreting a chemical equation in different ways means looking at the reaction from different standpoints. This is of greatest importance for any electrochemical proposition, and it is not generally appreciated, especially by electrical engineers, how manifold the points of view are for considering a chemical problem.

**3. Electrochemical processes.** This will be followed by a concise summary of those electrochemical processes which have attained industrial importance. For the purpose of convenience a division into the following three classes will be made: Electric furnace processes; electrolytic processes; and processes involving electric discharges through gases, although a sharp separation of these three classes cannot be made in reality. Each class will be introduced by a summary of the principles governing the processes in that class. In giving references to available literature, the aim has been to refer to those articles and papers which contain the latest and fullest technical information and which are most easily accessible to American readers.[1]

### INTERPRETATION OF CHEMICAL EQUATIONS

**4. A gram-atom** is that number of grams of an element which is equal to the atomic weight. A kilogram-atom is the same number of kilograms, etc. A **gram-molecule** (or "mol") is that number of grams of a substance which is equal to the molecular weight. It is very important to always clearly distinguish between atoms and molecules; thus a gram-atom of chlorine = Cl = 35.45 g., while a gram-molecule or a mol of chlorine = $Cl_2$ = 70.90 g. A gram-atom of oxygen = O = 16 g.; but a gram-molecule of oxygen = $O_2$ = 32 g., and a gram-molecule of ozone = $O_3$ = 48 g. A kilogram-molecule of calcium carbide = $CaC_2$ = 64.1 kg.

**5. Interpretation of chemical equations.** The equation of the reaction between burnt lime and ground coke in the production of calcium carbide in the electric furnace is

$$\underset{56.1}{CaO} + \underset{36}{C_2} = \underset{64.1}{CaC_2} + \underset{28}{CO}. \qquad (1)$$

[1] For further literature reference must be had to the transactions of the three electrochemical societies, namely: the *Transactions* of the American Electrochemical Society, the *Transactions* of the (British) Faraday Society, and the *Zeitschrift für Elektrochemie*, which is the organ of the (German) Bunsen Society. The principal independent publications specialising in electrochemistry are *Metallurgical and Chemical Engineering* (New York), *Elektrochemische Zeitschrift* (Berlin), *Journal du Four Electrique et de l'Electrolyse* (Paris), *La Houille Blanche* (Lyons and Grenoble).

Digitized by Google

The figures placed below the chemical symbols are the molecular weights. The equation states that when 56.1 kg. of burned lime combine with 36 kg. of coke, there are formed 64.1 kg. of calcium carbide and 28 kg. of carbon monoxide. Instead of kilogram, we could use just as well any other unit of weight (pound, ton, etc.), since the chemical equation gives only the *relative* weights of combination. The table of atomic weights is given in Sec. 4.

## RELATION BETWEEN VOLUME, PRESSURE AND TEMPERATURE IN GASES

**6. Avogadro's law.** If any of those substances taking part in a reaction at a certain temperature is in the gaseous state and we know the pressure, we can find its volume directly from the equation of the reaction; or if we know its volume we can directly find the pressure. According to Avogadro's rule, equal numbers of molecules of different gases fill equal volumes under the same conditions of temperature and pressure. One gram-molecule of any gas (for instance, 2 g. hydrogen, $H_2$, or 32 g. oxygen, $O_2$) at atmospheric pressure (760 mm. mercury) and at a temperature of 0 deg. cent. fills 22.42 liters. One kilogram-molecule fills 22.42 cu. m.

**Example:** The 28 kg. of carbon monoxide gas set free in the formation of 64.1 kg. of calcium carbide according to the above equation (Eq. 1, Par. 5) are 1 kilogram-molecule and will therefore fill 22.42 cu. m. when brought to a temperature of 0 deg. cent. and to a pressure of 1 atmosphere.

**7. Boyle-Mariotte-Gay-Lussac law.** To calculate the volume for other temperatures and pressures, the Boyle-Mariotte-Gay-Lussac law is to be applied, according to which

$$p\,v = R\,T = R \times (273 + \text{deg. cent.}) \qquad (2)$$

In this equation $p$ is the pressure, $v$ the volume; hence $p\,v$ the work done in the expansion of the gas. T is the absolute temperature = temperature in degrees centigrade plus 273. R is the gas constant. If we measure the pressure in atmospheres and the volume in liters, then Avogadro's rule states that for $p = 1$ and $T = 273$, 1 gram-molecule of gas fills the volume $v = 22.42$, hence $R = 22.42/273 = 0.0821$. Hence for 1 gram-molecule, if we give

$p\,v$ in liter-atmospheres, $R = 0.0821$
$p\,v$ in kilogram-meters, $R = 0.848$
$p\,v$ in gram-calories, $R = 1.987$.

For $n$ gram-molecules the value of $p\,v$ is $n$ times the value found from the above equation.

**Example:** If we electrolyze a dilute acid or alkaline solution for the purpose of producing oxygen and hydrogen gas and if we wish to use the hydrogen, for instance, for filling a balloon, then the main reaction is simply the decomposition of water.

$$H_2O = H_2 + O; \qquad (3)$$

*i.e.*, 1 kilogram-molecule or 18 kg. $H_2O$ are decomposed into 1 kilogram-molecule or 2 kg. H, occupying 22,420 liters at 0 deg. cent. and atmospheric pressure, and 0.5 kilogram-molecule or 16 kg. O, occupying 11,210 liters under the same conditions of temperature and pressure. If the hydrogen gas is contained in a balloon which is to rise in the atmosphere, it will be under atmospheric pressure, and the hydrogen produced from 18 kilograms of water, will under this condition fill 22,420 liters at 0 deg. cent. If the temperature is higher, for instance $t$ deg. cent., and the pressure less, for instance, $760 - x$ mm. of mercury (when the balloon rises), then the volume in liters $= \dfrac{22{,}420 \times 760 \times (273 + t)}{(760 - x) \times 273}$.

**8. Units employed.** The calculation is quite as simple for English units instead of metric units. As J. W. Richards[1] has remarked, the same numerical factor can be used as in the metric system. This coincidence is due to the fact that there is practically the same relation between an ounce (av.) and a kilogram, as between a cubic foot and a cubic meter, the difference being negligible. Hence 1 ounce-molecule of a gas (for instance 28 oz. carbon monoxide) at 0 deg. cent. and 1 atmosphere fills 22.42 cu. ft.

**9. Gas mixtures.** If we have a mixture of different gases in the same space, two different views are *a priori* possible. Instead of $p\,v = R\,T$ we

[1] Richards, J. W. "Metallurgical Calculations," 1912; Vol. I, p. 3.

Digitized by Google

might write in this case $p(v_1+v_2+v_3+\ldots)=RT$, assuming that all the gases have the same pressure $p$, but each occupies only a certain part of the total volume (the same as it would occupy alone under the same conditions of temperature and pressure); $v_1$ $v_2$ $v_3$ . . being the **partial volumes** of the different gases 1, 2, 3, . . and their sum being the volume of the mixture; or we may write

$$(p_1+p_2+p_3+\ldots)v=RT, \qquad (4)$$

assuming that every one of the gases fills the total volume $v$ of the mixture, but that each exerts only part of the total pressure; $p_1$ $p_2$ $p_3$ . . being the **partial pressures.**

**10. The composition of a gas mixture may be defined** either by the ratio of the weights of the constituent gases (or in per cents. of weight) or by the ratio of the partial pressures or the ratio of partial volumes (or in per cents. of volume). For instance, if atmospheric air is a mixture of 23.1 per cent. by weight of oxygen and 76.9 per cent. by weight of nitrogen, then the partial volumes are found as follows: In 100 g. of air are 23.1 g. or 0.72 gram-molecule of oxygen and 76.9 g. or 2.74 gram-molecules of nitrogen. At atmospheric pressure and 0 deg. cent. the partial volume of the oxygen is therefore $0.72\times22.42=16.2$ liters, the partial volume of the nitrogen is $2.74\times22.42=61.5$ liters. The total volume of air is 77.7 liters. Hence the per cents. by volume are 20.8 per cent. of oxygen and 79.2 per cent. of nitrogen. In an analogous way the partial pressures may be calculated.

**11. Hypothesis of partial pressures vs. partial volumes.** For many calculations the hypothesis of partial volumes is as good as that of partial pressures but the latter is the only one strictly tenable. For instance, we have steam in the atmosphere at 0 deg cent., although we know, that at atmospheric pressure and 0 deg. cent., water could not exist in gas form. Therefore we must conclude that in the atmosphere steam is under less than atmospheric pressure; this leads directly to the conception of partial pressure. Finally it must be added that the above rules are strictly true only for ideal gases.

## RELATION BETWEEN OSMOTIC PRESSURE, CONCENTRATION AND TEMPERATURE IN SOLUTIONS

**12. Analogy between gaseous and osmotic pressures.** On account of the analogy between the laws of gaseous pressure and of osmotic pressure in dilute solutions we can apply directly the results of Par. **6** to **11** to dilute solutions; *i.e.*, if one of the products of a chemical reaction appears in aqueous solution of given volume and if we know that the laws of osmotic pressure are strictly valid for the solution in question, then we can state at once the osmotic pressure from the equation.

**13. Osmotic pressure.** If an $n$ per cent. aqueous solution of a non-electrolyte is placed in a closed vessel, the walls of which are semi-permeable, *i.e.*, permit water only to pass through, but not the solute, and if we place this vessel in a larger reservoir filled with water, then the solution inside the smaller vessel attracts water from the outside until a certain pressure is produced within the vessel. This pressure is called the osmotic pressure and its value in atmospheres is $0.0821\times$number of gram-molecules per liter$\times$absolute temperature (Van't Hoff). This is the same equation as in Par. **7** with the exception that instead of the volume $v$ (the number of liters which are filled by 1 gram-molecule) we use here the reciprocal value, $c=1/v$ which is the concentration in gram-molecules per liter), so that the equation $pv=RT$ is written in this case $p=RcT$.

**Example.** As an example we want to find the osmotic pressure of a 1 per cent. sugar solution at 7 deg. cent. The molecular weight of sugar $=342$; 1 liter of a 1 per cent. solution contains 0.01 kilogram or 10 grams or 10/342 gram-molecules of sugar. Hence $c=10/342$, $T=280$, and the osmotic pressure $=\dfrac{0.0821\times10\times280}{342}=\dfrac{2}{3}$ atmosphere (Pfeffer). (5)

**14. Explanation of osmotic pressure.** We may describe the general phenomenon in another way by saying that the pure water outside attracts the solute inside, and since the latter cannot pass outside it presses against the walls. Thus the osmotic pressure may be pictured as the pressure which is produced by the solute inside the vessel due to its inability to move

Digitized by Google

freely to the outside—just as a gas inside a reservoir exerts a pressure on the walls, because it cannot follow its tendency to pass outward. Moreover, for the osmotic pressure and the gaseous pressure the same numerical law holds true as shown above (Par. 13). In the case of the sugar solution the osmotic pressure exerted by the dissolved sugar molecules is numerically equal to the gas pressure which the same molecules would exert if the same weight of sugar existed in gaseous form in the same volume and at the same temperature. This is the foundation of **Van't Hoff's theory of solutions.** Instead of measuring the osmotic pressure directly, it is possible to calculate it from the changes of the vapor pressure or of the freezing point, due to the addition of the solute to the solvent.

15. **Electrolytes form an exception.** However, the above law does not hold good in general and all aqueous solutions which are electrolytes form an important exception, if we base the calculation on ordinary molecular weights in the same way as in the above case of sugar. This discrepancy is removed by the hypothesis of an electrolytic dissociation in solutions (Planck and Arrhenius). According to Arrhenius not all the molecules of the dissolved substance are electrolytically active, but only those which are "dissociated" into electrically charged ions; this is the foundation of **the electrolytic dissociation theory.** In applying the laws of the osmotic pressure to electrolytes a larger number of molecules must therefore be assumed according to the degree of dissociation.

## RELATION BETWEEN MASS AND ELECTRIC QUANTITY IN ELECTROLYTIC REACTIONS

16. **Faraday's first law** gives the exact relation between the weight of the products of electrolysis and the quantity of electricity passing during the electrolysis. There are always two reactions. One is the anodic reaction, its product or products appearing at the anode. The other is the cathodic reaction, its product or products appearing at the cathode. Faraday's first law states that if nothing but the one desired reaction occurs at the anode or cathode as the result of the passage of the electricity, the quantities of material changed at the anode or cathode depend only on the quantity of electricity which passes, measured in coulombs or ampere-seconds; in other words, these quantities depend only on the product of the current in amperes and the time. With $i$ amperes the same quantities of chemicals are changed in $t$ seconds, as with $i/n$ amperes in $nt$ seconds, where $n$ may be anything; the quantities depend only on the product of current and time and not on anything else, for instance, not on the voltage or on the size of the electrodes or on the temperature, etc. This should not be misunderstood; all these statements are valid under the supposition placed at the beginning of our statement of Faraday's first law, namely that nothing but the one desired reaction takes place. As long as this is true, the quantities of materials changed are strictly proportional to the quantity of electricity passing. But if, for instance, by raising the voltage, a new reaction is started, the conditions are of course changed.

17. **Faraday's second law** gives the numerical relation between the quantity of electricity and the quantity of material changed. It can be most easily expressed for the special case that the chemical reactions occurring at the anode and cathode are simply a liberation of a gas or a deposition of a metal. For this case Faraday's second law states that the quantity of gas set free or of metal deposited is proportional to the **equivalent weight** of the gas or metal, and that 96,540 coulombs deposit or set free 1 **gram-equivalent** of metal or gas. The equivalent weight, or gram-equivalent is defined as the atomic weight divided by the valency. For instance, 63.6 is the atomic weight of copper; the equivalent weight is 63.6/2 = 26.8 for a bivalent salt, like copper sulphate, and 63.6 for a monovalent salt like cuprous chloride. Hence 96,540 coulombs deposit 26.8 g. of copper from copper sulphate, but 63.6 g. from cuprous chloride.

18. **Faraday's law stated in general form.** Faraday's law will now be stated in what appears to the writer to be the most general and complete form. It is valid for all electrolytic processes and all such processes require essentially direct current.

In any electrolytic process there is chemical reduction at the cathode and chemical oxidation or perduction at the anode. Reduction means a loss of bonds, perduction a gain of bonds. Exactly as many bonds are lost at the

Digitized by Google

cathode as are gained at the anode. *If the number of bonds lost at the cathode and gained at the anode in an electrolytic process is n, then each symbol of the elements in the equation of the reaction represents a gram-atom of the element involved in the reaction, when* $96,540 \times n$ *coulombs are passing.*

**19. The figure 96,540 coulombs per monovalent gram-ion** is based on the atomic weight of silver 107.93 and the electrochemical equivalent of silver adopted by the International Electrical Congress of Chicago in 1893 in the definition of 1 amp., namely 0.001118 g. of silver per coulomb. This gives $107.93 + 0.001118 = 96,538.5$ coulombs for the monovalent gram-ion of silver, or approximately 96,540, which figure is very widely used.

**20. Definitions of valence and bonds.** For the understanding of Faraday's law which is the most fundamental law of electrolysis, a proper understanding of the terms valence and bonds is absolutely essential. This subject must be approached from the chemical side and for the purpose of acquainting electrical engineers with these fundamental chemical conceptions, the notation of Prof. Otis C. Johnson seems to be particularly suitable. While for a detailed study of notation the reader must be referred to Prescott and Johnson's "Qualitative Chemical Analysis," the following summary will be sufficient to explain the chief points.

The **valence** represents the number of bonds uniting an element with others in a chemical compound. A **bond**—that is, a unit of **active valence**—is either a positive one or a negative one. The oxidation of an element is shown by an increase, and its reduction by a decrease of the number of bonds. Hydrogen (in combination) has always one positive bond. Oxygen (in combination) has always two negative bonds. Free elements have no bonds. The sum of all bonds of any compound is zero. In salts the bond of the metal is always positive. In acids and in salts the acid radical has always negative bonds.

**21. Determination of valence.** These rules enable one easily to determine the valence in any compound. For instance, in HCl, H has one positive bond, hence Cl must have one negative bond in order to have the sum of all the bonds in the molecule equal to zero. In all chlorides Cl has one negative bond. In $H_2SO_4$ we see that $H_2$ has two positive bonds and $O_4$ eight negative bonds, hence S has six positive bonds, or the radical $SO_4$ has two negative bonds. In CuCl, Cl has one negative bond, hence Cu one positive bond. In $CuSO_4$, $SO_4$ has two negative bonds, hence Cu two positive bonds. In other words, Cu is monovalent in the chloride and bivalent in the sulphate. $CO_3$ in carbonates has two negative bonds. $ClO_3$ in chlorates has one negative bond. See also Par. **142** and **143**.

**22. Example.** The final step of the **Siemens and Halske copper process** consists in depositing copper on the cathode from a $CuSO_4$ solution and simultaneously oxidizing ferrous sulphate to ferric sulphate at a carbon anode in a diaphragm cell. The equation in its simplest form is

$$\begin{array}{cccccc} CuSO_4 & + & 2FeSO_4 & = & Cu & + & Fe_2(SO_4)_3 \\ 159.66 & & 303.92 & & 63.6 & & 399.98 \end{array} \qquad (6)$$

The figures given below the chemical symbols are the molecular weights.

Cu has two positive bonds in $CuSO_4$ and when deposited as metal on the cathode it has no bonds; hence the loss of bonds of Cu in its reduction to the metallic state is two. Fe in $2FeSO_4$ has two positive bonds, hence the 2Fe have four positive bonds; but Fe has three positive bonds in $Fe_2(SO_4)_3$ and $Fe_2$ six positive bonds; hence in the oxidation from ferrous to ferric sulphate two positive bonds are gained. Therefore, if the symbols in the above equation represent gram-atoms or gram-molecules, the reaction corresponds to the passing of $2 \times 96,540$ coulombs through the cell. Thus, $2 \times 96,540$ coulombs deposit in this process 63.6 g. of copper, or 100,000 coulombs 33 g. of copper. The above equation may be completely interpreted as follows: If $2 \times 96,540 = 193,080$ coulombs pass through the cell, 159.66 g. of $CuSO_4$ and 303 92 g. of $FeSO_4$ are changed into 63.6 g. of Cu and 399.98 g. of $Fe_2(SO_4)_3$. This example makes it clear that the statement of Faraday's second law in Par. **17** for the special case of metal deposition follows directly from the more general statement of the law in Par. **18**.

The Siemens and Halske process of producing copper has never attained industrial importance. But it has been chosen here as an example for the explanation of Faraday's law, since the importance of valence is clearly

Digitized by Google

illustrated by a comparison of this process with that of Hoepfner which was devised later to compete with the Siemens and Halske process. While sulphate solutions are used in the latter, Hoepfner proposed to use a chloride solution. The ferric sulphate and cupric chloride are used for leaching the ore.

**23. Example.** The scheme of the **Hoepfner copper process** was essentially to deposit copper on copper cathodes from a cuprous chloride solution and oxidize simultaneously the cuprous chloride to cupric chloride at carbon anodes, the essential reaction being

$$2CuCl = CuCl_2 + Cu \qquad (7)$$
$$198.1 \quad 134.5 \quad 63.6$$

The figures placed below the chemical symbols represent again the weights, found from the table of atomic weights. In this case Cu in the cuprous chloride CuCl, has one positive bond, while it has two positive bonds in cupric chloride $CuCl_2$. At the cathode the reduction of one CuCl to metallic Cu (which has no bonds) involves therefore a loss of one positive bond. At the anode the oxidation of one CuCl to $CuCl_2$ involves the gain of one bond. Hence in this case, we have a monovalent reaction, the change of bonds being 1, and we find that when 96,540 coulombs pass through the cell, 198.10 grams of CuCl are changed into 134.5 grams $CuCl_2$ and 63.6 grams Cu. The metallic copper is the principal product in the process, 96,540 coulombs deposit 63.6 grams of copper or 100,000 coulombs deposit 65 grams of copper, *i.e.*, just twice the amount obtained with the same current and in the same time by the Siemens and Halske process.

**24. Explanation of different outputs in the two examples.** (Par. **22** and **23**.) It is quite clear from the above argument what causes the different output of both processes; it is simply the fact that Cu has two bonds or is bivalent in $CuSO_4$ and has one bond or is monovalent in CuCl. It is also clear that to find the amount of an element set free from a compound it is not necessary to write down the whole equation of the reaction, as was done above for the sake of completeness. We can state that if 1 gram-atom of a metal is deposited in free metallic state by electrolysis, 96,540 coulombs are necessary for deposition from a monovalent compound (like CuCl), twice as many from a bivalent compound (like $CuSO_4$), three times as many from a trivalent compound, etc. But this rule is only a special case and does not give any information, for instance, on the quantity of ferrous sulphate oxidized to ferric sulphate in the Siemens and Halske process.

**25. Procedure in calculations.** The **method of writing** down the whole **equation**, determining the number of bonds lost and gained and applying the above rule gives complete information in all cases on the relation between the quantity of electricity, which passes a cell and all the quantities changed thereby in chemical composition.

**26. Method of calculation under the electrolytic dissociation theory.** The above method of calculation becomes easier if we use the picture of the electrolytic dissociation theory. The equation of the Siemens and Halske process is then written in the form

$$Cu^{\cdot\cdot} + SO_4'' + 2Fe^{\cdot\cdot\cdot} + 2SO_4'' = Cu + 2Fe^{\cdot\cdot\cdot} + 3SO_4'', \qquad (8)$$

that is, instead of $CuSO_4$ in solution we write $Cu^{\cdot\cdot} + SO_4''$, the copper sulphate being dissociated into its ions, the positive copper ion $Cu^{\cdot\cdot}$ and the negative ion $SO_4''$. Each dot at the top of $Cu^{\cdot\cdot}$ represents a positive electric charge. Each stroke at the top of $SO_4''$ represents a negative electric charge. Each such charge, positive or negative, is 96,540 coulombs, if the chemical symbols represent gram-atoms or as we now say, gram-ions. The gram-ion $Cu^{\cdot\cdot}$ is bivalent and charged with $2 \times 96{,}540$ coulombs. Each gram-ion $Fe^{\cdot\cdot}$ (ferrous) is bivalent and charged with $2 \times 96{,}540$ coulombs. The gram-atom Cu (metal deposited on the cathode) is not charged. Each gram-ion $Fe^{\cdot\cdot\cdot}$ (ferric) is trivalent and charged with $3 \times 96{,}540$ coulombs. The above ionic equation may be somewhat simplified by writing

$$Cu^{\cdot\cdot} + 2Fe^{\cdot\cdot} = Cu + 2Fe^{\cdot\cdot\cdot} \qquad (9)$$

If this equation shall be right, not only the chemical symbols but the dots must balance on both sides, since otherwise free electrostatic charges would appear somewhere. In this case we see $Cu^{\cdot\cdot}$ has 2 charges and each of the two $Fe^{\cdot\cdot}$ has also 2 charges, hence the total sum is 6 charges on the left side of the equation. On the right side Cu has no charge, each of the two $Fe^{\cdot\cdot\cdot}$ has 3 charges, hence the total sum is again 6 charges.

Digitized by Google

What happens according to this view is that at the cathode a bivalent $Cu^{\cdot\cdot}$ ion (from copper sulphate) is reduced to metallic copper, thus giving off 2 charges to the cathode, while simultaneously two $Fe^{\cdot\cdot}$ ions (ferrous) are oxidised to two $Fe^{\cdot\cdot\cdot}$ ions (ferric) at the anode, each taking one charge from the anode. Hence the above ionic reaction will take place in the electrolyte when $2 \times 96{,}540$ coulombs pass through it, entering from the anode and leaving into the cathode.

**27. Reconcilement of theories.** While these statements differ greatly from our former discussion of the same equation in the notation adopted and in the expressions employed it will be seen that there is no essential difference. The two dots on top of $Cu^{\cdot\cdot}$, *i.e.*, the two positive charges, represent exactly the same thing as the two positive bonds which Cu has in Johnson's notation. According to the electrolytic dissociation theory the reactions in electrolytes are reactions between ions. The characteristic feature of an ion is, that it is electrically charged. Any gram-ion—whatever may be its chemical nature—carries one or two or three, etc., charges, each of 96,540 positive or negative coulombs, according to whether it is monovalent or bivalent or trivalent and whether it is positive or negative. There are everywhere in the interior of the electrolyte as many positive as there are negative ions, *i.e.*, there is no free electricity anywhere.

**28. Difference between electrolytic and chemical dissociation.** It should be emphasised that electrolytic dissociation is essentially different from chemical dissociation. The ion $Cu^{\cdot\cdot}$ is essentially different (in electric charge, energy content, properties) from the atom Cu or from the monovalent ion $Cu^{\cdot}$.

**29. Examples.** To write the equation of the Hoepfner process in the notation of the electrolytic dissociation theory, we write $Cu^{\cdot} + Cl'$ instead of CuCl (in solution) and $Cu^{\cdot\cdot} + 2Cl'$ instead of $CuCl_2$ (in solution). Hence the equation becomes

$$2Cu^{\cdot} + 2Cl' = Cu^{\cdot\cdot} + Cl' + Cu \qquad (10)$$

or

$$2Cu^{\cdot} = Cu^{\cdot\cdot} + Cu. \qquad (11)$$

At the anode one monovalent $Cu^{\cdot}$ ion (cuprous) is oxidized to $Cu^{\cdot\cdot}$ (cupric), taking one charge from the anode. Simultaneously one monovalent $Cu^{\cdot}$ ion (cuprous) is reduced to metallic copper Cu at the cathode-giving off one charge to the cathode.

**30. Application of electron theory.** We may go a step further and apply the modern theory of electrons to our problem. This has been done by Nernst. We will assume there are positive and negative electrons, although only negative electrons have so far been isolated. We may consider them as kinds of new elements (only for the sake of illustration), with so small atomic weights that, for all practical calculations, they may be considered sero; while their characteristic and distinguishing feature is that each positive electron has an electric charge of 96,540 positive coulombs and each negative electron has an electric charge of 96,540 negative coulombs. Nernst, therefore, considers any monovalent positive gram-ion as a compound of the gram-atom with a positive electron; also any bivalent gram-ion as a compound of the gram-atom with two electrons, and so on. This view emphasises the essential difference between atoms and ions, and at the same time gives a very convenient scheme for applying Faraday's law, which appears as a consequence of the laws of definite and multiple proportions. Johnson's bonds are, then, a very substantial thing. His positive bonds are positive electrons, and his negative bonds are negative electrons. This view, although it may be called very hypothetical, offers the safest method of applying Faraday's law. There is no possibility of making a mistake if we always keep the mechanical model in mind.

**31. Definition of a "Faraday."**—The charge of a monovalent positive ion, which is 96,540 coulombs, is the fundamental unit for all electrolytic processes and is called one **Faraday** and designated by F, so that F represents one positive electron and $-F$ one negative electron. A bivalent ion is charged with 2F, etc.

**32. Use of the Faraday notation.** With this notation it is easy to write down the anodic and cathodic reactions separately. For instance, in case of the Siemens and Halske process the anodic reaction is $2F + 2Fe^{\cdot\cdot} = 2Fe^{\cdot\cdot\cdot}$, two positive electrons being absorbed by the two $Fe^{\cdot\cdot}$ ions from the anode,

Digitized by Google

while the cathodic reaction is $Cu^{\cdot\cdot} = Cu + 2F$, one Cu ion giving off its two positive electrons to the cathode.

**33. Use of larger units in practical work.** In the above we have based the calculation on 96,540 coulombs as the charge of 1 gram-ion. This is the laboratory unit, but although universally used in discussions of Faraday's law, it seems too small for practical purposes. If one monovalent gram-ion carries 96,540 coulombs, then one monovalent kilogram-ion carries a charge of 96,540,000 coulombs or 26,817 amp-hr. Hence, if the symbols in the equation of the reaction represent kilogram-atoms, then the reaction requires 26,817 amp-hr. if monovalent, $2 \times 26{,}817$ amp-hr., if bivalent, etc.

**34. Practical use of the gram-equivalent.** Finally the above numerical relations may be very briefly stated by using the term **gram-equivalent** which means gram-ion divided by the valency, so that one gram-equivalent equals a gram-ion if it is monovalent, but one-half gram-ion if it is bivalent as already explained in Par. 24. In the same way the term kilogram-equivalent means kilogram-ion divided by valency. Then Faraday's law states that 1 gram-equivalent of any chemical composition whatever carries an electric charge of 96,540 coulombs. One kilogram-equivalent carries an electric charge of 26,817 amp-hr.

**35. Johnson's rule for balancing equations.** In the procedure recommended above for the application of Faraday's law a difficulty may be found in writing down the equation of the reaction. Since in any electrolytic process we have to do with reduction and oxidation the following rule of Prof. O. T. Johnson for **balancing equations** of this kind may be found useful. This rule states that "the number of bonds changed in one molecule of each shows the number of molecules of the other which must be taken," the words "each" and "other" referring to the oxidising and reducing agents. One example may illustrate this rule, which appears to be purely formal from a chemical point of view, while its electrical meaning will be shown below. In the Bunsen cell Zn is oxidized; it becomes $ZnSO_4$. The metal Zn has no bond. Zn in $ZnSO_4$ has two bonds, hence the increase in bonds is two. There are several actions possible at the other electrode. We may consider that NO is developed. N in $HNO_3$ has five positive bonds, while in NO it has two positive bonds, hence the decrease in bonds is three. Now Johnson's rule states that we have to take three molecules of Zn and two molecules of $HNO_3$ and we get the equation

$$3Zn + 3H_2SO_4 + 2HNO_3 = 3ZnSO_4 + 2NO + 4H_2O. \qquad (12)$$

**36. Application of Johnson's rule.** This rule becomes self-evident if applied to an electrochemical action. It simply means that just as much electricity passes from the anode into the electrolyte as from the electrolyte into the cathode. In the case of the Bunsen cell if the chemical symbols represent gram-atoms, then, as Zn gains two bonds and as we have three Zn atoms, $3 \times 2 \times 96{,}540$ coulombs pass into the electrolyte from the anode. On the other hand, N loses three bonds, and, as two N are reduced, $2 \times 3 \times 96{,}540$ coulombs are given off to the cathode. Of course we may also consider $HNO_3$ to be ionised into H and $NO_3$ ions, both monovalent, etc. The result is the same. Johnson's rule for balancing equations enables one to write down the equation which represents the electrochemical action, and in the further calculation there is no mistake possible if one keeps in mind that each bond corresponds to 96,540 coulombs, providing the chemical symbols represent gram-atoms.

**37. Faraday's law is always exactly fulfilled** in the sense that the anodic oxidation and cathodic reduction of given quantities of materials require a certain amount of coulombs, not more nor less. For instance, the deposition of 1 gram-atom or 63.6 g. of copper from the solution of a monovalent cuprous salt requires 96,540 coulombs. But this does not mean that if we send 96,540 coulombs through such solution, we must always deposit 63.6 g. of copper on the cathode. It may be that we have a second reaction at the cathode besides copper deposition, for instance, evolution of hydrogen gas. The conditions may be such that, say 75 per cent. of the coulombs only deposit copper; then we get $0.75 \times 63.6 = 47.7$ g. of copper. The other 25 per cent. of the coulombs deposit hydrogen and therefore evolve 0.25 gram-atom = 0.25 g. hydrogen. Thus Faraday's law is fulfilled, but in practice we are interested in this case only in the copper

Digitized by Google

deposition; we consider the hydrogen evolution as waste and say that we have deposited the copper with an "ampere-hour efficiency" of 75 per cent. The ampere-hour efficiency therefore indicates to which degree the one reaction which we desire to obtain (in the above example, the copper deposition) really takes place. It is also called "current efficiency" although somewhat loosely.

## HEAT AND CHEMICAL ENERGY

**38. Transformations of energy.** The symbols in a chemical equation, besides being considered as masses and volumes, and as masses charged with electricity, may also be considered as masses endowed with energy, because simultaneously with the transformation of matter there is a transformation of energy. Since the energy stored in the starting materials differs from the energy stored in the final product of a process, the balanced equation of the chemical transformation of matter no longer balances as an equation for energy transformation. For instance, if carbon burns to carbon dioxide, the ordinary chemical equation is

$$C + O_2 = CO_2. \qquad (13)$$

But we know that this reaction evolves heat; *i.e.*, if at the end of the reaction the $CO_2$ is brought back to the same temperature as that of C and $O_2$ at the start, a certain amount of heat is carried off to the surroundings, and from experiments this heat is found to be 97,200 g-cal., if the symbols in the above equation represent gram-atoms. To balance the energy equation we must therefore write

$$C + O_2 = CO_2 + 97{,}200 \qquad (14)$$

This equation states that the combination of 12 g. C with 32 g. O, forming 44 g. $CO_2$, evolves 97,200 g-cal.

**39. A thermochemical equation** is therefore the total sum of the heat balance sheet of a process. To give this for any reaction, we need thermochemical data, namely the formation heats of all compounds.

**40. Thermochemical data.** For these, as they have been determined, the reader must be referred to the large thermochemical treatises of Berthelot, Thomsen and others. A very convenient and handy set of those data which are most important for the engineer, may be found in J. W. Richards' "Metallurgical Calculations," Vol. I.

**41. Use of different units.** In applying these data, attention must be paid to the fact that different authors write the same equation in different ways. Thus, the above statement of the formation heat of carbon dioxide is written by Richards, Hess and Naumann in the form $(C,O_2) = 97{,}200$; by Berthelot in the form $(C,O_2) = 97.2$; by Ostwald in the form $(C,O_2) = 972K$: *i.e.*, if the chemical symbols of the reacting substances represent gram-atoms, then Richards, Hess and Naumann give the energy in gram-calories, Berthelot in kilogram-calories and Ostwald in terms of a unit 100 times as large as a gram-calorie.

Sometimes the energy is given in British thermal units; this unit is the heat that will raise the temperature of 1 lb. of water 1 deg. fahr. Then since 1 deg. cent. = 1.8 deg. fahr., we have simply to multiply the figures in the Richards-Hess-Naumann notation by 1.8 and the thermochemical equation will be correct if the chemical symbols represent pound-atoms. Thus $(C,O_2) = 97{,}200 \times 1.8 = 174{,}960$ B.t.u. states that the combination of 12 lb. C with 32 lb. $O_2$, forming 44 lb. $CO_2$ evolves 174,960 B.t.u.

**42. Application of heat balance sheet.** In many electric furnace processes the object is to heat the charge up to a certain high temperature, at which the desired chemical reaction will then go on. Whether this reaction will evolve or consume energy will be seen from the thermochemical heat balance sheet. If it evolves energy, then this amount is added to the heat produced by the electric current. If it consumes energy, then this amount must be furnished by the electric current. To find the electrical energy equivalent to the heat given in calories, it is to be noted that 1 g-cal. = 4.186 watt-sec. Direct currents and alternating currents are equally suitable for producing the heat effect.

**43. Change of reaction heats with temperature.** In making up a heat balance sheet, the thermochemical data relating to the temperature at which the reaction is carried out, must be chosen since the reaction energy depends on the temperature. The data may not be available for the desired

Digitized by Google

temperature. In such cases the following consideration is often useful, if the specific heats of all substances which are represented in the equation are known. Suppose a certain reaction evolves $a$ calories at the temperature, $t_1$, and we want to find the reaction heat at the higher temperature, $t_2$. Then we consider the materials on the left hand of the equation, *i.e.*, the starting materials, and raise them from $t_1$ to $t_2$; the heat, necessary for this purpose, may be $b$ calories and is directly found from the specific heats of the starting materials and the temperature difference, $t_2 - t_1$. That is $b$ more calories are now stored in the system than were in it at the temperature, $t_1$. We now let the desired chemical reaction go on at the temperature, $t_2$. This may evolve, $x$, calories, which is the figure to be determined. If we finally cool the system back to the temperature, $t_1$, it gives out a certain amount of heat, $c$, which can be found for the temperature difference, $t_2 - t_1$, and the specific heats of the end products. Then we know that the system has stored in it $(b - x - c)$ more calories than at the start, which according to the principle of the conservation of energy must be equal to $-a$, or $x = a + b - c$.

## CHEMICAL AND MECHANICAL ENERGY

**44. Definition of liter-atmosphere.** If as a result of a reaction between solid or liquid bodies a gas is evolved, work is done against the pressure of the atmosphere. The work done by the evolution of 1 liter of gas under atmospheric pressure is 1 liter-atmosphere.

1 liter-atmosphere = 10.333 kg-m.
= 24.2 g-cal.
= 101.3 watt-sec. (15)
= 0.136 horsepower-second.

**45. Work performed by evolution of gas.** For instance, if hydrogen and oxygen gas are produced under atmospheric pressure by electrolysis of a dilute acid or alkaline solution, 18 kg. water yield 2 kg. H, occupying 22,420 liters at 0° C, and the work done in expanding the hydrogen gas against the pressure of the atmosphere is 22,420 liter-atmospheres = 543 kg-cal. = 2,271 kw-sec. Simultaneously 16 kg. O, occupying 11,210 liters, are evolved and the work done in expanding the oxygen gas against the pressure of the atmosphere is 11,210 liter-atmospheres = 271 kg-cal. = 1,135 kw-sec. Hence the total work done in expanding both gases to 33,630 liters is 814 kg-cal. = 3,406 kw-sec. This energy consumed is, of course, not to be confounded with the energy required for the electrolytic decomposition of the water. It is simply the mechanical work performed in expanding the gases against the pressure of the atmosphere.

A very simple way to calculate this work approximately is to remember the formula $p\,v = RT$, in which R very approximately = 2, if $p\,v$ is given in gram-calories and the mass of 1 gram-molecule is considered. In words, the work done in expanding 1 gram-molecule of any gas from a solid or liquid to gas at the absolute temperature T is 2T g-cal.; for instance, at 0 deg. cent. or 273 deg. absolute temperature it is 546 g-cal. (as compared with 543 found above). In the reverse change from gas to solid the same amount of work is performed upon the system or the same amount of energy is gained by the system.

**46. Expansion of gas at constant pressure.** The characteristic feature of processes like those just described is that they take place at constant pressure. In general if a gas expands at constant pressure, $p$, from volume, $v_1$ to $v_2$, the work done is $p\ (v_2 - v_1)$. In the special case that a gas expands from a solid or liquid, the volume of the solid or liquid, which disappears is negligible compared with the gas formed and $v_1 = o$, from which results at once the above calculation.

**47. Expansion of gas at constant temperature.** An entirely different case is the calculation of the work done when a given mass of gas expands its volume at constant temperature, the pressure decreasing correspondingly. For 1 gram-molecule, expanding from volume $v_1$ to volume $v_2$ at constant temperature, T, this work is

$$R\,T\,\log_e \frac{v_2}{v_1}, \tag{16}$$

where $\log_e$ means the natural logarithm. In view of the parallelism between gaseous pressure and osmotic pressure in solutions, the above statements on gases may be made in an analogous way for solutions.

## CHEMICAL AND ELECTRICAL ENERGY

**48. Transformation of electrical energy to chemical energy.** In electric-furnace reactions, as noticed above in Par. **42**, electrical energy is changed into chemical energy, but this transformation is only partly direct, since that part of the electrical energy which serves for raising the charge of the furnace to the desired temperature (physical change) is first changed into heat. Another amount of electrical energy may be necessary for the chemical reaction according to the thermochemical balance sheet. Such an electric-furnace process should therefore be treated exactly like a thermochemical process (**38 to 43**). Direct current and alternating current are equally suitable.

**49. A direct change of electrical energy into chemical energy** occurs in electrolytic processes requiring direct current, and we will first assume that no other forms of energy besides electrical and chemical are involved in the reaction. This assumption is never strictly fulfilled, but approximately in many cases. Under this supposition the chemical equation of any electrolytic reaction gives directly the e.m.f. required to perform it or the e.m.f. which it can give out according to whether we have to do with an electrolytic process changing electric energy into chemical energy or with a battery changing chemical energy into electrical energy.

**50. Calculation of e.m.f. of reaction.** We need for this calculation the thermochemical data to write down the energy-balance sheet; while we thereby get the energy of the reaction in heat units or calories, we can easily change it into electrical units or watt-seconds = volt-ampere-seconds. From Faraday's law we know the coulombs or ampere-seconds which correspond to the same equation. By dividing the volt-ampere-seconds by the ampere-seconds, we get the volts corresponding to the reaction.

**51. Example.** In the **Daniell cell** the essential reaction is

$$Zn + CuSO_4 = Cu + ZnSO_4. \qquad (17)$$

According to Richards, "Metallurgical Calculations," Vol. I, p. 24, the formation heats of $ZnSO_4$ and $CuSO_4$ from the elements, if the chemical symbols represent gram-atoms, have the following values in gram-calories:

$$Zn + S + O_4 = ZnSO_4 + 248{,}000 \text{ (in solution)},$$
$$Cu + S + O_4 = CuSO_4 + 197{,}500 \text{ (in solution)}.$$

By subtraction we get the energy balance of the Daniell cell

$$Zn + CuSO_4 = Cu + ZnSO_4 + 50{,}500. \qquad (18)$$

Since the change of bonds or change of valency is two, we know that $2 \times 96{,}540$ coulombs are involved in the reaction which gives out 50,500 g-cal. or $50{,}500 \times 4.186 = 211{,}400$ watt-sec. or volt-ampere-seconds. This divided by $2 \times 965{,}400$ amp-sec. gives 1.1 volt which is almost exactly correct.

**52. As a second example** we may use our former equation of the Siemens and Halske copper process. From Richards (Vol. I, pp. 24 and 25) we find

$$Cu + S + 4O = CuSO_4 + 197{,}500,$$
$$2Fe + 2S + 8O = 2FeSO_4 + 469{,}800,$$
$$2Fe + 3S + 12O = Fe_2(SO_4)_3 + 650{,}500.$$

By subtracting the sum of the first two equations from the third equation we get

$$CuSO_4 + 2FeSO_4 = Cu + Fe_2(SO_4)_3 - 16{,}800. \qquad (19)$$

Hence in order to let this reaction go on from the left to the right hand in the equation, if each symbol of an element means a gram-atom, energy in the amount of 16,800 g-cal. must be furnished, which is equal to about 70,000 volt-amp-sec. Since this reaction involves the passage of $2 \times 96{,}540$ amp-sec., the theoretical voltage which must be applied is somewhat less than 0.4 volt.

**53. Thomson's rule.** Let W be the total energy of the reaction in gram-calories when all symbols of the elements in the equation of the reaction represent gram-atoms. The same energy, measured in watt-seconds, is 4.186 W. The electrical work equals electromotive force $\times$ coulombs = $e \times n \times 96{,}540$, if $e$ is the electromotive force in volts and $n$ the change of valence (change of bonds) in the reaction. If the total chemical energy equals the electrical energy, we get

$$e = \frac{4.186\ W}{96{,}540\ n} = 0.0000434\ \frac{W}{n}. \qquad (20)$$

Digitized by Google

At ordinary temperatures this rule is, in general, approximately fulfilled and is therefore exceedingly useful for making a first approximate calculation.

**54. Terminal voltage.** The voltage, $e$, is the e.m.f. absorbed or produced in the electrochemical process. It is different from the voltage at the terminals. The voltage at the terminals of a battery equals the e.m.f., $e$, minus the voltage drop due to internal resistance. The voltage at the terminals of an electrolytic cell through which electricity is passed from an outside source, equals the e.m.f., $e$, of the reaction plus the voltage drop due to internal resistance.

## CHEMICAL ENERGY, ELECTRICAL ENERGY AND HEAT

**55. Error in Thomson's rule.** Thomson's rule is wrong in principle because in an electrochemical action we never have an interchange of chemical energy and electrical energy alone, since heat is always involved. This does not mean the Joulean heat which, of course, is also present. We may assume we have an electrolytic system of such dimensions and design that its internal resistance is so small that the Joulean heat developed in it is negligible compared with the amount of energy involved in the reaction. Under such conditions we know from experience that the cell while electricity passes through it, either tends to cool or to heat. To maintain the temperature constant it is therefore necessary to supply heat from the surroundings or to carry it off to the surroundings. In the case of a battery, if it tends to cool, and we supply heat to maintain the temperature, not only chemical energy but also the heat supplied during discharge are changed into electrical energy; hence the e.m.f. at that temperature has a greater value than that found from Thomson's rule. If the battery tends to give up heat during the passage of the electricity, heat is given off to the surroundings, and the e.m.f. is smaller than found by Thomson's rule.

**56. Distinction between energy of reaction and capacity for performing work.** This question is intimately connected with the essential difference between the total energy of a reaction at a certain temperature, as defined in Par. 38 to 43 and its capacity of performing work. The reason is that among all different forms of energy, heat has an exceptional place. We can always change all other kinds of energy completely into heat, but we cannot do the reverse. In case of a chemical reaction we can change the chemical energy completely into heat and this is exactly what we are doing in thermochemistry when we determine the heat or **energy of a reaction.**

**57. The capacity of performing work** (mechanical work in the expansion of gases or electric work in case of a battery) is something different. As an example, let us assume a concentration cell, consisting of two different concentrations of the same salt solution, each containing an electrode made of the metal of the salt. If then the reaction is that at the anode metal is dissolved and forms more salt, while simultaneously salt disappears at the cathode, metal being deposited, then the energy corresponding to the solution of metal from the anode and deposition of exactly the same amount of metal on the cathode is zero. If we assume further that we have to do with solutions so diluted that the energy of further diluting them is zero, then the energy corresponding to the concentration changes in the cell is also zero. Hence the total chemical energy of the reaction in the cell is zero. Nevertheless the cell will give out electricity and will perform work, the electricity produced being in such a direction as to equalize the concentrations (*i.e.*, the electricity passes in the cell from the dilute to the concentrated solution, because under this condition more salt is formed in the dilute solution from the anode, while the concentrated cathode solution is diluted by metal being deposited on the cathode). Of course, the energy must come from some source, and under the conditions of the experiment it must come from heat; *i.e.*, the cell while giving out electricity tends to cool down, and heat must be supplied from the outside to keep the temperature constant. This is therefore a case in which the chemical energy of reaction is zero, but its capacity of performing work has a positive value; correspondingly the e.m.f. would be zero according to Thomson's rule, but has in reality a positive value.

**58. Helmholtz equation of energy.** If $W$ = energy of the chemical reaction at a certain absolute temperature $T$ and if $W_0$ is the maximum amount of work which it is capable of performing at that temperature under

Digitized by Google

ideal conditions (characterized by complete "reversibility"), then Helmholtz has shown that

$$W_0 = W + T\frac{dW_0}{dT}. \qquad (21)$$

Helmholtz calls W the total energy of the reaction and $W_0$ the **free energy**, *i.e.*, that amount which is free to perform work. The second term at the right hand is the temperature coefficient of the free energy multiplied by the absolute temperature.

**59. Gibbs-Helmholtz equation.** In the case of an electrolytic reaction which is supposed to be reversible, $W_0$ is the total energy of the reaction in gram-calories when all chemical symbols of the elements in the equation of the reaction represent gram-atoms. Measured in watt-seconds, this energy is 41.86 W. The free energy $W_0$ is in this case the electrical work $= e \times n \times$ 96,540 watt-sec. if $e$ is the electromotive force and $n$ the change of valence in the reaction. The above energy equation may therefore be transformed into

$$e = 0.0000434\,\frac{W}{n} + T\frac{de}{dT}. \qquad (22)$$

where $e$ is given in volts, W in gram-calories and T is the absolute temperature. This equation differs from Thomson's rule by the second term on the right hand which may be considered as a term of correction or refinement, since for approximate calculations of practice, at ordinary temperature, Thomson's rule is good enough. The above equation permits the calculation of the temperature coefficient of the e.m.f., if the e.m f. and the energy of reaction are known.

## ELECTRIC FURNACES

**60. Distinguishing feature.** There is no specific feature which distinguishes an electric-furnace reaction as a reaction from those taking place in ordinary chemical or metallurgical processes. The **distinguishing feature** rests in the apparatus, the heat required for the reaction being produced electrically. If the same amount of heat would be generated in the same material in some other way than by electricity, the reactions would be exactly the same.

**61. Advantages.** Compared with the production of heat in the ordinary way from fuel, electrical heat has the following advantages. First, a considerably higher temperature may be obtained; it is limited in arc furnaces by the temperature of the arc which is around 3700 deg. abs. (Waidner and Burgess) or around 3,400 deg. cent. and in resistance furnaces chiefly by structural considerations, such as the availability of insulating refractories, etc. While in ordinary chemical and metallurgical furnaces temperatures up to 2,000 deg. cent. are obtainable, temperatures up to 3,500 deg. cent. can be produced without special difficulty in the electric furnace. Secondly, for reactions requiring certain refinements, the electric furnace has the advantage of permitting easier control of the conditions of operation (temperature, chemical nature of atmosphere, etc.). On the other hand, in most places where chemical or metallurgical processes are now carried out, heat produced from electrical energy is much more expensive than heat produced from fuel.

**62. Limitations.** Under exceptional local conditions fuel may be so expensive and electrical energy produced, for instance, from water-power, may be so cheap, that electrical heat, because cheaper than heat from fuel, will be most economical for any purpose. Such exceptional conditions need not be considered here. Under ordinary normal conditions, the use of the electric furnace is economically restricted to reactions requiring a high temperature and to such reactions in which easy and strict maintenance of conditions of operation is of importance and in all such cases it is of the highest importance to utilize the electrical energy to the utmost. An electric horsepower-year contains the same heat as a short ton of coal with a heating value of 11,150 B.t.u. per pound.

The whole problem turns on two items: (a) The heat generated in the furnace from electrical energy and (b) the heat lost during the operation to the surroundings. If we first eliminate the size of the furnace from consideration, the rate of heat production in the furnace charge depends on the supply of electric power per unit of mass of charge, *i.e.*, on the kilowatts per cubic meter. The rate of heat loss depends on the heat carried off by conduction

Digitized by Google

and radiation per unit of the surface of the furnace, *i.e.*, on the kilowatts lost per square meter. Hence if the size of an electric furnace is increased, then *ceteris paribus* the generation of heat from electricity increases as the third power of the dimension, and the losses as the square of the dimension; hence the thermal efficiency of an electric furnace is the higher, the larger the size. The maximum size of a furnace is limited by the consideration that the more we increase the size, the greater becomes the difficulty of maintaining uniform conditions of operation.

## ENERGY BALANCE, REFRACTORIES

**63. Analysis of energy required.** The energy per unit of mass is, in general, consumed in five different items, viz.:

(*a*) To produce the heat necessary to raise the starting materials to the temperature of the reaction.

(*b*) To provide the energy required for any change from solid state to liquid or from liquid to gas or from solid to gas.

(*c*) To provide the energy for the chemical reaction.

(*d*) To supply the heat lost by conduction.

(*e*) To supply the heat lost by radiation.

**64. Heat necessary to raise starting materials to operating temperature.** The heat necessary to raise the starting materials, if cold, to the temperature of the reaction (Par, **63a**) equals the weight of charge multiplied by temperature difference multiplied by mean specific heat.* To reduce this item of energy as much as possible, the starting materials are often preheated by waste gases, etc. It is often advantageous to divide the heating of the charge into two stages, the lower ranges of temperatures being obtained by burning fuel and only the higher range of temperatures from electrical heat.

**65. Heat necessary for change of state.** The heat required for a change of the charge from solid to liquid or from liquid to gas or from solid to gas (Par. **63b**) is equal to the weight of the charge multiplied by the latent heats (see J. W. Richards, "Metallurgical Calculations," Vol. I). This item of energy expense should also be eliminated wherever possible. For instance, for electric steel refining, the steel is preferably supplied to the electric furnace in molten state from the open-hearth furnace or Bessemer converter. If a gas is evolved from solid materials, the work done in the expansion of the gas must also be considered. See (**44**).

**66. The energy required for the chemical reaction** (Par. **63c**) at the temperature of the reaction (Par. **48** to **54**), is an item of expense, only if the reaction absorbs energy. If the reaction evolves energy, this energy is added to that of the electric current and changed into useful heat, so that the amount of electrical energy to be supplied from the outside is reduced.

**67. The loss of heat by conduction** (Par. **63d**) depends on the difference of temperature inside the furnace and outside and on the thermal conductivity of the furnace walls. To reduce this loss as much as possible, the furnace walls are built up of highly insulating refractory materials. In the choice of the material its heat-insulating property must be taken into consideration as well as the maximum temperature which it is intended to stand and the chemical nature of the reactions for which the furnace is to be used; further, the ability to withstand expansion and extraction must be taken into consideration. See Par. **69** to **89**.

**68. The loss of heat by radiation** (Par. **63e**) is treated in Par. **90**.

**69. Loss of heat through terminals.** All electric furnaces, except the induction furnace, have terminals (often called electrodes) for introducing the electrical energy into the furnace, and these represent the weakest point in the heat insulation. But the conduction of heat through an electrode (due to the temperature difference between its two ends) is a more complicated phenomenon than the single heat conduction through the refractory wall, because in the former case each particle of the electrode is not only a conductor of heat, but a seat of generation of new heat (from electrical energy). There is a superposition, therefore, of two phenomena; first, simple heat con-

* For tables of specific heats see J. W. Richards, "Metallurgical Calculations," Vol. I, also Sec. 4.

Digitized by Google

duction from the hot to the cold end, and second, generation of Joulean heat within the electrode, this heat tending to flow off impartially one-half to one end and the other half to the other end. (Par. 106.)

**70. Refractories.** For ordinary metallurgical furnaces the refractories are generally subdivided into three classes: Acid, basic and neutral. For a basic charge no acid lining of the furnace will of course be admittable, etc. The chief constituent of acid refractories is silica. Lime, magnesia, bauxite* and dolomite are basic refractories. Neutral refractories are fire-clays, chromite, carbon.

**71. Kieselguhr.** A useful refractory for many purposes is kieselguhr† (infusorial earth). Its chemical characteristics are its siliceous nature, its easy solubility in alkalies, and its insolubility in acid or neutral solutions. It is available in the following four forms: (1) natural kieselguhr blocks (melting point 1610 deg. cent.) for insulation of moderately heated bodies and for cold-storage work; (2) pulverized kieselguhr, used as a filter for insulating purposes; (3) light weight kieselguhr insulating brick, used as an insulating backing for more refractory brick; (4) kieselguhr fire-brick for purposes where a light weight (sp. gr. 1), non-conducting, refractory brick is required (melting point 1,650 deg. cent., crushing strength 1,200 lb. per sq. in.).

**72. Compounds of carbon and silicon.** For the higher temperatures, used in the electric furnace, certain compounds of carbon and silicon as well as pure carbon are specially suitable.‡ The various silico-carbides (siloxicon, carborundum fire-sand, etc.), or amorphous compounds of carbon and silicon, or of carbon, silicon and oxygen, are useful up to the temperature of formation of crystalline carborundum. FitsGerald recommends using a comparatively thin lining of silico-carbide to protect the walls made of fire-brick; to substitute bricks made of a silico-carbide for fire-brick, dispensing with the latter altogether, is not advisable, since the silico-carbides are much better heat-conductors than ordinary fire-bricks. F. J. Tone (*Foundry*, August, 1904) recommends carborundum fire-sand as a furnace lining. The insulating properties of the silico-carbides are greatly improved by using them in the porous state.

**73. Concerning the methods of moulding silico-carbides** into forms such as bricks or tiles, FitsGerald gives the following instructions: When the material is put directly into place in the furnace, where it will not have to undergo any serious mechanical strains, a mixture of the powdered silico-carbide and a solution of glue in water gives satisfactory results. In order to obtain the best results with this method the mixture should be used hot. In those cases where very high temperatures are reached this method of making bricks is to be particularly recommended, for the silica which is usually present in commercial silico-carbides is fused at high temperatures, and thus strengthens the article considerably. When there is no free silica present, and the article is made up with the glue solution, it becomes very weak and crumbles after use. It is, therefore, advisable to analyse the silico-carbide before using, and if there is no silica present a small quantity may be incorporated with the mixture. The best form of silica for this purpose is infusorial earth.

In cases where the bricks will not be exposed to such high temperatures the silico-carbide may be mixed with a dilute solution of sodium silicate. The solution used for this purpose should not, as a rule, have a greater density than 1.03 to 1.05 according to FitsGerald. Tone recommends a solution having a density of 33 deg. Beaumé (1.277), but this is for ordinary furnaces, where relatively low temperatures are used.

**74. Binder for silico-carbides.** A very satisfactory bond for silico-carbides is found in gas tar. A good mixture contains 4 parts of the silico-carbide to 1 part of tar. In using tar, however, it must be remembered that a residue of carbon is left in the article, and this tends to diminish the insu-

*Concerning the use of alundum (made by electrically fusing and purifying bauxite) and alundum bricks as a refractory, see Saunders, *Met. & Chem. Eng'ing*, Vol. IX, p. 257, and FitsGerald, Vol, X, p. 129.

†Boeck. *Met. & Chem. Eng'ing*, Vol. XII, p. 109.

Digitized by Google

lating properties of the silico-carbide. Further, if the article is exposed at high temperatures to an oxidising atmosphere the carbon residue which acts as the binding agent is burnt out. If this happens the article will disintegrate, unless the temperature and oxidising conditions are such as to cause oxidation of the silico-carbide and consequent binding together of the particles. When, therefore, the article is exposed to oxidising actions at a comparatively low temperature, it is better to use sodium silicate as the binding agent. But where the conditions are such that neither oxidation or serious current leakage is to be feared, the tar bond is very satisfactory, giving articles of considerable mechanical strength.

When an article of great mechanical strength is required, and the use of tar is objectionable, the best method of making the article is, according to FitsGerald, to cause the particles of the silico-carbide to frit together by oxidation. To accomplish this result the silico-carbide is mixed with some temporary binding agent, such as a solution of glue in water and then heated to a high temperature for several hours in a strongly oxidising atmosphere. By this treatment the grains of the silico-carbide are superficially oxidised.

**75. Siloxicon.** When siloxicon is heated to, or above, 2,674 deg. fahr. (Acheson) or 1,468 deg. cent. in an oxidising atmosphere, decomposition takes place. If the siloxicon be in the form of a brick or other moulded mass the reaction occurs on the surface, producing a vitreous glaze. In the absence of free oxygen or in a reducing atmosphere, no such decomposition occurs, and the temperature may be raised to the point of the formation of carborundum, approximately 5,000 deg. fahr. (Acheson) or 2,760 deg. cent., solid crystalline carborundum remaining while the vapors of silicon and carbon monoxide are given off. For higher temperatures carborundum is a useful refractory; it is suitable up to such temperatures where it decomposes.

**76. Refractories for very high temperatures.** When the temperature to which the refractory material is submitted may be up to or above that of the formation of carborundum, it may be advisable, according to FitsGerald, to use **cyrstalline silicon-carbide** in the first place, allowing it to be converted into **carborundum** *in situ*. If this is done the silico-carbide should first be analysed to determine whether oxygen compounds are present or not. If oxygen compounds are present in appreciable quantities the silico-carbide may be unsuitable for the work, since at the temperature of the formation of carborundum, silicon will be reduced and the refractory lining will be impregnated with metallic silicon, or the furnace will be filled with silicon vapor. When the presence of the silicon is unobjectionable this reaction may be disregarded; otherwise there are two courses open; the silica may be removed or a material free from silica obtained; or from the analysis of the material the amount of carbon necessary to eliminate the oxygen and to form carborundum may be added to the mixture.

**77. Carborundum as a refractory material.** When it is desired to use carborundum directly as a refractory material the binding agents suggested in Par. **73** and **74**, for silico-carbides may be used. Carborundum may also be made into a strong article by the oxidation or fritting method described in **74**. Another method of making articles of carborundum is by recrystallisation. The carborundum in the form of grains or powder is mixed with some adhesive substance, such as a solution of glue in water, the mixture moulded in the desired form and the article then placed in an electric furnace and heated to the temperature of formation of carborundum. This causes a recrystallisation of the carborundum and forms a strong article which preserves perfectly the form in which it was moulded. Neither the **silico-carbides** nor **carborundum** can be used as refractory materials where they come **in contact with fused alkalies**, since these produce rapid decomposition. They are also attacked by chlorine at high temperatures.

**78. Binder for carborundum refractories.** For using **carborundum** (silicon carbide) **as refractory**, E. K. Scott (*Electrochemical and Metallurgical Industry*, Vol. III, p. 140) recommends that the carborundum be ground up very fine and mixed in the proportion of three parts by weight of carborundum to one part by weight of silicate of sodium (water-glass). After thoroughly brushing the newly set fire-brick to get rid of dust, etc. (the mixture will not stick to a surface which has already been fired), the carborundum is painted on to the depth of about half a millimeter. It is then left for 24 hr. to dry, and afterward the firing started up gradually.

Digitized by Google

Where basic slags or basic materials have to be taken into consideration, fire clay is employed as a binder, instead of the water-glass, the proportion being usually six parts by weight of carborundum to one part by weight of fire clay. Crystolon (silicon carbide) brick may be used to advantage in the construction of electric furnace roofs of special designs (*Met. & Chem. Eng'ing*, Vol. X, p. 131). Carborundum refractories* are now available in two different types; the first containing a vitrified or ceramic binder, the second consisting entirely of carborundum. The latter type is absolutely unattacked by acids and is inert to the influence of practically all other chemical agents. It is, however, extremely expensive to produce and its use is limited to those places where the ordinary brand of carborundum refractory is not suitable. Thus for certain parts of electric furnaces, as, for example, for heating furnaces of the carborundum-resistance type, it is the only material suitable for placing in contact with the carbon resistor. It also has advantages in constructing electric furnaces of the Hoskins carbon plate type, where, owing to the resistance to oxidation of the silicon carbide coating, the life of the carbon plates is increased five to ten times. It also has remarkable value for the construction of roofs of electric steel furnaces and furnaces of a similar type.

**79. The vitrified carborundum refractory** has, owing to its lower cost of production, a much wider application. The special features which distinguish carborundum among refractories are high softening or decomposition point, high thermal conductivity, low coefficient of expansion, hardness and mechanical strength, resistance to acids and other chemical agents, and comparatively low density.

**80. Magnesia lining.** For certain purposes a pure magnesia lining is recommended by E. K. Scott who treated crude pure magnesite from Southern India by shrinking it in an electric furnace. Crystallized magnesia, obtained in this way, can be used without further preparation than being crushed to suitable dimensions, as a refractory material in metallurgical practice, and an important point in connection with its use as linings for electric furnaces is that magnesia, unlike lime, does not form a carbide with carbon. Concerning the use of electrically calcined magnesia as a refractory see also FitsGerald, *Met. & Chem. Eng'ing*, Vol. X, p. 129.

**81. Temperature limit with carborundum.** The upper temperature limit to the use of carborundum is reached when that substance decomposes into silicon vapor and graphite. At such high temperatures the only available refractory is carbon, and the best form of carbon for this purpose is charcoal, since its electric resistivity is high. Where carbon cannot be employed, the only remedy is to dispense with a special refractory altogether and to use a solid layer of the furnace charge as lining. The solid layer is obtained from the fused charge by artificially cooling the walls of the furnace.

**82. Heat insulation.** Besides the ability to stand high temperatures and to resist the chemical effects of the materials in the furnace charge, the heat-insulating property is of greatest importance. It is in general necessary to make the walls of the furnace not of one single material, but to choose the inner lining with regard to the maximum temperature which it has to stand and the chemical effects to which it will be subjected from the charge, and to build the outer walls of a material of high heat-insulating quality. The total thermal resistance of a furnace wall is the sum of the resistances of the different layers of which the wall consists; these layers—the inner lining and the outer brick construction—are in series, and the thermal resistances are added in the same way as electrical resistances in series. The total thermal conductance of the furnace wall is the reciprocal of the total thermal resistance.

**83. Thermal conductivities.** The following table† of thermal conductivities gives the conductivities of materials suitable for heat insulation of electric furnaces, as far as determined, in the order of their heat-conducting qualities. This table is collected from J. W. Richards' "Metallurgical Calculations," Vol. I, p. 183 and from R. S. Hutton and J. R. Beard, *Elec-*

* Tone. *Met. & Chem. Eng'ing*, Vol II, p. 484.

*trochem. and Met. Ind.*, Vol. III, 1905, p. 291, and S. Wologdine and A. I Queneau, *Electrochem. and Met. Ind.*, Vol. VII, p. 383. The figures taker from Hutton are marked (H); most of the granular powders tested by Hut ton and Beard just passed through a sieve with 600 meshes per sq. cm. The figures taken from Wologdine are marked (W). All the conductivities λ are given in centimeter-gram-second units, *i.e.*, each figure represents the quantity of heat in gram-calories, which is transmitted per sec. through a plate 1 cm. thick per sq. cm. of its surface when the difference of temperature between the two faces of the plate is 1 deg. cent. The therma conductivity of various other substances is given elsewhere (see index). The figures under *t* represent the ranges of temperature in deg. cent. within which the conductivity figures are valid. The figures found by different investigators are considerably at variance. Probably those marked (W) are the best available at present for the grade of refractory materials or the marked for everyday furnace work. Concerning the method of measur ing the thermal conductivity of refractories see Clement, *Met. and Chem Eng'ing*, Vol. VIII, p. 414.

**84. Table of Thermal Conductivities of Various Substances**

| Substance | *t* | $\lambda_t$ |
|---|---|---|
| Graphite brick (W) | 100°–1000° | 0.025 |

**85. Calculations of heat flow** can be made analogous to calculations of electric flow. Carl Hering defines the thermal ohm* as that thermal resistance which will require a drop of temperature of 1 deg. cent. for 1 watt of heat flow. Ohm's simple law then applies numerically to calculations of thermal flows. If $R$ is the thermal resistance in thermal ohms, $W$ is the heat flow in watts and $T$ the drop in temperature in centigrade degrees, then Ohm's law in thermal form is $W = T/R$, which may be unhesitatingly used in calculations, as the units are then such as will avoid all coefficients and reduction factors.

1 thermal ohm = 4.18617 gram-calorie units.

1 g-cal. unit of thermal resistance = 0.238882 thermal ohm. Hering's analogous definition of the thermal mho is that conductance which will allow 1 watt of heat flow to pass when the difference of temperature is 1 deg. cent.

1 thermal mho = 0.238882 gram-calorie unit

1 g-cal. unit of thermal conductance = 4.18617 thermal mhos.

**86. Table of thermal resistivities and conductivities.** Hering gives the following table of heat resistivities and conductivities of various refractories in his new units.

| Substance | Resistivities in Thermal Ohms | | Conductivities Thermal Mhos | |
|---|---|---|---|---|

**87. Example of thermal calculations.** As an illustration of the simplicity of the calculations when these units are used, let the inside of a small furnace be a 6-in. cube; let the wall consist of a 4-in. layer of silica brick on the inside and 4 in. of brick on the outside. The true average cross-section of the layer of silica brick perpendicular to the heat flow (namely, the geometric mean, that is, the square root of the product of the extreme sections) for the whole furnace will be 504 sq. in. If its resistivity from the above table is 47 thermal ohms, its resistance will be

$$R = \frac{r \times l}{S} = \frac{47 \times 4}{504} = 0.37 \text{ thermal ohm.}$$

A similar calculation for the outside layer of fire-brick having a resistivity of 22 thermal ohms gives its resistance as 0.048 thermal ohm. Hence, the total is the sum of these two, which is 0.42 thermal ohm. Incidentally, it shows what a very much smaller insulating effect this much larger outside layer has.*

Suppose the drop of temperature through the wall to be 1,500 deg. cent. Then, according to the thermal ohm's law, the loss of heat will be

$$W = \frac{T}{R} = \frac{1,500}{0.42} = 3,580 \text{ watts, or about 3.6 kw.}$$

The analogy between heat flow and electric flow has been analyzed very carefully by E. F. Northrup† with applications of the results to an analysis of methods for measuring thermal resistances.

**88. Formulas for flow of heat through plates.** The ordinary formula for the flow of heat through plates or rods of solid materials may be written:

$$W = (A/t)k\ (T - To) \tag{23}$$

Where $W$ = the heat flow, expressed in watts, $A$ = area of plate or cross-section of the rod, $t$ = thickness of the plate or length of the rod, $T - To$ = the difference of temperature between the two sides of the plate or between the ends of the rod, and $k$ = heat conductivity of the material of the plate or rod in watts per cm. per deg. In most practical cases of heat flow the problem is more complicated than this. Usually the heat is not flowing between parallel surfaces, or at least the areas of the two bounding surfaces are different. The above equation as it stands, applies only between parallel surfaces through a body of uniform cross-section. For bodies of other shapes Langmuir treats the case as follows. While $A$ will vary along the path of heat flow, yet if the area of inflow and outflow is fixed, the ratio $A/t$ will have a definite value, depending only on the shape of the body. This quantity, Langmuir terms the shape factor, and represents it by $S$. The formula (Eq. 23) thus becomes:

$$W = Sk\ (T - To) \tag{24}$$

In case the heat conductivity is a function of the temperature, the equation should be written:

$$W = S \int_{To}^{T} k\,dT \tag{25}$$

$S$, the shape factor, is a quantity of the dimension of a length which depends only on the shape and size of the body and the position of the surfaces by which the heat enters and leaves the body.

Langmuir‡ has given formulas for the shape factor for parallel places, concentric cylinders, concentric spheres, square edges, square corners, plane edges, plane corners, small square rods, small cubes, and for rec-

tangular parallelopipeds covered with a uniform thickness of insulation For a cube the formula is

$$S = \frac{6\,a^2}{t} + 6.5\,a + \frac{1.2\,t}{\sqrt{1+0.16\,\frac{t^2}{a^2}}} \qquad (26)$$

where $a$ is the length of the side of the cube and $t$ is the thickness of the insulation covering it.

**89. Abrupt discontinuities in the thermal circuit or path.** It is to be considered that there is, in general, no thermal equilibrium between the furnace charge and the furnace lining, nor between the outer wall and the surrounding air. This means that at both these contact surfaces there is a sudden drop of temperature. Since this is analogous to the voltage drop at an electrode, one speaks of heat-transfer resistances at these places which are added to the heat resistance of the wall itself. These transfer resistances depend on the materials in contact as well as on the degree of motion or circulation which may exist in one of the materials. For instance, if a furnace wall is water-cooled, the transfer resistance, corresponding to the transfer of heat from the furnace wall to the circulating water (which is proportional to the difference of temperatures between wall and water), depends on the flow of water.*

**90. The loss of heat by radiation** from the furnace walls to the surroundings is, according to the Stefan-Boltzmann law, proportional to $T^4 - T_0^4$, where T is the absolute temperature (or deg. cent. +273) of the outer surface of the furnace wall and $T_0$ the absolute temperature of the surrounding atmosphere. This law is strictly correct only for absolutely "black bodies" (which is not the case for the surface of a furnace) but may be used for a first approximate estimate. The gram-calories radiated per sec. from a surface at 100 deg. cent. to the surroundings at 0 deg. vary, according to Peclet, between 0.00054 g-cal. for polished silver and 0.01684 for lamp-black; the figure for wood, plaster and building stone is 0.015, for polished sheet-iron 0.00189, leaded sheet-iron 0.00273, ordinary sheet-iron 0.01164, new cast-iron, 0.01332, oxidized cast-iron 0.01410 (see also Richards, "Metallurgical Calculations," Vol. I, Chapter 8).

**91. Total heat required.** The five items given in Par. **63** represent together the total heat produced, which is partly utilised and partly wasted. This total heat is equal to the electrical energy consumed within the furnace, according to the following relations:

1 watt-hr. = 0.86 kg-cal. = 860 g-cal.,
1 kg-cal. = 1,000 g-cal. = 1.163 watt-hr.

**92. The electrical energy is changed into heat** by either of the following ways: first, by producing an electric arc and thereby generating heat; or, second, simply by the Joulean effect, the electric energy being changed into heat on account of the electric resistance of the path of the current, the rate of heat produced being $I^2R$ watts or 0.24 $I^2R$ g-cal. per sec., if I is amperes (effective amperes in case of alternating current) and R is ohms (resistance, not impedance). Accordingly, electric furnaces are divided into arc furnaces and resistance furnaces. The material in a resistance furnace in which the electrical energy is changed into heat is called the resistor (FitzGerald). In many cases it is difficult to say whether a furnace belongs to one or the other class, since both effects may be superposed.

## CONSTRUCTION AND DESIGN OF ELECTRIC FURNACES

**93. A typical arc furnace** is shown in Fig. 1 which represents the original furnace of H. Moissan, composed of two blocks of lime placed one on the other. The lower piece had a longitudinal groove through which passes two carbon rods, between which the arc played. In the centre of the lower block below the arc a cavity was provided which served as a crucible or which

* Concerning further details see J. W. Richards, "Metallurgical Calculations," Vol. I, Chapter 8. The flow of heat through contact surfaces is discussed by Carl Hering in *Met. & Chem. Eng'ing*, Vol. X, p. 40, where he gives a table of contact resistances in thermal ohms.

Digitized by Google

contained a special carbon crucible in which the material to be heated was placed. The upper block was slightly rounded out directly above the arc. By the strong heat of the arc the surface of the lime was fused and highly polished so as to form a perfect reflector sending all the heat down upon the crucible.

**94. Direct and indirect arc furnaces.** In the former the furnace charge is directly exposed to the arc, in the latter it receives the heat of the arc by radiation and by reflection from the roof and walls. It is clear that in many cases there is combined direct and indirect heating. A typical example of indirect arc heating is the **Stassano furnace.** For operation by three-phase currents, there are three electrodes at the top. The arcs play between the ends of the three electrodes and heat the metallic bath below by radiation (there being no arcs between the electrodes and the bath itself). To mix the charge thoroughly, the furnace is built revolvable. (*Electrochem. & Met. Ind.*, Vol. VI, p. 315.)

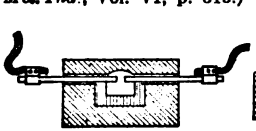

FIG. 1.—Moissan Arc Furnace.

FIG. 2.—Acheson Carborundum Furnace.

**95. A typical resistance furnace** is the carborundum furnace of E. G. Acheson, shown in plan and vertical section in Fig. 2, the dimensions referring to a capacity of 750 kw. The charge which consists of carbon, silica sand and salt, surrounds a carbon core which acts as resistor and is placed in the centre of the furnace. It runs through the furnace from end to end and is connected at both ends with the carbon terminals or electrodes in the end walls of the furnace. (For further details see F. A. J. FitzGerald, *Electrochem. and Met. Ind.*, Vol. IV, p. 54.) The current through the resistor produces heat which passes outward into the charge, resulting in the production of carborundum.

**96. Resistance furnaces** may again be **subdivided** according to the nature of the resistor, whether the electric heat is produced in the charge itself or in a special resistor, in contact with the charge. The former is possible only if the charge itself is a conductor of electricity; an example is the induction furnace for melting steel, etc. In case the furnace charge is not itself a conductor of electricity, a special resistor must be provided in contact with the charge; the electricity takes a predetermined path in passing through the resistor in which the heat is thereby developed. An example is the carborundum furnace described above. Finally it is possible to so arrange the resistor that it is not in direct contact with the charge, but is arranged above it and heats the charge by radiation.* Concerning materials suitable for resistors see Par. 111.

No sharp distinction is always possible between the two subclasses of resistance furnaces with or without a special resistor. For instance, in the Acheson furnace for changing carbon electrodes into graphite electrodes, the electrodes are embedded in granular graphite; most of the heat is developed in the latter, but since the electricity also passes through the electrodes themselves, some heat is also directly produced within the same. An example of a furnace operation which changes in character during a run is Acheson's furnace for producing graphite in bulk; in the centre of the anthracite coal, coke, etc., to be graphitized the resistor in form of a series of carbon rods, is placed through which the electricity first passes exclusively; when the anthracite coal next to the core is changed by the heat into graphite, the electricity also passes through it and so on. Therefore, while the electricity had first only a restricted definite path, its path gets broader and broader during operation.

**97. Pinch phenomenon.** A peculiar limitation of the temperature obtainable in that class of resistance furnaces in which the charge itself forms

* FitzGerald. *Met. & Chem. Eng'ing*, Vol. VIII, p. 317; Vol. IX, p. 29.

Digitized by Google

the resistor, is the "*pinch phenomenon*,"* described by Carl Hering in the *Transactions* American Electrochemical Society, Vol. XI and XVI.

This same pinch phenomenon is made use of by Carl Hering in his **pinch effect furnace**,† which is a special type of resistance furnace. The charge is contained in a crucible and the current is introduced through electrodes in the bottom, the upper part of which (that is, the part in contact with the charge in the crucible) forms at the same time the resistor. These resistor tubes are so dimensioned that the proper amount of heat is generated in them. At the same time the liquid metal in the resistor tubes is ejected by the pinch effect into the crucible whereby an effective agitation and circulation of the metal in the crucible is obtained.

**98. Héroult furnace.** An example of an electric furnace which is strictly neither an arc furnace nor a resistance furnace is the steel furnace of P. Héroult. The steel to be purified in the furnace chamber is covered by a layer of slag so chosen as to produce the desired chemical reactions. Two vertical carbon electrodes are suspended through the top of the furnace if

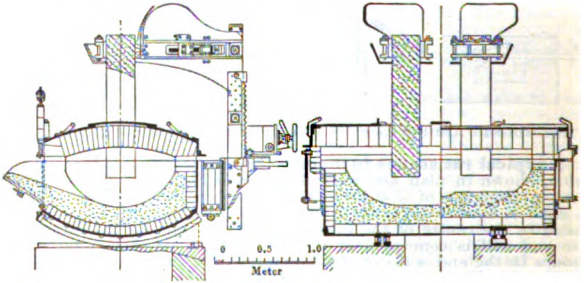

FIG. 3.—Héroult Steel Furnace.

operated by single-phase current. The operation is started by striking arcs between the ends of the electrodes and the surface of the slag, and in this respect the furnace is an arc furnace. But since the electricity passes from one electrode into the slag, through the slag and out into the other electrode, further heat is produced within the slag itself due to the Joulean effect and in this respect the furnace is a resistance furnace.

**99. The Girod furnace** differs from the Héroult furnace, because it has one or several bottom electrodes, in form of steel rods inserted in the bottom and water-cooled from the outside. There is one or several electrodes at the top, but if more than one is used, they are all electrically connected in parallel (instead of the series connection in the Héroult furnace). The current passes from these top electrodes through the arcs into the slag and downward through the metallic bath and out of the furnace through the bottom electrodes. (*Met. & Chem. Eng'ing*, Vol. IX, p. 581.)

**100. The Keller furnace** differs from the Girod furnace only in details of the bottom construction. (*Transactions* Am. Electrochem. Soc., Vol. XV.)

**101. Loss of energy.** Whatever the type of the furnace, the electrical energy which is changed into heat within the furnace itself, is less than the electrical energy which must be supplied outside, since the transfer of the energy from the outside, into the furnace always involves losses. This transfer of electrical energy may be made either by electromagnetic induction or through terminals, extending through the furnace walls.

**102. Induction furnace.** An electric furnace into which the electrical energy is transmitted by electromagnetic induction is called an induction

* Formulas for the pinch phenomenon are given by E. F. Northrup, *Phys. Rev.*, Vol. XXIV, p. 474, and C. Hering, *Met. & Chem. Eng'ing*, Vol. IX, p. 86.

† *Met. & Chem. Eng'ing*, Vol. IX, pp. 277, 371.

Digitized by Google

furnace. It is essentially a transformer, the secondary of which is a single turn, represented by an annular channel which contains the charge. It is necessarily operated by alternating current which is fed to the primary winding, thus setting up an alternating magnetic flux in the transformer core of laminated iron; this again produces alternating current in the furnace charge in the secondary annular channel, thus heating the charge directly by the Joulean effect. A tilting induction furnace for melting metals (A. E. Colby, F. A. Kjellin) is shown diagrammatically in Fig. 4.

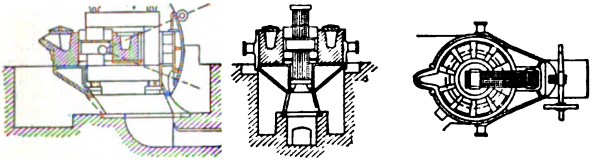

FIG. 4.—Colby-Kjellin Induction Furnace.

The **chief advantage** of this type of furnace lies in the fact that there are no electrodes which could contaminate the bath, so that the chemical composition of the bath can be absolutely controlled by carefully selecting the raw materials. The nature of the atmosphere in which the reaction takes place is also in absolute control of the operator. It is also possible to heat up such a furnace very quickly. (FitsGerald, *Electrochem. & Met. Ind.*, Vol. VII, p. 10, 1909.)

The **losses of energy** in transfer from the primary to the secondary are calculated exactly as in the case of the ordinary transformer (Sec. 6). The induction furnace differs (quantitatively, not qualitatively) from commercial alternating-current transformers, since it has necessarily considerable magnetic leakage fluxes due to the necessity of careful insulation of the fused-bath channel from the primary winding. The **power-factor** is low, due to two causes: the low resistance of the secondary and its high self-induction, due to its wide separation from the primary. The power-factor can be improved by any of the following means: decreasing the frequency of the alternating current, or increasing the ohmic resistance of the fused charge, or increasing the magnetic reluctance of the two leakage fields.

**103. The Roechling-Rodenhauser combination furnace** is a modification of the simple induction furnace. It is heated by a superposition of two heating effects: firstly, according to the simple induction principle; secondly, an auxiliary secondary circuit is provided, the ends of which are connected to metallic pole plates embedded in the furnace walls. When the furnace is started, it is first heated by induction alone. When the refractory layer which separates the pole plates from the metallic bath thereby becomes hot, it becomes an electric conductor and supplementary heat is now produced by the electric current passing between the pole plates through the furnace charge. The advantages of this furnace over the simple induction furnace are that it can be used for refining (not only melting) purposes and that it can be built with ordinary commercial frequencies for large charges so as to operate with a good power-factor. (*Electrochem. & Met. Ind.*, Vol. VI, pp. 10, 143, 438, 458; *Met. & Chem. Eng'ing*, Vol. VIII, p. 338, Vol. X, p. 263, Vol. XI, pp. 99 and 599; *Transact.* Am. Electrochem. Soc., Vol. XX, p. 293.) Another combination of arc and resistance furnace is the "paragon furnace" (Harden, *Met. & Chem. Eng'ing*, Vol. IX, p. 38, 595).

**104. Electrodes.** If the electrical energy is introduced into the furnace through terminals, they consist almost always either of amorphous carbon or of graphite, at least for large furnaces. In this country amorphous carbon electrodes are generally made from petroleum coke, while in Europe electrodes made from anthracite coal are also used. However, artificial graphite electrodes made by the Acheson process in the electric furnace, are very extensively employed now. They are more expensive, but can be easily machined into any shape (C. E. Collens, 2nd, *Transactions* of the American Electrochemical Society, Vol. I; *Electrochemical Industry*, Vol. I, p. 26 and Vol. II, p. 277; W. McA. Johnson, *Electrochemical Industry*, Vol. II, p. 345),

Digitized by Google

are more resistant to combustion and have a higher electric conductivity; on the other hand, graphite has also a higher thermal conductivity than amorphous carbon. Electrode holder construction is fully treated in *Met. & Chem. Eng'ing*, Vol. XI, p. 321. Concerning the dimensioning and arrangement of the conductors, carrying the heavy currents to the electrodes, see Randall, *Transact.* Am. Electrochem. Soc., Vol. XVII, p. 139.

**105. Loss of heat through electrodes.** As mentioned in Par. **69**, the heat loss through an electrode (if the heat insulation to the surrounding walls is assumed to be perfect) can best be considered as the sum of the pure heat conduction loss, due to temperature difference $T$ between the two electrode ends, plus one-half the Joulean heat loss in the electrode itself. For a given current and a given temperature difference $T$ the heat loss through an electrode becomes a minimum if the dimensions of the electrode are so chosen that the Joulean heat loss is twice the pure heat conduction loss; this leads to a simple calculation of the ratio of length to cross-section of the electrode. This rule is rigidly correct if no heat leaks into the walls and if the thermal conductivity and the electrical conductivity of the electrode material are assumed to be independent of the temperature within the temperature limits in the electrode. In this case this is also the condition under which the hot electrode end within the furnace is in temperature equilibrium with the interior of the furnace, no heat passing through the hot electrode end in either direction. For practical applications this method of determining the ratio of length to cross-section can be made independent of any assumption as to the variations of the conductivities, if the ratio of length to cross-section is directly determined by experiments under the conditions of electrode operation. The following figures (C. Hering) give directly for copper, iron, graphite, and carbon those numerical values with which the product of length in centimeters and current in amperes is to be multiplied in order to find the proper or rational cross-section; proper or rational means that under these conditions there will be heat equilibrium at the hot electrode end.

| | T = 800 deg. cent. | 1000 | 1200 | 1400 | 1600 |
|---|---|---|---|---|---|
| Copper | 0.000036 | 0.000035 | 0.000035 | 0.000035 | 0.000034 |
| Iron | 0.00026 | 0.00025 | 0.00025 | 0.00025 | 0.00025 |
| Graphite | — | 0.00063 | 0.00059 | 0.00057 | 0.00055 |
| Carbon | — | 0.00187 | 0 00162 | 0.00145 | 0.00132 |

| | 1800 | 2000 | 2500 | 3000 deg. cent. |
|---|---|---|---|---|
| Copper | 0.000034 | 0.000034 | — | — |
| Iron | 0.00025 | 0.00025 | — | — |
| Graphite | 0.00054 | 0.00053 | 0.00051 | 0.00050 |
| Carbon | 0.00123 | 0.00115 | 0.00102 | 0.00093 |

In this table the temperature difference $T$ is given in deg. cent. The figures in the table are given in centimeters per ampere so that when these figures are multiplied by the length in centimeters and the current in amperes, the cross-section is obtained in square centimeters. For instance, the current may be 1,000 amp. and the temperatures of the furnace 2,100 deg. cent., that of the cold electrode end 100 deg. cent., hence the temperature difference 2,000 deg. cent.; further the electrode length may be 25 cm., then the graphite cross-section is $0.00053 \times 1{,}000 \times 25 = 13$ sq. cm. These figures relate, however, only to the "essential part" of the electrode, that is, that part which is embedded in the furnace walls, and are valid if the heat insulation is as good as in the tests in which the above values were determined. Concerning the whole theory see Carl Hering, *Electrochem. & Met. Ind.*, Vol. VII, pp. 442, 473, Vol. VIII, p. 471. *Transactions* Am. Electrochem. Soc., Vol. XVI, pp. 265, 317. and Vol. XVII, pp. 151 and 171, *Proc.* Am. Inst. Elec. Eng., March, 1910; *Met. & Chem. Eng'ing*, Vol. VIII, pp. 128, 188, 276; *Elec. World*, June 16, 1910; C. **106. Regulation of the heat production** is of greatest importance; this is, of course, identical with regulation of the electric energy supply. In arc furnaces this is obtained by adjusting the position of the electrodes, which may be done either by hand or automatically. A simple automatic method in case of a furnace with one electrode, the crucible forming the other terminal, is to control the position of the electrode by an electromagnetic device, the magnet winding being in shunt with the crucible and the electrode, so that the exciting current of the magnet depends on the current through the furnace. In the single-phase Héroult steel furnace which has two electrodes, there being current from one electrode through the slag to the other electrode, it is important to know that both arcs are playing properly. For this purpose a voltmeter is connected in parallel with each of the electrodes and the molten furnace charge: one terminal of the voltmeter is connected with the electrode and the other with some contact in the molten steel charge. Each voltmeter may, of course, be provided with an automatic regulating attachment.

**107. In the operation of resistance furnaces** it is a fact of great importance that the resistance is a variable quantity during the run of the furnace, both on account of variation of temperature and of the chemical changes in the charge. In order to work economically, it is usually important that the maximum power available be used throughout the furnace run, and if the resistor changes its resistance it is necessary to provide some means of regulating the voltage, and the maximum and minimum voltages attainable must have to each other the ratio of the square roots of the maximum and minimum resistance of the resistor (FitsGerald). If carbon is used as a resistor, it is advisable to raise it previously to the maximum temperature to which it will be submitted in practice. The best plan is to use graphitised carbon, for that form of carbon is stable in its physical characteristics so that the only change that is experienced when using it as a resistor is temporary and due to the increase in temperature.

**108. Direct current and alternating current may both be used** for operation of an electric furnace, but alternating current has two advantages: first, electrolytic effects which are not desired in pure electric-furnace reactions, are excluded; second, alternating current permits easier regulation. The induction furnace always requires alternating current.

**109. Rheostats.** As rheostats for voltage regulation, water rheostats or granular-carbon rheostats are suitable. (For details see F. A. J. FitsGerald, *Electrochemical and Metallurgical Industry*, Vol. III, p. 9).) Rheostat design, see Sec. 5).

**110. Tube furnace.** A special type of resistor furnace for experimental work which permits very exact regulation of temperature, is the tube furnace, *i.e.*, an electric furnace in which the resistor has the form of a tube. For various designs of such furnaces see Hutton and Patterson, *Electrochemical and Metallurgical Industry*, Vol. III, p. 455; S. S. Sadtler, *Electrochemical and Metallurgical Industry*, Vol. IV, p. 434; S. A. Tucker, *Electrochemical and Metallurgical Industry*, Vol. V, p. 227; J. A. Harker, *Electrochemical and Metallurgical Industry*, Vol. III, p. 273; William C. Arsem, *Transactions* American Electrochemical Society, Vol. IX; and especially the elaborate designs of H. N. Potter, U. S. Patents, 715507; 715508; 715509; Dec. 9, 1902; 719507, Feb. 3, 1903; 756891, April 12, 1904; 770312, Sept. 20, 1904; 814726 and 814727, March 13, 1906 Tube furnaces may be so constructed as to carry out the reaction either under increased or reduced pressure, as in the furnace of Arsem and the last two patents of Potter.

**111. In another special type of resistor furnace,** due to FitsGerald and Thomson, the charge is heated by radiation from a resistor above the charge; this furnace has been applied for zinc smelting (*Met. & Chem. Eng'ing*, Vol. VIII, pp. 289, 317). Various materials are suitable for the resistors, according to the special design of the furnace, such as granular carbon ("kryptol"), carbon rods, silundum rods, platinum strip or wire, nickel strip

Digitized by Google

or wire, tungsten or molybdenum strips or wire (Winne and Dantsizen, *Transact.* Am. Electrochem Soc., Vol. XX, p. 287), etc.; an alloy of nickel and chromium has an advantage over pure nickel that it will not oxidize even if heated in air to incandescence for a considerable time ("nichrome").

**112. Comparatively simple resistance furnaces** for heating crucibles are described by F. A. J. FitsGerald, *Electrochemical and Metallurgical Industry*, Vol. III, p. 55; Oliver P. Watts, *Electrochemical and Metallurgical Industry*, Vol. IV, p. 273; Samuel A. Tucker, *Electrochemical and Metallurgical Industry*, Vol. V, p. 227; D. F. Calhane, *Met. & Chem. Eng'ing*, Vol. X, p. 461; a vertical-arc furnace for laboratory work by Samuel A. Tucker, *Electrochem. and Met. Industry*, Vol. IV, p. 263. A high-temperature laboratory furnace with very exact temperature regulation is described by E. F. Northrup, *Met. and Chem. Eng'ing*, Vol. XII, p. 31.

**113. Resistance furnace design and construction.** An excellent serial of articles on resistance furnace design and construction was published by F. A. J. FitsGerald in *Electrochemical and Metallurgical Industry*, Vols. II, III, IV. Two papers by F. A. J. FitsGerald, *Transactions* of the American Electrochemical Society, Vol. IV; and by C. L. Collens, 2nd, *Transactions* of the American Electrochemical Society, Vol. IX, deal with the theory of the resistance furnace; a paper by J. W. Richards, *Transactions* of the American Electrochemical Society, Vol. II, with the efficiency of electric furnaces. A serial on electric furnaces, their design, characteristics and commercial applications, for students, engineers, and business men, by W. McA. Johnson and G. N. Sieger appears in *Met. & Chem. Eng'ing*, Vols. XI and XII. Concerning the classical electric-furnace researches of H. Moissan, see his book on the electric furnace which is available for the English reader in an American as well as in the English edition.

**114. Reducing agent.** It should be emphasized that in an electric furnace the electrical energy provides the heat required for the reaction, but that if the object is **to reduce an element from a compound**, a reducing agent like carbon is also required. For instance, if we compare reduction of iron ore in the electric furnace with the blast-furnace process, both processes require so much carbon as is necessary to combine with the oxygen in the iron oxide; but the blast furnace also requires carbon for producing the necessary high temperature and it is only this last portion of carbon the calorific value of which is replaced by electrical energy in the electric furnace.

**115. Carbon as a reducing agent.** For most purposes some form of carbon is used as a reducing agent in the electric furnace and it has been claimed that at the temperature of the electric furnace carbon is able to reduce any known oxide.

**116. In special cases other reducing agents may be used,** especially when the object is to produce metals or alloys for use in the steel industry, where it is of advantage to use metals or alloys free from carbon. Such metals and alloys are produced by the **aluminothermic method** of Hans Goldschmidt of reducing a metal from its oxide by means of aluminum; on account of the very high oxidation heat of aluminum the reaction when once started goes on by itself, no outside source of power being necessary, neither fuel nor electrical energy. On account of its strong reducing power aluminum may also be used in electric furnace reactions for special purposes, as is done by A. J. Rossi for production of ferrotitanium (*Electrochemical Industry*, Vol. I, p. 523). Other suitable reducing agents are silicon and carborundum (for instance F. M. Becket, *Electrochemical and Metallurgical Industry*, Vol. V. p. 237, also E. F. Price, for the production of other ferro-alloys). Other reducing agents for special purposes are calcium carbide and metallic calcium.

**117. Comparison of electric furnace with coal furnace.** Since in an electric furnace electrical energy replaces the heat of combustion of coal in coal-fired furnaces, a numerical comparison of the economy of both processes in this single respect may be given. But it must not be forgotten that this is the most unfavorable way of looking at the economy of the electric furnace, since we purposely ignore all its special advantages.

One kilowatt-hour is equivalent to 860 kg-cal., *i.e.*, the full heat which can be produced from 0.1 kg. of good coal when completely burnt to $CO_2$. If the cost of 1 ton (2,000 lb. = 907 kg.) of coal is $a$ dollars and if the efficiency of heat production by burning coal is $m$ per cent. then the cost of producing

Digitized by Google

860 kg-cal. from burning $\frac{10}{m}$ kg. coal is $\frac{a}{90.7\ m}$ dollars. On the other hand, if the cost of 1 kw-hr. is $b$ cents and if the efficiency of producing heat from electrical energy is $n$ per cent. then the cost of 860 kg-cal. from $\frac{100}{n}$ kw-hr. is $\frac{b}{n}$ dollars. Hence electric heat will be cheaper than heat produced by combustion of fuel if $an$ is greater than 90.7 $bm$.

If we assume efficiency figures which are not unfair under practical conditions, namely an efficiency $m = 25$ per cent. for fuel heating and an efficiency $n = 75$ per cent. for electric heating, then electric heat is cheaper than fuel heat if $a$ is larger than 30.2 $b$, *i. e.*, if the cost of 1 ton of coal in dollars is more than 30.2 times greater than the cost of 1 kw-hr. in cents. For instance to compete with coal at $6 per ton, the electric kilowatt-hour would have to cost less than ½ cent. This shows that were it not for its other important features, electric heat could not compete with fuel heat under ordinary conditions. If we had an electric furnace process which would work continuously with full load all year, then the cost of the electric horsepower-year will be 65.7 $b$ dollars; hence electric heat will be cheaper than fuel heat if the cost of 1 ton of coal in dollars is more than $\frac{30.2}{65.7}$ or say, one-half the cost of the electric horsepower-year. This is apparently a more favorable view of the situation, especially in neighborhoods where fuel is expensive and water-power is really cheap (say below $10 per electric horsepower-year). But unless absolute continuity of the process is assured, it is safer to base such calculations on the cost of the kilowatt-hour instead of the horsepower-year.

## COMMERCIAL PRODUCTS OF THE ELECTRIC FURNACE

**118. A brief summary** of the most important commerical products of the electric furnace will now be given. Concerning the production of various modifications of carbon (including artificial diamonds) and the production of chromium, manganese, molybdenum, tungsten, uranium, vanadium, zirconium, as well as carbides, silicides, borides, phosphides, arsenides and sulphides on an experimental scale, see Moissan's "Electric Furnace." A very useful bibliography on borides and silicides may be found in O. P. Watts, "Investigation of the Borides and the Silicides," Bulletin University of Wisconsin, No. 145. A. Stansfield's "Electric Furnace" is a reliable and concise descriptive book. Askenasy's "Einführung in die technische Elektrochemie," Vol. I (Electrothermie) contains valuable information on various electric furnace processes. Concerning new proposed applications of the electric furnace the reader is referred to the current abstracts of new electrochemical patents in *Met. & Chem. Eng'ing.* The following list includes only the most important products which are made in the electric furnace on an industrial scale.

**119. Artificial graphite** is made by the processes of E. G. Acheson in three forms: hard graphite in bulk, suitable for paint, pigment, etc.; artificial graphite electrodes for electric furnace and electrolytic work; soft graphite suitable as lubricant, stove polish, etc. See descriptions of the three processes in *Electrochemical and Metallurgical Industry*, Vol. III, p. 41β and Vol. IV, p. 502, Vol. VII, p. 187.

Concerning the conditions of transformation of amorphous carbon into graphite see Arsem, *Trans.* Am. Electrochem. Soc., Vol. XX, p. 105.

**120. Silicon Carbide*** (trade names carborundum, crystolon) is made by the process of E. G. Acheson from a charge of carbon, sand and salt, the essential reaction being $SiO_2 + 3C = SiC + 2CO$. The chief uses of carborundum are as an abrasive and a refractory.

---

Digitized by Google

**121. Artificial emery or alundum,*** another artificial abrasive, is made according to C. B. Jacobs by fusing bauxite in the electric furnace.

**122. Aloxite.** Another artificial abrasive, aloxite† consisting also principally of fused alumina, is made by an electric furnace process of Tone from aluminum silicate.

**123. Siloxicon‡** is a series of silicon-carbon-oxygen compounds of a very refractory nature, made by the process of E. G. Acheson.

**124. Metallic Silicon§** is made by the process of F. J. Tone, in which the reaction $SiO_2+2C=Si+2CO$ is used. **Silicon monoxide‖** (monox) was made by the process of Henry Noel Potter. **Silundum¶** is obtained by action of silicon on carbon and is useful as a refractory and resistor.

**125. Fused quartz** or **fused silica** or **silica-glass** articles are made in the electric furnace by smelting quartz into the desired shape, and are useful since they have such a small temperature coefficient of expansion that they can be subjected to very wide variations of temperature without danger of cracking.

**126. Bisulphide of carbon** is made from sulphur and carbon by the process of E. R. Taylor (*Electrochemical and Metallurgical Industry*, Vol. I, pp. 60, 63, 70, Vol. IV, p. 32; *Transactions* American Electrochemical Society, Vol. I and II). This is an example of an electric furnace process, the product of which is obtained in vapor form and condensed outside.

**127. Zinc** is another example of the same class. It has been made in the electric furnace commercially by the process of C. G. P. deLaval.** The chief obstacle in the commercial development of electric zinc smelting has been the difficulty of condensing the zinc vapor into liquid spelter, as almost all early experimenters have been troubled with the production of an excessive amount of blue powder. But this trouble seems now to have been overcome to a large extent. Of American experimenters W. McA. Johnson has so far gone furthest in commercial operation. Most electric zinc furnaces use carbon as reducing agent, the ore being previously roasted and preheated; the electric-furnace reaction is $ZnO+C=Zn+CO$. In the Imbert process zinc sulphide is reduced by iron as reducing agent, the reaction being $ZnS+Fe=Zn+FeS$. There is a large literature in existence on electric zinc smelting.††

**128. Phosphorus** is a third example of producing a volatile product. In the Readman-Parker process a mixture of natural phosphate, carbon and sand is treated in a resistance furnace. (*Electrochem. & Met. Ind.* Vol.

Ind.*, Vol. VI, p. 196; Cote & Pierron, Vol. VII, p. 468. Among recent papers are Johnson, *Met. & Chem. Eng'ing*, Vol. X, pp. 281, 537, Vol. XI, pp. 678; Ingalls, Vol. X, p. 481; Louvrier, Vol. X, p. 747, Vol. XI, pp. 603 and 710; Clerc, Vol. XI, p. 637. Concerning the condensation problem see *Met. & Chem. Eng'ing*, Vol. X, p. 451 (an electrolytic method of Bleecker for reduction of blue powder is described in *Transact.* Electrochem. Soc., Vol. XXI, p. 359). See also papers by Johnson, Peterson, Lyon in *Transact.* Am. Electrochem. Soc., Vol. XXIV, and chapter 12 in Stansfield's "Electric Furnace."

Digitized by Google

V, p. 407). Concerning the electric distillation of turpentine see F. T. Snyder, *Transactions* Am. Electrochem. Soc., Vol. XIII.

**129. Calcium carbide** ($CaC_2$) production is one of the largest and most important electric-furnace industries (T. L. Wilson, H. Moissan, L. M. Bullier). The reaction is

$$CaO + 3C = CaC_2 + CO, \qquad (27)$$

the furnace charge consisting of burnt lime and ground coke. The chief use of calcium carbide is the production of acetylene gas $C_2H_2$ for lighting according to the equation:

$$CaC_2 + H_2O = CaO + C_2H_2, \qquad (28)$$

acetylene gas being developed when calcium carbide comes into contact with water.* **Calcium cyanamide** is made from calcium carbide and nitrogen. See Par. **263**.

**130. The application of the electric furnace in other branches of non-ferrous metallurgy** is largely experimental.† Experiments have been made on electric smelting of copper ores,‡ nickel ores,§ and tin ores.‖

**131. Ferro-alloys,**¶ as well as other alloys, like copper-silicon, are made in the electric furnace according to the old process of A. H. Cowles, by treating a mixture of pig iron (or copper in the case of copper alloys), an oxide of the element to be alloyed with the iron (*e.g.*, silica in the case of ferrosilicon) and carbon. Various variations are possible. The production of ferro-alloys in the electric furnace is a commercial success; various alloys, especially those of high percentage and low in carbon, can only be made in the electric furnace. The usual reducing agent is carbon. But silicon or ferrosilicon or carborundum have also been proposed for the production of other ferro-alloys, free from carbon.

**132. In the steel industry**** the electric furnace is rapidly increasing in importance for three purposes. The first†† is the manufacture of high-grade steel in competition with the crucible steel process, being considerably cheaper on account of larger units and smaller wages, while the product of the electric furnace is as good as that of the crucible steel process and it is not necessary to use as pure and expensive starting materials. The second application‡‡ is a more recent one, for the refining of molten Bessemer converter metal or molten open-hearth metal for large-tonnage products, like rails of improved quality. For steel refining in the electric furnace the possibility of producing a higher temperature in the slag§§ is important, but of

---

Digitized by Google

greater importance seem the neutral or reducing atmosphere since it permits chemical reactions which are impossible in oxidising furnaces (removal of sulphur as calcium sulphide, removal of phosphorus as phosphide). The cost of refining steel in the electric furnace depends on the composition of the starting material and the degree to which the impurities are to be eliminated, but is relatively small, if the steel to be refined is supplied to the electric furnace in molten state from a Bessemer converter or open-hearth furnace. The third large application* is the use of the electric furnace for making castings. The following furnaces are employed for these three purposes on a commercial scale: Héroult (**98**), Girod (**99**), Stassano (**94**), Roechling-Rodenhauser (**103**), Groenwall†, Nathusius‡ besides some others on a smaller scale. Special smaller applications of electric furnaces in the steel industry are the melting of ferro-manganese§ and the heating of bars and billets.‖

**133. Iron reduction**¶ in the electric furnace is economical only in the localities where electric energy is cheap and fuel expensive. According to Harbord, when electrical energy is available at $10 per electric horsepower year and coke costs $7 per ton, the cost of production of pig iron in the electric furnace is approximately the same as the cost of producing it in a modern blast furnace. On the other hand the electric furnace has distinct advantages. Ores can be treated in it which could not be economically worked in the past. Ores of high-sulphur content can be made into pig iron containing only a few thousandths of a per cent. of sulphur. Titaniferous iron ores containing up to 5 per cent. can be successfully treated. The silicon content can be varied as required for the class of pig to be produced. As reducing agent it is not necessary nor advisable to employ coke, since charcoal and peat-coke can be satisfactorily used.

**134. "Pig Steel"** (a metal with 2.2 or less per cent. of carbon, a very small amount of silicon and manganese, low in sulphur and phosphorus) can be produced directly from ore in the electric furnace.** Commercial success has been obtained with iron reduction in electric shaft furnaces in Scandinavia†† and in California.‡‡

## ELECTROLYTIC PROCESSES

**135. The characteristic feature of an electrolytic process** is the chemical oxidation (or perduction) at the anode and the chemical reduction at the cathode; the anode being that electrode through which the (positive) electricity enters the electrolyte, and the cathode that electrode through which it leaves. The result of an electrolytic process is, therefore, a chemical change in the electrolyte, different products appearing at the two electrodes. The contact surfaces between the two electrodes and the electrolyte are the only places at which oxidation and reduction take place. The relation between the quantity of the chemical change and the quantity of electricity passing through the cell is given by Faraday's law as explained in **16** to **37**. Electrolytic processes essentially require direct current.

**136. The chief distinction** between electric conductors of the first class or **metallic conductors** and electric conductors of the second class or **electrolytes** is brought out if we form an electric circuit of any number of metallic conductors and electrolytes in series and see what happens at the different boundary surfaces. At the junction of two metallic conductors

Digitized by Google

there is nothing but a heat effect. At the junction of a metal and an electrolyte there is either chemical oxidation or reduction according to the direction of the current. At the junction of two electrolytes there is neither oxidation nor reduction, though there may be a chemical change (*e.g.*, at the junction of NaCl and KOH, if the current is directed from the former to the latter, there will be formation of NaOH).

**137. The most important electrolytes** for industrial applications are; first, **solutions**, and especially aqueous solutions or solutions in water, and second, **fused salts.**

**138. Cells.** An electrolyte with two electrodes represents either a **galvanic cell**, *i.e.*, an electrochemical system through which a current will be voluntarily established when the two electrodes are electrically connected through an outside circuit (in other words an electrochemical system which can be used as a source of electricity), or an **electrolytic cell**, *i.e.*, an electrochemical system through which an electric current will be established if the outside circuit connected to the two electrodes contains a sufficiently strong source of electrical energy.

**139. Galvanic cells.** In the case of a galvanic cell or battery the **energy equation** written on the basis of Thomson's rule states that the chemical energy consumed in the cell is partly lost in form of Jourlean heat within the cell ($I^2R \times$ time) the balance being available in form of electrical energy in the outside circuit between the terminals of the cell. If this energy equation, the symbols of which represent gram-equivalents, is divided by 96,540 coulombs, *i.e.*, the electric charge of 1 gram-equivalent, the voltage equation is obtained which states that the electromotive force of the cell in volts equals the loss of the volts within the cell due to internal resistance (IR), plus the voltage available at the terminals of the cell. This is correct for a monovalent change. If the change of valency is $n$, the energy equation is to be divided by $96{,}540 \times n$.

**140. Electrolytic cells.** In the case of an electrolytic cell through which electricity is forced from the outside, the energy equation states that the electrical energy impressed upon the cell at its terminals from the outside is partly changed into the chemical energy required for the chemical process in the cell and partly changed into Joulean heat ($I^2R \times$ time). In many cases, when the process requires an elevated temperature, especially in the electrolysis of fused salts, this evolution of Joulean heat serves a useful purpose, since it is the easiest way of providing the requisite high temperature (as in the Bradley "internal heating" patent of the aluminium process). The corresponding voltage equation states that the voltage impressed at the terminals of the cell from the outside equals the electromotive force required for the chemical reaction according to Thompson's rule plus the volts lost in the cell due to internal resistance.

**141. The model of migrating ions** is a picture of electrolytic phenomena. It is a dynamical model which has been found exceedingly useful to illustrate what happens in an electrolytic cell. Any electrolyte contains positive ions or cations and negative ions or anions.

**142. Typical anions** are:

(a) **monovalent** (each gram-ion carrying a negative charge of 96,540 coulombs):

| | |
|---|---|
| Br | in hydrobromic acid and bromides, |
| Cl | in hydrochloric acid and chlorides, |
| I | in hydriodic acid and iodides, |
| Fl | in hydrofluoric acid and fluorides, |
| OH | (hydroxyl ion) in hydroxides or hydrates, |

**143. Typical cations** are:
(a) **monovalent** (each gram-ion carrying a positive charge of 96,540 coulombs):
H, K, Na, Cu (in cuprous compounds), Li, Ag, Hg (in mercurous salts).
(b) **bivalent** (each gram-ion carrying a positive charge of $2\times96,540$ coulombs);
Cu (in cupric compounds), Fe (in *ferrous* compounds), Zn, Ba, Ca, Pb (in usual or plumbic salts), Cd, Co, Mg, Mn (in *manganous* salts), Ni (in *nickelous* salts), Sn (in *stannous* compounds), Hg (in *mercuric* salts).
(c) **trivalent** (each gram-ion carrying a positive charge of $3\times96,540$ coulombs):
Al, Cr (in *chromic* salts), Fe (in *ferric* compounds), Au (in *auric* salts), Mn (in *manganic* salts), Ni (in *nickelic* salts).
(d) **tetravalent** (each gram-ion carrying a positive charge of $4\times96,540$ coulombs):
Sn (in *stannic* compounds).

**144. Example.** In a solution of hydrochloric acid, HCl, in water the anions are $Cl'$ and the cations $H^{\cdot}$ and according to the picture of migrating ions free hydrogen gas is set free at the cathode and free chlorine gas is set free at the anode, because as a result of the migration of the ions in opposite directions through the electrolyte, an excess of positively charged $H^{\cdot}$ ions appears at the cathode and an excess of negatively charged $Cl'$ ions appears at the anode (while at any place inside of the electrolyte there are always the same number of $H^{\cdot}$ and $Cl'$ ions, hence no excess of positive over negative or of negative over positive ionic charges). The excess of $H^{\cdot}$ ions at the cathode gives off its positive charges to the cathode, while simultaneously the excess of $Cl'$ ions gives off its negative charges to the anode or (what is electrically the same) takes over from the anode an equal amount of positive electricity in order to neutralize the negative ionic charges. Hence, according to this view the maintenance of an electric current through an electrolyte is performed by the migrating ions which transport the electricity bodily through the electrolyte, and the chemical reduction and oxidation at the two electrodes, being essentially a discharge of the ions, is the necessary consequence of the electricity entering into the electrolyte from the anode and leaving the electrolyte into the cathode. As another example of the application of the model of ions the **electrolytic theory of the corrosion of iron** may be mentioned (Whitney, Cushman, Walker). According to this theory the surface of commercial iron and steel is not of absolutely uniform composition, on account of the presence of particles of slag, manganese oxide, etc., irregularly distributed in the iron. In contact with a solution, some spots of the iron surface will tend to become anodes and other spots cathodes, forming short-circuited galvanic cells. Iron then goes into solution from the anodic spots as ferrous ions and hydrogen ions are discharged at the cathodic spots. The fundamental primary reaction is therefore $Fe+2H^{\cdot}=Fe^{\cdot\cdot}+H_2$. The ferrous ions are then oxidized to ferric by the oxygen of the air. The loose colloidal ferric hydroxide moves toward the cathode under the influence of the current and piles up in the form of rust. (Cushman and Gardner's book on "Corrosion and Preservation of Iron and Steel.")

**145. Mobility.** In working out the above model in greater detail, a certain mobility is assigned to each ion. All the ions pass along the lines of electric force which extend through the electrolyte from one electrode to the other; and the speed with which they travel is directly proportional to the force at any point, *i.e.*, to the potential drop in volts per unit of length (or the differential quotient of the potential taken along the line of electric force through that point). The constant of proportionality is called the mobility, so that **speed of migration** of an ion equals mobility multiplied by potential drop per unit of length of electric line of force. We will designate the mobility of positive ions by $u$ and those of negative ions by $v$. (Concerning the geometrical configuration of the electric lines of force from one electrode to the other, see M. U. Schoop, *Electrochemical and Metallurgical Industry*, Vol. IV, pp. 268 and 307.)

Digitized by Google

**146. The method of determining the mobilities,** $u$ and $v$, separately consists in determining their sum and their ratio. According to Faraday's law if $q$ coulombs pass through a cell, $\frac{q}{96,540}$ positive monovalent gram-ions (or $\frac{q}{2\times 96,540}$ positive bivalent gram-ions, etc.) are concerned in the reduction at the cathode and the same number of negative gram-ions in the oxidation at the anode. According to the picture of migrating ions this means that when $q$ coulombs pass, the sum of the number of positive monovalent gram-ions passing through any imaginary cross-section of the cell toward the cathode and of the number of negative monovalent gram-ions passing through the same cross-section in the opposite direction is $\frac{q}{96,540}$.

**147. Conductivity proportional to the sum of the mobilities.** In other words, when there is a current of $i$ amperes through an electrolytic cell, the sum of the numbers of positive and negative monovalent gram-ions passing per sec. in opposite directions through any imaginary cross-section of the cell is $\frac{i}{96,540}$. This sum of the numbers of positive and negative gram-ions passing per sec. is, of course, directly proportional to the sum of their speeds or to the voltage drop per unit length of electric line of force multiplied by the sum of their mobilities. Hence, the sum of the mobilities, $u+v$, is proportional to the current in amperes divided by the voltage drop, hence proportional to the conductance and also proportional to the conductivity of the electrolyte.

**148. Constant of proportionality.** The statement that $u+v$ is proportional to the conductivity will now be supplemented by finding the constant of proportionality. For this purpose we necessarily need a further hypothesis as to the number of ions we have to assume for a given number of molecules.

**149. Equivalent ionic concentration.** Formerly it was silently assumed that in a fused salt all the molecules of the salt participate equally in the transport of electricity, while in the case of solutions the solvent (for instance, water) was assumed to be inert, and all the molecules of the solute (the dissolved salt) were assumed to participate equally in the transport of electricity. Hence for a fused salt the equivalent ionic concentration was defined as the number of positive monovalent gram-ions per c.c. = number of negative monovalent gram-ions per cu. cm. = number of gram-molecules of the fused salt multiplied by valency per cu. cm. For a solution the equivalent ionic concentration was defined as the number of positive monovalent gram-ions per cu. cm. = number of negative monovalent gram-ions per cu. cm. = number of the gram-molecules of dissolved salt per volume multiplied by valency per cu. cm.

**150. Dissociation theory.** For fused salts our conceptions have not yet been decidedly changed, while a decided change has been brought about for solutions by Arrhenius' electrolytic dissociation theory. According to him only a certain number of the dissolved salt molecules are ionised and only these are active in the transport of the electricity, while the non-ionised dissolved salt molecules, like the molecules of the solvent, are electrically inert. If we write $j$ for the ratio of the number of ionised molecules to the total number of dissolved molecules where $j$ is smaller than unity, the equivalent ionic concentration is defined as the number of positive monovalent gram-ions per cu. cm. = number of negative monovalent gram-ions per cu. cm. $= jc$, where $c$ is the number of gram-equivalents of dissolved salt per cu. cm.

**151. Universal formula for use in calculations.** We render our calculations general by using the factor $j$. For fused salts we have to make $j=1$, while for solutions we are free to take our choice. If we make $j=1$, we follow the old conception, while if we make $j$ smaller than unity we are on the basis of the electrolytic dissociation theory. For a given fused salt of uniform constitution, $c$, has a fixed value depending on the density, while for a solution $c$ is variable according to the degree of concentration. As can be easily shown, in the statement that conductivity is proportional to the sum of mobilities, the constant of proportionality has the value $96,540\,jc$. In other

Digitized by Google

words, conductivity = 96,540 $jc$ $(u+v)$. This is generally true if we accept the model of travelling ions, and is not dependent on the electrolytic dissociation theory. If we do not wish to accept the latter, we have simply to write $j = 1$.

**152. Equivalent conductivity** is defined as conductivity divided by concentration in gram-equivalents per cu. cm. It may be calculated from measurements of the conductance of a cylinder of cross-section, $a$, and length, $l$, through which the current has the direction $l$. For solutions the number of gram-equivalents per cu. cm. is a variable quantity; we may establish this experimentally by using as our cylinder a vertical rectangular trough into which we place a solution of a certain concentration which fills the trough to a certain height, and then add more and more solvent (*e.g.*, water). The length, $l$, of our cylinder remains thereby constant, while the cross-section, $a$, is varied simultaneously with the number of gram-equivalents of solute per cu. cm. The latter equals the number of dissolved gram-equivalents (which is held constant in this experiment) divided by the volume $la$ (which is varied, since $a$ is varied). Hence in this experiment the conductance of the solution in the trough equals $\frac{a}{l}$ × conductivity =

$$\frac{\text{equivalent conductivity} \times \text{dissolved gram equivalents}}{l^2} \qquad (29)$$

This equation is correct whatever may be the dimensions of the trough whose conductance is measured and whatever may be the number of gram-equivalents dissolved. In the special case, that $l = 1$ cm. and that the trough contains a solution of 1 gram-equivalent of solute in a variable quantity of water, the conductance is numerically directly equal to the equivalent conductivity. For this reason the equivalent conductivity is often defined as the conductance of a solution containing 1 gram-equivalent of the solute, when placed between parallel electrodes 1 cm. apart.

**153. Equivalent conductivity and dilution.** From very extended measurements, by F. Kohlrausch, it appears that as a general rule when a solution is gradually more and more diluted, the conductivity decreases but the equivalent conductivity increases and gets nearer a definite constant value for infinite dilution. This is clearly shown in Par. **156** which contains among other results the most recent ones obtained by Kohlrausch and which is reproduced from M. Le Blanc, W. R. Whitney and J. W. Brown's "Textbook of Electrochemistry." Doubtful values in Par. **156** are given in parentheses.

**154. Table of values of equivalent conductivities.** In Par. **156** all figures represent equivalent conductivities, *i.e.*, conductivities in mhos per cu. cm. (or described more properly in ohms$^{-1}$ cm$^{-1}$), divided by concentration in gram-equivalents per cu. cm. This table enables one to find easily the conductivity at different concentrations. For instance we want to find the conductivity of a solution of hydrochloric acid containing 1 gram-equivalent or 36.5 g. HCl per liter (about 3.6 per cent. acid). According to Par. **156** the equivalent conductivity, as just defined, is 301; the concentration is 0.001 gram-equivalent per cu. cm.; hence the conductivity is 0.301 ohms$^{-1}$ cm$^{-1}$. The conductance of 1 cu. cm., HCl, is therefore 0.301 mhos; that of 1 liter = 3.01 mhos. In both cases the volume is assumed to be in cubic form and the conductance is measured between opposite sides.

**155. Concentration.** It will be noted that in the figures of concentration given in the first column (Par. **156**) the concentration is defined in gram-equivalents per liter because this is the usual method in practice. On the other hand in the definition of equivalent conductivity we follow Kohlrausch who is responsible for the whole matter and who, in order to remain on the basis of the centimeter gram-second system defines concentration as gram-equivalents per cu. cm. This should be taken into consideration in the use of the table. A solution containing 1 gram-equivalent per liter is called a "normal" solution; a solution containing 0.1 gram-equivalent per liter is called 0.1 normal, etc.

**157. The increase of equivalent conductivity with increasing dilution** may be interpreted in different ways on the basis of the picture of migrating ions. Since conductivity $= 96{,}540\, j\, c\, (u+v)$, equivalent conductivity $= 96{,}540\, j\, (u+v)$.

First, according to the old view, all dissolved gram-equivalents participate equally in the transport of the electricity and $j = 1$; hence equivalent conductivity $= 96{,}540\ (u+v)$. Since the equivalent conductivity increases with increasing dilution, we must assume that the sum of the mobilities simultaneously increases.

Secondly, according to Arrhenius' electrolytic dissociation theory, $u$ and $v$ do not change, but the degree of ionisation $j$ changes with dilution. With increasing dilution, $j$ must be assumed to increase until for infinite dilution it reaches a certain definite value. $j$ is the ratio of the number of ionised molecules to the total number of dissolved molecules. For infinite dilution $j = 1$, *i.e.*, all molecules are ionized. The less the dilution or the higher the concentration, the smaller is $j$, *i.e.*, the smaller the degree of ionisation or the smaller the proportion of dissolved gram-equivalents which are ionised.

**158. Conductivity of electrolytes.** Concerning the measurement of the conductivity of electrolytes see Kohlrausch and Holborn's "Leitvermögen der Elektrolyte." This book contains an enormous amount of detailed information and of figures of conductivities of aqueous solutions. Concerning fused electrolytes see R. Lorenz' "Electrolyse geschmolsener Salse," 3 volumes (figures of conductivities in Vol. II).

**159. Determination of the ratio of $u$ to $v$.** From Faraday's law and

Digitized by Google

from conductivity measurements it is only possible to determine the sum $u+v$, but not $u$ or $v$ separately. This becomes possible, however, for solutions, since from the concentration changes occurring at the electrodes (besides the chemical changes of reduction and oxidation) it is possible to calculate the ratio of the mobility, $u$, of the cation to the mobility, $v$, of the anion, as was shown by Hittorf.

The ratio $v$ to $u+v$ is called the transport number or transference number $n$ of the anion, the ratio $u$ to $u+v$ is that of the cation $=1-n$. Tables of transport numbers may be found in any text-book on theoretical chemistry. They were determined experimentally from concentration changes at the electrodes. Reversely we will now show how it is possible to predict concentration changes from the knowledge of the transport numbers.

Let us assume a monovalent solution, or in case of bivalent, etc., solutions, let us consider gram-equivalents. Then if 96,540$q$ coulombs pass through the solution, there is reduction of $q$ gram-equivalents at the cathode and oxidation of $q$ gram-equivalents at the anode. Through any arbitrary cross-sectional plane in the centre of the electrolyte $nq$ gram-equivalents of the anion pass toward the anode and $(1-n)$ $q$ gram-equivalents of the cation toward the cathode. In the anode compartment, right at the anode, $q$ gram-equivalents of the anion are oxidised and form something new (what depends on the special case) and besides this there is due to ionic import and export, a gain of $nq$ anions and a loss of $(1-n)$ $q$ cations. There is, therefore, a combined effect, that of oxidation at the anode and that of ionic migration. At the cathode $q$ gram-equivalents of the cation are reduced and form something new and, besides this, there is on account of ionic import and export, a gain of $(1-n)$ $q$ cations and a loss of $nq$ anions. Here we have also the combined effect of reductions at the cathode and of ionic migration.

**160. Numerical example.** As a numerical example we will first consider the electrolysis of hydrochloric acid, HCl, with platinum electrodes, the transport number of the anion, Cl being assumed to be $n=0.2$, when 96,540 coulombs pass, 1 gram-equivalent H (1 g) is set free at the cathode and 1 gram-equivalent Cl (35.5 g.) is set free at the anode, both hydrogen and chlorine being set free as gases. From Par. 159 we see that 0.2 gram-equivalent HCl (7.3 g.) are lost at the cathode and 0.8 gram-equivalent HCl (29.2 g.) are lost at the anode. The whole phenomenon is this: 36.5 g. of HCl disappear by decomposition and the solution becomes diluted both at anode and cathode, but more quickly at the anode. The decomposed 36.5 g. HCl appear in form of 35.5 g. Cl gas at the anode and 1 g. H gas at the cathode.

The safest way in any case is to write down the equation of the whole process, interpret it by the picture of migrating ions, divide the cell arbitrarily into two compartments by a cross-section and calculate separately what happens in the anode and cathode compartments. In the foregoing example, when 96,540 coulombs pass, 0.2 gram-ion Cl passes our arbitrary cross-sectional plane in the direction to the anode and 0.8 gram-ion H in the direction to the cathode. Hence in the anode compartment we have

loss, by setting free as gas, of 1 gram-atom Cl,
loss, by ionic export to cathode compartment, of 0.8 gram-ion, H,
gain by ionic import from cathode compartment of 0.2 gram-ion Cl.

Hence the total result in the anode compartment is the evolution of 1 gram-atom = 35.5 g. Cl and a loss, from the solution, of 0.8 gram-molecule HCl (29 g.). This is the same result as above.

**161. As another example** we give the electrolysis of an aqueous solution of common salt, NaCl, with an inert anode and inert cathode, such as used in a diaphragm cell. When 96,540 coulombs pass, the reaction is represented by the following equation, all symbols representing atoms:

$$NaCl + H_2O = \underbrace{Cl}_{\text{at anode}} + \underbrace{NaOH + H}_{\text{at cathode}} \qquad (30)$$

If we take the transport number of the Cl ion in NaCl as 0.6, then during the passage of 96,540 coulombs there passes 0.6 Cl gram-ion through any arbitrary cross-section toward the anode and 0.4 Na gram-ion toward the cathode. In the anode compartment we have, therefore;

| | |
|---|---|
| loss, by gas evolution at anode, of | 1 gram-ion Cl, |
| gain, by ionic import from cathode compartment, of | 0.6 gram-ion Cl, |
| loss, by ionic export into cathode compartment, of | 0.4 gram-ion Na. |

Digitized by Google

The net result in the anode compartment is the setting free of 1 gram-atom Cl gas and the loss in solution of 0.4 gram-molecule NaCl.

In the cathode compartment we have;

loss, by gas evolution at cathode, of 1 gram-ion H,
loss, by ionic export to anode compartment, of 0.6 gram-ion Cl,
gain, by ionic import from anode compartment, of 0.4 gram-ion Na,
gain, by chemical formation of NaOH of 1 gram-ion OH,
loss, by the same reaction, of 1 gram-molecule $H_2O$.

The net result in the cathode compartment is the setting free of 1 gram-atom H gas, the loss in solution of 1 gram-molecule of water, while the solute NaCl has now been changed into a mixture of NaCl and NaOH since the positive ions have been increased by 0.4 Na gram-ions, while the negative ions have gained 1 OH gram-ion and lost 0.6 Cl gram-ion. This latter change we may chemically express in the statement that 0.6 gram molecule NaCl have disappeared and 1 gram-molecule NaOH has been formed. (For a somewhat different and more detailed discussion of this reaction see W. H. Walker, *Transactions* American Electrochemical Society, Vol. III, p. 177.)

**164. Electrolysis may change the original electrochemical system.** This last fact is of great importance for many electrolytic processes. It emphasises the fact that electrolysis may change the original electrochemical system. In the present case we have no longer a pure NaCl solution at the cathode, since it is now mixed with NaOH, i.e., it contains $Na^{\cdot}$ and $OH'$ ions, and the $OH'$ ions will begin to travel toward the anode together with the $Cl'$ ions and make trouble there.

**165. Determination of the mobilities, $u$ and $v$, separately.** From $u+v$ as determined by equivalent conductivity measurements, and from $u+v$ as found from Hittorf's transport numbers, Kohlrausch calculated the mobilities, $u$ and $v$, separately. For infinitely dilute solutions he found the following important law: Any ion of a given chemical nature has a certain distinct mobility which is always the same whatever may be the other ions which are with it in solution; that is, for instance, the mobility, $u$, of Na in NaCl has the same value as in NaOH, etc. This is **Kohlrausch's law of the independent migration of the ions**, which foreshadowed to a certain extent the electrolytic dissociation theory. In Par. **162** the latest values of the migration velocities, $u$, of cations are given, in Par. **163**, those of anions together with their temperature coefficient. The figures under $u_{18}$ and $v_{18}$ relate to temperature of 18° C. For a temperature $t$, not very far from 18 deg. cent., the mobility is,

$$u_t = u_{18}\,[1+\alpha(t-18)+\beta(t-18)^2]. \qquad (31)$$

The table of ionic mobilities is often useful for determining the transport numbers

$$n = \frac{v}{u+v} \text{ and } 1-n = \frac{u}{u+v} \qquad (32)$$

but it must be taken into consideration that the values $u$ and $v$, in Par. **162** and **163** relate to infinitely dilute solutions. Anyway, they offer a means for approximately finding or checking transport numbers in many cases.

**166. Electrochemical Equivalents of Ions**

| Anions | Milligrams per coulomb | Grams per ampere-hour | Cations | Milligrams per coulomb | Grams per ampere-hour |
|---|---|---|---|---|---|

**167. Electric endosmosis.** Since the above reaction is that of the so-called diaphragm processes of brine electrolysis, it should be mentioned here that the introduction of a diaphragm into an electrolytic cell involves a further complication since it causes the phenomenon of electric endosmosis. Solution is bodily carried through the diaphragm, the amount depending on the nature of the diaphragm. This phenomenon may upset all results of calculation of concentration changes from the transport numbers of ions. This phenomenon is the reverse of the migration of colloids in solutions under the action of a current. The colloids correspond to the diaphragm in our former case, but the colloids are movable, while in our former case the diaphragm was fixed. Hence in our former case the liquid will be displaced with respect to the diaphragm. In the latter case the colloids move with respect to the stationary liquid.

**168. Short-cut calculations of electrochemical reactions.** It is strongly recommended to proceed in the way outlined above in making all calculations on electrochemical reactions; since in this way not only all questions as to details of the reaction are answered, but a clear picture of the mechanism of the reaction is obtained. With ordinary care it is then almost impossible to make a mistake. Nevertheless, for checking results thus obtained or for quick preliminary calculations, tables of electrochemical equivalents are found useful. We give two of them: Par. **166** referring to the electrochemical equivalents of all ordinary ions, Par. **170** to **172** to the electrochemical equivalents of the elements.

From Par. **166** one can find immediately by simple addition for most compounds of ordinary practice the **quantity of material involved in electrolysis.** For instance, for the reaction of sodium chloride electrolysis in a diaphragm cell

$$NaCl + H_2O = NaOH + Cl + H, \qquad (33)$$

we find directly from the table that 1 amp-hr. produces 0.03759 g. H and 1.322 g. Cl. We can further find the quantity of NaCl decomposed per ampere-hour, by adding the figures 0.860 (Na) and 1.322 (Cl), which gives 2.182 grams NaCl. In the same way the quantity NaOH formed per ampere-hour is found by adding 0.860 (Na) and 0.634 (OH), which gives 1.494 g. NaOH.

**An important precaution** which one has to take in the use of this table, is to **select** the ion of the **proper valency.** Thus it will be seen that figures are given for the monovalent $Cu^{\cdot}$ and for the bivalent $Cu^{\cdot\cdot}$ ion. In case of the bivalent compound $CuSO_4$, for instance, one has to select the figure for $Cu^{\cdot\cdot}$ and finds the quantity of $CuSO_4$, decomposed per hr. $= 1.186 + 1.791 = 2.977$ g. (Concerning the necessity of using this table cautiously and judiciously, see also Par. **169.**)

Par. **170** to **172** are tables of electrochemical equivalents of elements and answers directly the question as to the **quantity of the element oxidized at the anode or reduced at the cathode.** Since oxidation and reduction are special cases of change of valency, column 4 is headed "change of valency," as this covers the most general case. In the special case that a metal is deposited from a solution or that a gas is evolved at an electrode, it is to be considered that the metal or the gas has no bonds in the free elementary state, so that in this case the change of valency is equal to the valency in the compound. For instance, in the reduction of Cu from $CuCl_2$ the change of valency is 1, while in the reduction of Cu from $CuSO_4$, it is 2.

In column 4 those changes of valency are given which are most likely to occur in practice. Thus, for iron, Fe, the figures are given for the changes of valency 1, 2, 3. In the reduction of a ferric salt to a ferrous salt the change of valency is 1; in the reduction of a ferric salt to metallic iron it is 3; in the reduction of a ferrous salt to metallic iron it is 2. But for every element the figures are also given for the indefinite change of valency, $n$, so as to cover any possible case which may ever arise in practice. To give an example of the application of this table, let us assume that in the Bunsen cell nitric acid, $HNO_3$, is all reduced to nitric oxide, NO, and let us calculate the quantity of nitric acid thus consumed per ampere-hour. Since the valency of N is 5 in $HNO_3$ and 2 in NO, the change of valency of N is 3. From the table we find directly that for this change of valency 0.174 g. of N are involved in the reduction per ampere-hour. The amount of $HNO_3$ consumed and of NO produced is then found by the ordinary chemical method. The atomic weight of N is 14, the molecular weight of $HNO_3$ is $1+14+3\times16=63$, the

Digitized by Google

molecular weight of NO is $14+16=30$. Hence $63\times0.174\div14=0.78$ g. $HNO_3$ is reduced and $30\times0.174\div14=0.37$ g. NO is produced per ampere-hour. (A similar very elaborate table, but not covering all elements, is given by Carl Hering in *Electrochemical Industry*, Vol. I (1903), p. 170.

**169. Example.** The Bunsen-cell example in Par. **168** is an instructive example showing the precaution which must be taken in using the table in Par. **166** of the electrochemical equivalents of ions. If it is desired to find the grams of $HNO_3$ per ampere-hour, involved in the reaction of the Bunsen cells as sketched above, and if one would use directly, the figures 0.03759 for H and 2,312 for $NO_3$ the result would be 2.35 g. $HNO_3$ which is just three times the correct value found in (**168**). The reason for the mistake is evident if we write down the whole equation of the reaction

$$3Zn+3H_2SO_4+2HNO_3=3ZnSO_4+2NO+4H_2O, \qquad (34)$$

which shows that $2HNO_3$ are involved in the passage of $6\times96,540$ coulombs. If, therefore, anybody makes a mistake by injudicious use of the table, the table should not be blamed.

**171. Basis of tables** (Par. **170**). All the figures in our tables have been calculated on the basis of the atomic weight determinations (table of International Committee for 1907) and on the basis of the value 1.1180 mg. per coulomb for the electrochemical equivalent of silver, which value was adopted by the International Electrical Congress in Chicago in 1893. (They have not been recalculated for the changes in the international table of atomic weights since 1907, since the changes would be too small to be of practical importance.)

**172. Conversion ratios for electrochemical calculations.** To find **milligrams per ampere-second**, divide grams per ampere-hour (column 5) by 3.6.

Digitized by Google

To find **ampere-seconds per milligram** multiply ampere-hours per gram (column 6) by 3.6.

To find **grams per watt-hour** or **kilograms per kilowatt-hour**, divide grams per ampere-hour (column 5) by volts.

To find **watt-hours per gram** or **kilowatt-hours per kilogram**, multiply ampere-hours per gram (column 6) by volts.

To find **kilograms per horsepower-hour**, multiply grams per ampere-hour (column 5) by 0.74565 (about $\frac{3}{4}$) and divide by volts.

To find **horsepower-hours per kilogram**, multiply ampere-hours per gram (column 6) by 1.3411 (about $\frac{4}{3}$) and by volts.

To find **kilograms per electric horsepower-year**, multiply grams per ampere-hour (column 5) by 6,532 and divide by volts.

## THE E.M.F. OF ELECTROLYTIC REACTION

**173. E.m.f. and terminal voltage.** We have before explained that it is necessary to distinguish clearly between the voltage at the terminals of an electrolytic cell, and the e.m.f. of the electrolytic process proper (Par. **140**). We have also shown how to calculate approximately the latter e.m.f. by means of Thomson's rule from the total energy of reaction, while it should strictly be calculated from the free energy of reaction (Par. **58**). The easiest method to determine the latter, however, is by measurements of potential.

**174. Single potentials of elements** are determined against normal electrodes or standard electrodes. The most usual normal electrodes are the **hydrogen electrode** (platinized platinum, saturated and covered with hydrogen gas, in an acid solution of normal concentration of the hydrogen ions), and the **calomel electrode** (mercury covered with calomel, HgCl, in contact with a normal KCl solution). In order to have a zero point in the potential series of elements, Nernst proposes to make the potential of hydrogen zero. On this supposition the calomel electrode has the potential −0.283; in other words if we form a cell of a calomel electrode and a hydrogen electrode, it has the e.m.f. −0.283, the current in the cell being directed from the latter to the former. On the basis of a theory of Helmholtz on the surface tension of polarized mercury, Ostwald has endeavored to determine "absolute potentials;" in the absolute series the hydrogen electrode has the absolute potential −0.277 volt and the calomel electrode the absolute potential −0.560 volt. But this theory is very doubtful.

**175. Potential of Various Elements in Order of Their Nobility**

| | Potential against hydrogen electrode | Absolute potential |
|---|---|---|
| Mn | +1.075 volt | +0.798 volt |
| Zn | +0.770 | +0.493 |
| Cd | +0.420 | +0.143 |
| Fe | +0.344 (0.660) | +0.067 (+0.383) |
| Tl | +0.322 | +0.045 |
| Co | +0.232 (0.450) | −0.045 (+0.173) |
| Ni | +0.228 (0.600) | −0.049 (+0.323) |
| Pb | +0.151 (0.148) | −0.126 (−0.129) |
| H | ±0.0 (by definition) | −0.277 |
| Cu | −0.329 | −0.606 |
| Hg | −0.753 (0.750) | −1.030 (−1.027) |
| Ag | −0.771 (0.798) | −1.048 (−1.075) |
| Cl | −1.353 (1.400) | −1.630 (−1.677) |
| Br | −0.993 (1.095) | −1.270 (−1.372) |
| I | −0.520 (0.628) | −0.797 (−0.905) |

**176. Order of nobility of elements.** The table in Par. **175** gives in the first column the series of elements in the order of their nobility; those above H are called less noble than H, those below H are called more noble than H. A less noble metal passes into solution when in contact with hydrogen ions, a more noble metal is not attacked. The second and third columns give the potentials of the elements in a normal solution of one of their salts, for instance, silver in a silver salt solution. In the second column Nernst's

Digitized by Google

zero point of the potential of hydrogen is used; *i.e.*, the figures give directly the potentials of the different elements against the hydrogen electrode. The third column gives the absolute potentials. The figures in the second column are given from H. Danneel and E. S. Merriam's "Electrochemistry;" where Le Blanc, Whitney and Brown in their "Handbook of Electrochemistry" (1907) give different values, the latter are added in parenthesis. The voltage of the calomel electrode is 0.283 in the scale of the second column and 0.56 in the third column.

### 177. The Decomposition Voltage of Various Solutions

(Determined experimentally, chiefly for normal solutions, by Le Blanc and others)

| Acids | | Salts | |
|---|---|---|---|
| Sulphuric | = 1.67 volts | Potassium hydrate | = 1.67 volts |
| Nitric | = 1.69 volts | Ammonium hydrate | = 1.74 volts |
| Phosphoric | = 1.70 volts | 0.25 *n* Methylamine | = 1.75 volts |
| Monochloracetic | = 1.72 volts | 0.50 *n* Diethylamine | = 1.68 volts |
| Dichloracetic | = 1.66 volts | 0.125 *n* Tetramethylammonium hydrate | = 1.74 volts |
| Malonic | = 1.69 volts | | |
| Perichloric | = 1.65 volts | | |
| Dextrotartaric | = 1.62 volts | Zinc sulphate | = 2.35 volts |
| Pyrotartaric | = 1.57 volts | Zinc bromide | = 1.80 volts |
| Trichloracetic | = 1.51 volts | Nickelous sulphate | = 2.09 volts |
| Hydrochloric | = 1.31 volts | Nickelous chloride | = 1.85 volts |
| Hydrazoic | = 1.29 volts | Lead nitrate | = 1.52 volts |
| Oxalic | = 0.95 volts | Silver nitrate | = 0.70 volts |
| Hydrobromic | = 0.94 volts | Cadmium nitrate | = 1.98 volts |
| Hydriodic | = 0.52 volts | Cadmium sulphate | = 2.03 volts |
| | | Cadmium chloride | = 1.88 volts |
| **Bases** | | Cobaltous sulphate | = 1.92 volts |
| Sodium hydrate | = 1.69 volts | Cobaltous chloride | = 1.78 volts |

**178. Overvoltage.** In determining the decomposition voltage of a solution, which yields gas at an electrode, the peculiar phenomenon is observed that the decomposition voltage depends on the chemical nature of the electrode at which the gas is evolved. Thus hydrogen gas is most easily developed at a platinised platinum electrode while a higher voltage is required at other metals; for instance to evolve hydrogen gas at a zinc electrode, an excess of 0.70 volt is required over the voltage required to evolve hydrogen at a platinised platinum electrode; 0.70 is called the excess voltage or "overvoltage" (Überspannung) of hydrogen at a zinc electrode.

### 179. The Overvoltage of Hydrogen and Oxygen at Different Electrodes

| Overvoltage of hydrogen | | Overvoltage of oxygen | |
|---|---|---|---|
| Metal | Potential | Metal | Potential |
| Pt platinized | 0.00 volt | Au | 1.75 volts |
| Au | 0.01 | Pt polished | 1.67 |
| Fe in NaOH | 0.08 | Pd | 1.65 |
| Pt polished | 0.09 | Cd | 1.65 |
| Ag | 0.15 | Ag | 1.63 |
| Ni | 0.21 | Pb | 1.53 |
| Cu | 0.23 | Cu | 1.48 |
| Pd | 0.46 | Fe | 1.47 |
| Sn | 0.53 | Pt platinized | 1.47 |
| Pb | 0.64 | Co | 1.36 |
| Zn | 0.70 | Ni polished | 1.35 |
| Hg | 0.78 | Ni sponge | 1.28 |

**180. Thermo-chemical constants.** Since Thomson's rule (Par. 88) enables one to find the e.m.f. of an electrolytic process from the total energy of the reaction—at least as a first approximation, but with sufficient accuracy for most practical purposes—the tables in Par. 181 to 183—of voltages calculated from thermochemical data should be found useful. They are reproduced from a paper of J. W. Richards in *Journal* of the Franklin Institute, February and March, 1906. The great convenience in the use of

Digitized by Google

these tables rests in giving the "thermochemical constants" and the corresponding voltages separately for the basic elements and the acid elements and acid radicals. This separation of the two constituents of a salt in solution is possible on account of the experimental fact that taking the heats of formation of salts plus their heat of solution in excess of water (usually called "heat of formation to dilute solution"), these quantities are found to be additive in their nature, such being composed of the sum of two quantities, one characteristic once for all of the base, in all its combinations, and the other being characteristic once for all of the acid radical, in all of its combinations. There is thus for each basic element a thermochemical constant, which represents the amount of heat it contributes to the formation-heat of a salt, the latter taken in dilute solution; and for each acid radical a similar thermochemical constant, representing in a similar manner the part which it contributes; the sum of these two thermochemical constants is the formation heat of the salt, from its elements, to dilute solution. The thermochemical constant is nothing more nor less, in the case of a base, than energy drop which represents the decrease of energy in the element as it passes from the free, uncombined state into the dissolved (ionic) state in dilute solution; in the case of an acid element, the statement is entirely similar; in the case of an acid (or basic) radical, it is the total energy drop from free elements to the ionic state as a radical.

The arbitrary basis selected to which to refer these thermochemical constants is that of hydrogen constant equal to zero. This makes the thermochemical constant of every basic element the heat evolved when it displaces hydrogen from a dilute solution of acid; and that of an acid element or radical the heat of formation of the acid in dilute solution.

The "corresponding voltages" given are therefore those which according to Thomson's rule should be found against a "hydrogen electrode." The figures may therefore be compared with the table in Par. **175** of voltages of various metals against a hydrogen electrode. The difference between the values of the two tables correspond to the differences in the free energy and the total energy. For many elements the agreement is quite good. Thus for Zn the voltage corresponding to the free energy is 0.770, that corresponding to the total energy is 0.75.

**181. Thermochemical Constants of Basic Elements per Chemical Equivalent and Corresponding e.m.f.**

(J. W. RICHARDS)

| | Calories | Volts | | Calories | Volts |
|---|---|---|---|---|---|
| Li | +62,900 | +2.73 | Cd | 9,000 | 0.36 |
| Rb | 62,000 | 2.69 | Co | 8,200 | 0.36 |
| K | 61,900 | 2.69 | Ni | 7,700 | 0.33 |
| Ba | 59,950 | 2.60 | Fe (ferric) | 3,230 | 0.14 |
| Sr | 58,700 | 2.55 | Sn | 1,900 | 0.08 |
| Na | 57,200 | 2.48 | Pb | 400 | 0.02 |
| Ca | 54,400 | 2.36 | H | 0 | 0 |
| Mg | 54,300 | 2.36 | Tl | − 900 | −0.04 |
| Al | 40,100 | 1.74 | Cu | − 7,900 | −0.34 |
| (N+H$_4$) | 33,400 | 1.45 | Hg | −14,250 | −0.62 |
| Mn | 24,900 | 1.08 | Pt | −19,450 | −0.84 |
| Zn | 17,200 | 0.75 | Ag | −25,200 | −1.10 |
| Fe (ferrous) | 10,900 | 0.47 | Au | −30,300 | −1.32 |

The thermochemical constants in Dr. Richards' table are given in every case for *one* chemical equivalent and not for the number of equivalents which are designated by the number of dots (positive bonds) or strokes (negative bonds). In using these tables, it must be borne in mind that the sum of the thermochemical constants for the basic and acid constituents of any salts, gives the heat of formation of the salt from the constituent chemical elements, in dilute solution. Conversely, the heat of formation thus obtained is the energy necessary to separate the salt in dilute solution into its constituent chemical elements. The sum of the voltages, corresponding to this amount of chemical energy, is the voltage necessary to decompose the salt in solution into its constituents, free chemical elements. If these elements re-combine in the process of decomposition to form other chemical compounds, then the whole chemical reaction must be taken into

Digitized by Google

account, and when this is expressed in calories per chemical equivalent concerned, the necessary voltage for producing the change is obtained by multiplying this by 0.0000434.

**182. Thermochemical Constants of Acid Radicals**
From their elements (J. W. RICHARDS)

| Constituents | | Radical | Per chemical equivalent (calories) | Corresponding e.m.f. (volts) | Salts |

## INDUSTRIAL ELECTROLYTIC PROCESSES

**184. Electroanalysis.** As to electroanalysis reference should be had to the book of Edgar F. Smith or to that by A. Classen. The chief reason why electroanalytical methods have found introduction into industrial laboratories is the great ease and the very considerable reduction in time required for an analysis as a consequence of recent improvements mainly due to E. F. Smith and his school. The chief features of these improvements are the use of a rotating anode and of a mercury cathode. The mercury cathode absorbs the metal of the salt solution which is electrolysed. The anode is generally made of such a substance as to absorb the anion. The anode is rapidly revolved to provide such a circulation of the electrolyte that a high current density may be used with a corresponding reduction in the duration of an analysis. Concerning rapid methods of electroanalysis see the latest edition of Smith's "Electroanalysis."

**185. Electrotyping.** The object of electrotyping is to reproduce printers set-up type, engravings, medals, etc. A mould of the object to be reproduced is first made, for instance of wax, by impressing the object in wax. If the mould is a non-conductor of electricity, as in the case of wax, its surface is made conducting by giving it, with a brush, a coating of plumbago (graphite). (Instead of a plumbago coating, the mould may receive a metallic coating, for instance of copper as follows: Pour copper sulphate solution over the surface of the mould and dust on it from a pepper-box very finely divided iron filings, brushing the mixture over the surface.) By suitable electrical connections of clamps or wire to the surface of the mould the latter is then made cathode in an electroplating bath, which is made up by preparing an 8 to 10 per cent. solution of sulphuric acid in water and dissolving in it copper sulphate until the resulting solution is saturated at ordinary temperatures. The solution is maintained saturated by adding some crystals of copper sulphate, or by using a copper anode. In the case of reproducing type matter, always two cases containing prepared moulds are suspended back to back between two large copper anodes so that the conducting surfaces of the moulds directly face the anodes. The thickness of the copper deposit depends on the product of current (in amperes) and time; a certain circulation of the electrolyte is useful for the same reasons as in electroplating (see below). The copper shell is then separated from the mould on which it is deposited, and in order to give it the necessary strength for further use it is backed with type-metal.*

## ELECTROPLATING

**186. General principles of electroplating.** The object which is to receive a coating of a metal, is employed as cathode in a solution of a salt of this metal. The anode may either be soluble and consist of the same metal or it may be inert; the object of the former arrangement is to get as much metal dissolved from the anode as is deposited upon the cathode

* Description of a modern electrotyping plant in *Met. & Chem. Eng'ing*, Vol. X, p. 442.

Digitized by Google

during the plating process; on the other hand, if an inert anode is used it is necessary to regenerate the solution and add new material in some form to the solution at intervals during operation in order to make up for the metal lost by deposition on the cathode.

In an electroplating bath in which the anode consists of the same metal as that which is plated out on the cathode, the electrochemical reaction at the cathode is the reverse of that at the anode, so that no e.m.f. is required to bring this reaction about (if we neglect the very small e.m.f. required to overcome the concentration differences which establish themselves in the cell). The e.m.f. applied at the terminals of the cell is therefore lost by overcoming the ohmic resistance, and equals current multiplied by internal resistance of the cell. In case an inert anode is used, for instance a platinum anode in a copper sulphate solution for copper plating, oxygen is evolved and sulphuric acid is formed at the anode while the copper is plated out on the cathode. The anodic reaction is therefore not the reverse of the cathodic reaction and a certain e.m.f. is required to bring about the reaction. The voltage applied at the electrodes equals in this case the voltage required to overcome the ohmic resistance of the cell plus the decomposition voltage of the solution. The ohmic loss of voltage should always be made as small as possible, while the decomposition voltage of any solution is also always relatively small, never more than a few volts (see Par. 177). As a consequence of this it is clear that the voltage at the electrodes of a plating cell must be relatively low; it is in practice generally between a fraction of 1 volt and 6 volts. For this reason **dynamos for electroplating purposes** are low-voltage dynamos. It is, of course, possible and it is quite usual to connect a number of cells in series; in this case the value of the current is the same through all cells in series, while the voltage is the same at the electrodes of the different cells only if the resistance of all cells is the same. In all cases a voltmeter and ammeter should be used by the electroplater so that he always knows exactly the electrical condition of his cells and can regulate them accordingly. Some kind of a rheostat is needed for this purpose.

What the electroplater pays for in paying his electricity bills or in renewing his batteries, is the number of kilowatt-hours consumed. The amount of work performed, *i.e.*, the weight of metal plated out, depends on the other hand, solely on the ampere-hours (for figures see Par. 170, table of electrochemical equivalents). Hence the old saying that for electroplating (and electrolytic work in general) electrical energy consists of two factors, of which one, the volts, costs money and the other, the ampere-hours, brings money.

**187. The only way to reduce the voltage at the electrodes** of a plating tank is to reduce the internal resistance. This may be accomplished by increasing the conductivity of the plating bath by suitable additions of high-conductivity electrolytes. It may also be accomplished to a certain extent by placing the anodes very near the articles to be plated. But this should not be overdone, at least when the articles to be plated are in a fixed stationary position, since it is important to get a uniform deposit over the whole surface. For this purpose the density of the electric lines of force should be as uniform as possible over the whole surface, and this condition will be the more fulfilled the further the anode is away from the article to be plated. This precaution is especially necessary when the surface of the article is uneven and irregular and has projecting points.

**188. In case a great many small articles are plated simultaneously** in one plating tank, the arrangement is generally made to have the articles in continuous motion, so that they tumble over each other and present successively all parts of their surfaces to the electroplating action of the current.

**189. Current density at the cathode.** The higher the cathodic current density, the greater the total current for an article of given surface and therefore the shorter the time to produce a given weight of deposit on this surface. The output of a plating shop is therefore the greater, the higher the current density. A limit is set to the incease of current density by the fact that by the metal being plated out onto the article under treatment, the solution becomes more and more diluted right at the surface to be plated, and with the decrease of the number of the metal ions at this surface the danger increases that instead of the desired metal something else (for instance

Digitized by Google

hydrogen) is plated out. The exact calculation of the decrease of concentration at the cathode resulting from the passage of a certain number of ampere-hours, for copper-plating with copper anodes and a sulphate solution was given before in the discussion of Hittorf's transport numbers. In any case, the higher the current density the quicker is the loss from the solution at the cathode of the metal ions to be plated out and the smaller is the chance for diffusion and convection currents to bring fresh concentrated solution to the cathode surface where it is needed. The higher the current density, the greater is, therefore, the importance of artificial circulation or stirring; for this purpose either one or both electrodes may be revolved or a special stirring device may be employed in the solution. It seems, for instance, that with a smooth copper, zinc or nickel cathode, a good copper, zinc or nickel deposit can be obtained, however high the current density may be raised, if only the cathode is revolved at an increasing and sufficiently high speed. Heating also aids circulation.

**190. Junction between the metals.** In contradistinction to electrotyping it is very important in electroplating to get a deposit which will stick to the metal on which it is plated. There must be an intimate junction between the two metals and, according to L. Kahlenberg (*Electrochemical Industry*, Vol. I, p. 201), this requires that the two metals form an alloy together. Thus nickel may be successfully plated on copper and its alloys (brass, bronze, etc.), since with these nickel alloys readily. On the other hand, if an object of lead is to be nickeled, it is first copper plated and then the nickel is deposited on the copper because copper alloys better with lead than does nickel.

**191. In order to make the deposit stick** to the metal underneath, it is also of fundamental importance that the surface metal before being plated is carefully cleaned both mechanically and chemically, and that all traces of fat and oil, etc., are thoroughly removed. To remove grease, a caustic soda solution or a caustic potash solution is suitable, the latter being preferable. Acid solutions for cleaning gold, silver, copper, brass and zinc surfaces are being recommended by Trevert as follows:

| | Copper | Zinc | Silver | Iron |
|---|---|---|---|---|
| Water | 100 | 100 | 100 | 100 |
| Nitric acid | 50 | — | 10 | 2 to 3 |
| Sulphuric acid | 100 | 10 | — | 8 to 12 |
| Hydrochloric acid | 2 | — | — | 2 to 3 |

**192. The plating bath** contains principally the salt of the metal which is to be plated out, together with the addition of a solution of high conductivity, so as to reduce the voltage drop. However, other additions have also been found useful, for the following reasons: At moderate current densities a bad deposit is practically always due to the precipitation of a non-metallic solid with the metal, especially of an oxide, hydroxide or basic salt of the metal. Whatever will dissolve the oxide, etc., readily under the conditions of the operation will prevent its deposition and should therefore improve the quality of the deposit. W. D. Bancroft ("Transactions International Electrical Congress," St. Louis, Vol. II, p. 27, and *Transactions* American Electrochemical Society, Vol. VI) shows that a large majority of the more important additions recommended for various plating baths act in the way just described.

**193. Securing fine-grained deposits.** It seems that a fine-grained deposit is favored by high-current density and potential difference, by acidity and alkalinity and by low temperatures. Solutions containing oxidizing agents appear to yield small crystals while larger crystals are obtained from solutions containing reducing agents.

**194. To prevent the formation of "trees"** a very small addition of a colloid has been found useful in several cases. In the deposition of lead from a solution of lead-fluosilicate, containing an excess of fluosilicic acid, A. G. Betts found that the formation of trees and the deposition of spongy lead could be completely avoided and the deposition of perfectly solid and dense lead could be assured by the simple addition of a very small amount of gelatine or glue added to the bath. Similar observations have been made with silver and copper. The general rule seems to be that

Digitized by Google

the addition of a very small amount of such a colloid, which, under the action of the current, migrates toward the cathode, improves the uniformity and density of the deposit.*

**195. Practical rules for electroplating.** A tentative and very useful theory of the chemical principles which underlie electroplating has been given in the paper by W. D. Bancroft quoted above. Other suggestive hypotheses have been presented by A. G. Betts.† Bancroft has given the following "axioms of electroplating:" (*a*) Bad deposits are due to excessive admixture of some compound or to excessively large crystals; (*b*) excessive admixture of any compound can be eliminated by changing the conditions so that the compound cannot precipitate; (*c*) increasing the current density, increasing the potential difference at the cathode, or lowering the temperature, decreases the size of the crystals; (*d*) the crystal size is decreased when there are present at the cathode surface, substances which are absorbed by the deposited metal; (*e*) if a given solution will give a good deposit at any current density, it will give a good deposit at any higher current density, provided the conditions at the cathode surface are kept constant; (*f*) treeing is facilitated by a high potential drop through the solution and by conditions favorable to the formation of large crystals.

**196. For detailed prescriptions of solutions,‡** etc., the reader must be referred to special handbooks for electroplaters, like Watt's and Philip's "Electroplating and Electrorefining of Metals," or the smaller books of van Horne and others. In the following a brief account only is given of some solutions in most common use.

**197. Nickel plating.§** The nickel salt, generally used for nickel plating, is nickel ammonium sulphate. For small baths the salt is dissolved by boiling 12 to 14 oz. of the salt per gallon of water in a new stone jar and filling up the bath with water until a hydrometer placed in it stands at 6.5 deg to 7 deg. Beaumé. The solution should be slightly acid, but too much acid will cause peeling and too much alkali will darken the tone of the work according to van Horne. He recommends the following current density. For plating zinc with nickel, use 0.05 to 0.10 amp. per sq. in. of the surface of the object to be plated; for plating nickel on other metals use half this current density. To improve the quality of the nickel deposit, certain additions to the bath have been recommended. J. Powell recommends the addition of 0.125 oz. of benzoic acid per gallon of solution. E. Weston recommends a solution containing 10 parts nickel ammonium sulphate, 2.5 to 5 parts of boracic acid and 150 to 200 parts of water. Boracic acid is now much employed as an addition. According to F. Foerster, a good deposit of nickel is obtained from its sulphate solution, containing some slight amount of free citric acid or boracic acid, with a current density of 0.005 amp. per sq. cm. A very suitable nickel bath is obtained by dissolving 50 g. of nickel sulphate crystals so as to get one-half liter solution; 20 g. citric acid are then dissolved in water and neutralized by means of caustic soda to such a degree that blue litmus paper is just colored red, and the solution is then diluted to get one-half liter; this is then added to the nickel sulphate solution; this bath requires about 3 volts. There is no danger that the nickel deposit will peel off, as long as the thickness of the deposit thus produced is below 0.01 mm. Thicker deposits may be obtained from neutral or slightly acid nickel sulphate solutions, heated to 70 or 90 deg. cent. (F. Foerster, *Zeit. f. Elektrochemie*, Vol. IV, p. 160). If a more concentrated solution is used (containing 150 to 350 g. of nickel sulphate per liter and preferably also some sodium sulphate) the current

† *Transact.* Am. Electrochem. Soc., Vol. VIII, p. 63.

‡ An excellent set of papers summarising all the different solutions proposed and used for plating with gold, silver, cobalt, nickel, lead, tin, copper, brass and bronze may be found in Vol. XXIII of the *Transact.* Am. Electrochem. Soc.

§ A very extended summary of all solutions proposed and used for electroplating with nickel and cobalt is given in a paper by O. P. Watts in *Transact.* Am. Electrochem. Soc., Vol. XXIII, p. 99.

Digitized by Google

density may be raised to 0.02 to 0.08 amp. per sq. cm. and with moderate circulation of the electrolyte good deposits 1 mm. thick may be obtained.

**198. Difficulties in nickel plating.** A difficulty in nickel plating was formerly found in the fact that the nickel anodes do not dissolve freely in the nickel-ammonium sulphate solution. Cast nickel anodes are said to dissolve better than rolled nickel anodes. For the same reason it is important to use as large a surface of nickel anodes as possible. This has led to the introduction of corrugated anodes, etc., and it has been recommended to make the nickel anode surface $\frac{1}{3}$ times the surface to be plated. W. D. Bancroft has recently suggested (*Transactions* American Electrochemical Society, Vol. IX, p. 217) that the greater effectiveness of the cast nickel anodes is due to the fact that they contain iron. For this reason they will dissolve better, but iron will also pass into solution, which is a disadvantage. He recommends the use of a pure nickel anode in a nickel-ammonium sulphate solution containing a slight percentage of ammonium chloride or nickel chloride. If this addition is made, the nickel will dissolve as quickly from the anode as it is plated out on the cathode. If iron is to be nickeled it should first receive a coating of copper.

**199. Silver plating.*** The standard solution for silver plating is the double cyanide of silver and potassium, with silver anodes. As to working on a large scale and the production of the silver cyanide from silver nitrate and potassium cyanide and the production of the double cyanide from silver cyanide and potassium cyanide the reader must be referred to special textbooks. A good silver plating solution is obtained by dissolving 25 g. pure silver cyanide in a solution of 25 g. potassium cyanide in 300 to 500 cu. cm. water and diluting the solution so as to form 1 liter. The best current density is 0.001 to 0.0045 amp. per sq. cm., with about 1 volt at the terminals of the cell. Another prescription for experimental work is to dissolve 3 oz. of silver chloride (rubbed to a thin paste with water) in a solution of 9 to 12 oz. of 98 per cent. potassium cyanide in a gallon of water. A current density of $\frac{1}{10}$ amp. per sq. in. is recommended in the latter case.

**200. Gold plating.†** The standard solution is the double cyanide of gold and potassium and the problems involved in gold plating are similar in many respects to those of silver plating. In view of the expensive material involved, great care is necessary in details and the reader must be referred to special books on the subject. Gold is generally plated on copper; other metals to be coated with gold first receive a coating of copper; see also (**207**).

**201. Copper plating.‡** A copper sulphate solution, containing free acid, such as is used for electrolytic refining of copper, may be used for copper plating (see **208**), but better results are obtained with a cyanide solution. van Horne gives the following formula: to each gallon of water add 5 oz. copper carbonate, 2 oz. potassium carbonate and 10 oz. chemically pure potassium cyanide. Dissolve about nine-tenths of the cyanide of potassium in a portion of the water and add nearly all of the copper carbonate, previously dissolved in a portion of the water; then add the potassium carbonate, also dissolved in water, slowly stirring until thoroughly mixed. Bring the solution to 160 deg. Beaumé, put in a small article and test the solution, adding cyanide or copper or both, until the solution deposits freely and uniformly.

F. Foerster recommends for copper plating a solution made as follows: 20 g. copper acetate are dissolved in 500 cu. cm. water, 20 g. potassium cyanide, 25 g. sodium sulphite crystals and 17 g. sodium carbonate crystals are dissolved in another 500 cu. cm. water. The first solution is then added to the second one and a current density of 0.003 amp. per sq. cm. is used with 3 volts at the terminals of the cell.

Digitized by Google

**202. Brass solutions*** of any desired color are made according to van Horne by adding zinc carbonate in varying proportions to the copper solution. This is done by dissolving about one part by weight of carbonate of zinc to two parts of cyanide of potassium in sufficient water to dissolve them and adding them slowly to the copper bath.

**203. Zinc plating.** The protection of iron surfaces against rusting by means of a zinc coating is now becoming an important industry. Zinc-coated iron is often called "galvanized" iron. Most processes used in the United States use soluble zinc anodes, while Cowper-Coles in England uses insoluble (lead) anodes in an electrolyte containing 35 oz. of zinc sulphate ($ZnSO_4$, $7H_2O$) and 0.1 oz. sulphuric acid (specific gravity 1.84) per gallon of water.

A suitable zinc plating solution is obtained, according to Foerster, by dissolving 200 g. pure zinc sulphate (free from iron), 40 g. glauber salt, 10 g. zinc chloride and 0.5 g. boracic acid so as to get 1 liter solution; with a current density of 0.005 to 0.02 amp. per sq. cm. good dense deposits up to 0.05 mm. thickness are thereby obtained at temperatures between 18 and 50° C. The method of producing the zinc coating by electrolysis ("cold galvanising") has the following advantages over the old dipping process ("hot galvanising"); electrolytic zinc, when properly applied, is denser, tougher, more uniform and more resistant against corrosion† (C. F. Burgess, *Electrochemical and Metallurgical Industry*, Vol. III, p. 17).

**204. Plating upon aluminium.** As an example of the great importance of thoroughly cleaning a surface preliminary to plating upon it, the difficulties of plating upon aluminium may be cited. A coating on aluminium will not stick in general for any length of time and this trouble is due to the invisible film (oxide or hydroxide film) which is always present on an aluminium surface in contact with air, and which prevents the necessary intimate junction between the aluminium and the plated metal. C. F. Burgess and C. Hambuechen (*Electrochemical Industry*, Vol. II, p. 85) found that this film can best be eliminated by using a soluble fluoride in the plating bath; further that of all metals zinc will adhere best to aluminium. Therefore, aluminium should first receive a zinc coating. If the object is to plate gold on the article, the gold should not be plated directly on the zinc since the gold will soon alloy with the zinc and apparently disappear; for this reason the zinc should first receive a copper coating and then the gold coating.

The **mode of operation** recommended is to first clean the aluminium by immersion for a few minutes in a dilute hydrofluoric acid bath where it remains long enough to produce a suitable roughening of the surface. It is then rinsed in running water and dipped for a few seconds in a mixture of 100 parts of sulphuric acid and 75 parts of nitric acid, both concentrated, from which, after rinsing in water, the aluminium comes perfectly white and clean. The article is then transferred to the zinc plating solution, which is a mixture of zinc and aluminium sulphates, very slightly acidified and having a density of about 15 deg. Beaumé and containing about 1 per cent. of hydrofluoric acid or an equivalent amount of potassium fluoride. After the deposition has proceeded for about 10 or 15 min. with a current density of from 10 to 20 amp. per sq. ft., the article may be taken from the solution and dried. It may then be given a coating of copper or silver from their cyanide solutions, using such precautions as are commonly observed in the deposition of such metals upon zinc. Where the final coating is to be of gold, it is advantageous to polish the copper coating before depositing the gold, as otherwise a thicker gold coating will be necessary to produce the final polish.

**205. Detinning.‡** The reverse of electroplating is the electric removal

---

of a metallic coating from the surface of an article. This is generally carried out as an anodic reaction. The most important industry in this field is the detinning of tin scrap, which has assumed quite considerable dimensions in recent years as a consequence of the enormous growth of the tin-can industry. While formerly only the tin scrap of the tin-can factories (a pure material, consisting of sheet iron, covered with tin) was treated, the treatment of tin cans, tin boxes, etc., which have been in use, has recently been taken up on a commercial scale; since they contain many impurities, these must first be very thoroughly removed (carbonized, etc.).

The object of the electrolytic process is to remove the tin from the iron so as to get both the tin and iron separate and pure. The iron is sold as scrap to open-hearth steel works, etc., and must therefore be absolutely free from tin and in good condition. The process which has been most successful on a very large scale is that of the firm of Theodor Goldschmidt in Essen; it is a secret process and employs the scrap as anode in a solution of caustic soda. Since 1906 detinning with chlorine has entered into competition with electrolytic detinning. Detinning with chlorine may be considered as an electrolytic process only in so far as electrolytic chlorine (see **220**) is used. While the products of electrolytic detinning are tin and iron, those of chlorine detinning are tin tetrachloride and iron. (Karl Goldschmidt, *Electrochem. & Met. Ind.*, Vol. VII, p. 79.)

**206. Other stripping processes.** A comparatively small, but interesting application of electrolytic stripping is the process of C. F. Burgess for removing from bicycle frames the films of brass which are left there from brazing the joints. A sodium nitrate solution is used for this purpose. (For this and similar processes see C. F. Burgess, *Electrochemical Industry*, Vol. II, p. 8.) As an example of the cathodic removal of a surface coating, the process of C. J. Reed for removing an oxide scale from iron and steel may be mentioned. The iron sheets, rods or wire are treated as cathode in a 27 per cent. solution of sulphuric acid of specific gravity 1.20, with a current density of 0.25 to 0.5 amp. per sq. in. at a temperature of 60° C. Under these conditions the heavy scale on rolled iron rods is removed in from 2 to 3 min. The iron oxide is not reduced to metallic iron, but to a lower state of oxidation and is then dissolved, ferrous sulphate being produced. (*Transactions* American Electrochemical Society, Vol. XI.) Concerning the sharpening of tools by electrolytic etching see Schneckenberg, *Met. & Chem. Engring*, Vol. IX, p 512.

## ELECTROLYTIC REFINING OF METALS

**207. Fundamental principles.** In electrolytic refining of metals the starting material is a highly concentrated alloy and the purpose is to remove the last impurities and to recover not only the principal metal in pure form, but also the foreign metals, especially the precious metals. The impure metal is made the anode and the fundamental principle of the process is that by the electrolytic action the metal to be refined is dissolved from the anode, passes into the electrolyte and is deposited from the electrolyte on the cathode in pure form; the foreign metals (impurities) are intended either to remain back in the anode or anode slime without being dissolved, or if they are dissolved in the electrolyte, they are intended to remain in the electrolyte without being deposited on the cathode. This cannot be satisfactorily accomplished, except with a comparatively pure, high-grade anode; in American practice of copper refining the impure copper anode is generally 98 to 99.5 per cent. pure. The cost of the electrolytic-refining process is covered first by the higher price of the refined metal and secondly by the value of the foreign metals recovered, especially silver and gold.

**208. Copper refining.** The electrolyte is a copper sulphate solution containing free sulphuric acid. The copper should not exceed 3 per cent. at the most, or 12 per cent. if figured as bluestone. The acid may advantageously be run up to about 13 per cent.* (Usually a very small amount of a soluble chloride, like NaCl, is added to precipitate as chloride

* Figures of the conductivity of mixtures of copper sulphate and sulphuric acid are given by Richardson and Taylor in *Trans.* Amer. Electrochem. Soc., Vol. XX, p. 179.

Digitized by Google

any silver which may dissolve and to slime antimony as oxychloride.) An anode of typical composition contains 98 to 99.5 per cent. copper, up to 300 oz. silver per ton, up to 49 oz. gold per ton and up to 2 per cent. arsenic. The cathode copper is exceedingly pure, usually running about 99.93 per cent. copper, with hydrogen as the chief impurity. In order to have high electric conductivity, the copper must be free from arsenic and antimony (the amount should be but a few thousandths of a per cent.); in order to prevent brittleness, the cathode copper must be free from tellurium and lead. Since the electric conductivity of copper very delicately indicates its purity, it is used for giving the figure of the purity. Matthiessen's standard—according to which the resistance of one meter-gram of pure soft copper at 0 deg. cent. is 0.14172 international ohm—is generally used although it is some 3 per cent. too low. It is a "fact that the quality of the [electrolytic] copper on the market to-day often exceeds by as much as 1 per cent. the purest laboratory copper of forty years ago." (L. Addicks.)

It is customary to circulate the electrolyte from tank to tank and this is more important the higher the current density. The **current density** varies in American refineries between 12 and 35 amp. per sq. ft.; the question of what current density to carry is largely one of energy cost. An elevated temperature of the electrolyte is used. Soluble sulphates of impurities in the anode pass into the solution which therefore needs purification generation at intervals. This is usually done by working up a certain quantity of electrolyte regularly into bluestone and adding fresh acid to the electrolyte.

**209. Arrangement of electrodes in copper refining.** With respect to the arrangement of the electrodes two different systems are in use. In the parallel system or multiple system all cathodes are in parallel and all anodes are in parallel; the arrangement is shown in Fig. 5. In the series system or Hayden system, diagrammatically shown in Fig. 6, only the first

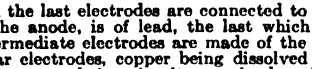

FIG. 5.—Multiple System.

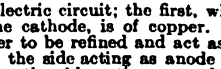

FIG. 6.—Series System.

and the last electrodes are connected to the electric circuit; the first, which is the anode, is of lead, the last which is the cathode, is of copper. All intermediate electrodes are made of the copper to be refined and act as bipolar electrodes, copper being dissolved from the side acting as anode and pure copper being simultaneously deposited on the side acting as cathode. According to Addicks, the main points of difference between the multiple system and the series are in energy cost, compactness and cost of preparing anodes. The power in the series system is about 70 per cent. of that in the multiple system. In the multiple tank close attention must be paid to the contacts (B. Magnus, *Electrochemical Industry*, Vol. I, p. 561, Vol. II, p. 74; C. T. Hutchinson, Vol. II, p. 13). The series tank has relatively no contacts or conducting bars, and the electrodes are very close together, the anodes being thin, even plates. To produce such anodes they must either be rolled or specially hand-cast, and the grade of material used must be good. The interest on the metal tied up in process and the investment in plant is less in the series system. The series system requires no starting sheets, but much closer supervision to keep the quality of the cathodes up. As lead-lined tanks cannot be used in series work, due to the relatively high voltages used, tank maintenance becomes an important item.

**210. Statistics of copper refining.** According to T. Ulke (*Electrochemical Industry*, Vol. I, pp. 240 and 276) the yearly output of American electrolytic copper refineries in 1902 was 279,000 tons. At the same time the amount of silver and gold recovered per year in the copper refineries was 27,000,000 oz. of silver and 346,020 oz. of gold. It is also known that the capacity of American electrolytic copper refineries has about been doubled up to 1908, although exact figures as to the present statistics are not available.

**211. References to literature on copper refining.** A very good and concise summary of modern copper refining methods is the article by L. Addicks, *Electrochemical and Metallurgical Industry*, Vol. IV, p. 16.

Digitized by Google

See also the monograph of T. Ulke on modern electrolytic copper refining. Concerning treatment of the slimes of copper refineries see below under silver refining, also Kern, *Met. & Chem. Eng'ing*, Vol. IX, p. 417. A full description of the Great Falls refinery is given by Burns in *Bulletin* American Inst. Min. Engrs., August, 1913, p. 2011. Concerning the power problem in electrolytic copper refining see papers by Addicks, Longwell, and Newbury, Transact. Amer. Electrochem. Soc., Vol. XXV.

**212. Silver refining.** The chief commercial problem of silver refining relates to the treatment of the bullion produced by copper refineries, to recover the silver and gold. This bullion may be treated either with the old sulphuric acid parting process or electrolytically by one of the following methods (for a critical comparison see F. D. Easterbrooks, *Transactions* American Electrochemical Society, Vol. VIII, p. 125). In the electrolytic methods the electrolyte is a silver nitrate solution.*

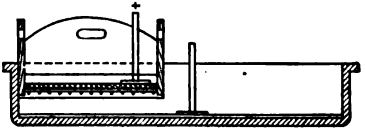

FIG. 7.—Balbach Cell.

**213. Balbach process.** The cross-section of a tank is shown in Fig. 7. The cathode is made of ½-in. Acheson graphite slabs fitted to the bottom. Two silver contact pieces rest respectively on the bullion to be parted and the graphite slabs. Bullion cast in thin square slabs is contained in a cloth case which is supported on a wooden frame suspended over the tank. The gold slimes accumulate on the under side of the bullion, between it and the cathode, increasing the resistance as the operation continues. Each tank has a cathode surface of 8 sq. ft., and a current density of 20 to 25 amp. per sq. ft. is used. The voltage averages 3.8 per tank, and an average ampere-hour efficiency of 93 per cent. is obtained on a continued run, while occasionally an efficiency of 98 per cent. is secured. The energy required is 31.5 watt-hr. per oz. of fine silver produced. At 20 amp. per sq. ft. about 32 per cent. of the daily output of each tank is held permanently in stock in electrolyte and contacts. (For a description of the Balbach refinery see *Electrochemical Industry*, Vol. II, p. 302.) Thum's modification of the Balbach process, as employed on the Raritan Copper Works, is described by Easterbrooks in *Electrochem. & Met. Ind.*, Vol. VI, p. 277.

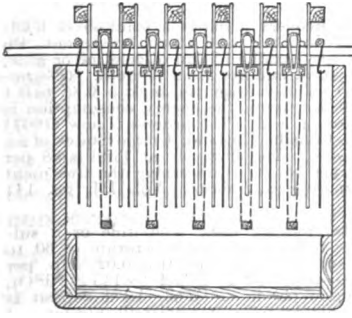

FIG. 8.—Moebius Cell.

**214. Moebius process.** The cross-section of a tank is shown in Fig. 8. They are arranged in units of 6 placed end to end, each unit being provided with apparatus for raising the boxes containing the deposited silver together with the anodes and cathodes, and with arrangements for imparting a reciprocating motion to the wooden scrapers. There is no system of circulating the electrolyte, but the scrapers moving back and forth agitate it. The anodes are contained in a cloth frame which holds the gold slimes, and the silver is brushed off from the silver cathodes by the wooden scrapers, and drops into a box with hinged bottom. It is removed by raising the boxes above the top of the tanks and emptying them into a tray placed beneath. This operation requires ½ hr. per day per unit. Each tank has a cathode surface of about 16.5 sq. ft., and a current density of 20 to 25 amp. per sq. ft. is used. The voltage

* See also Kern, *Met. & Chem. Eng'ing*, Vol. IX, p. 443.

Digitized by Google

between electrodes is 1.4 to 1.5 and the energy consumption is 13.2 watt-hr. per oz. of silver deposited. A mean ampere-hour efficiency of 94 per cent. is obtained. At 20 amp. per sq. ft. 41 per cent. of the daily output of each unit is permanently in stock in cathodes and electrolyte.

In both the Balbach and the Moebius processes which are in use at various copper refineries the silver is deposited in a loose crystalline form at a relatively high current density. With a lower current density (10 amp. per sq. ft.) silver is deposited in adherent form from a copper-silver nitrate solution, with a small addition of gelatine, with rapid circulation of the solution. The energy consumption is nearly identical with the Moebius method. 28 to 32 per cent. of the daily output is retained in cathodes and electrolyte. A. G. Betts (*Transactions* American Electrochemical Society, Vol. VIII, p. 121) recommends an electrolyte of methyl sulphuric acid with a small addition of carbon bisulphide.

**215. Treatment of bullion at United States mints.** The **bullion** to be **parted and refined** is divided into two classes, by selection and blending. One class is largely gold (see below gold refining). The other class contains largely silver; the anodes are composed of 300 parts of gold in 1,000, the remaining 700 parts consisting of silver, copper and other material. The electrolyte consists of a 3 per cent. solution of silver nitrate to which is added 1.5 per cent. free nitric acid. The silver deposit is obtained in coherent form if a very small amount of gelatine is added to the electrolyte (D. K. Tuttle, *Electrochemical and Metallurgical Industry*, Vol. IV, p. 306).

**216. Gold refining.** The **Wohlwill process** of gold refining with recovery of platinum and palladium employs a gold chloride solution strongly impregnated with hydrochloric acid, at a temperature of 65 to 70 deg. cent. A slight modification of the Wohlwill process (55 deg. cent, purer anodes and lower current density) is in use in the United States mints. See E. Wohlwill, *Electrochemical Industry*, Vol. II, pp. 221 and 261, Vol. VI, p. 450; D. K. Tuttle, *Electrochemical Industry*, Vol. I, p. 157; also Vol. VI, pp. 355 and 408. The applicability of the Wohlwill process to alloys richer in silver has been rendered possible recently by the employment of a pulsating current (obtained by superposing an alternating current on the direct current) instead of a purely direct current. (*Met. & Chem. Eng'ing*, Vol. VIII, p. 82). See also Kern, *Met. & Chem. Eng'ing*, Vol. IX, p. 446.

**217. Lead refining.** The **Betts process** employs a solution of lead-fluosilicate, containing an excess of fluosilicic acid (5 to 7 per cent. Pb and 12 to 15 per cent. $SiF_6$) with a very small addition of gelatine or glue, depositing lead in dense coherent form and free from bismuth. (*Electrochemical Industry*, Vol. I, p. 407.) The voltage per tank is 0.35 to 0.4 including losses, the temperature 30 deg. cent., the energy consumption is from 5½ to 6 horsepower-days per ton of lead. The process is now (1907) used commercially in three plants in Canada, England, United States of an aggregate capacity of 175 tons per day. The efficiency at Trail is 88 per cent. the current density 15 amp. per sq. ft. Concerning the treatment of limes see *Electrochemical & Metallurgical Industry*, Vol. III, pp. 141 and 235.

**218. Nickel refining.** For nickel refining either a chloride or a sulphate solution is used. F. Foerster recommends a temperature of 60 to 70 deg. cent., good circulation and a current density of 0.01 to 0.02 amp. per sq. cm., with a solution containing about 30 g. nickel (= 145 g. $NiSO_4$, $7H_2O$ or 121 g. $NiCl_2$, $6H_2O$) or more per liter. The nickel deposit is of such density and tenacity that it may be rolled immediately into form of sheets. Concerning the possibility of obtaining thick coherent nickel deposits see W. McA. Johnson, *Electrochemical Industry*, Vol. I, p. 212; and D. H. Browne, *Electrochemical Industry*, Vol. I, p. 348. Browne obtained good coherent deposits from a neutral solution containing 70 g. $NiCl_2$, 180 NaCl per liter, heated to 50 to 75 deg. cent., with a current density of 100 to 200 amp. per sq. m. with efficient circulation of electrolyte. From sulphate solutions thick cathodes may be deposited, with a solution of neutral nickel-sulphate or nickel-ammonium sulphate, kept at about 50 deg. cent. with efficient circulation and a current density of 50 to 300 amp. per sq. m.

**219. Zinc refining.** In the **Hoepfner process** which is in use in a plant in England, a zinc chloride solution is subjected to electrolysis. De-

Digitized by Google

tails of electrolysis as carried out in England are not known; see, however, E. Guenther's "Darstellung des Zinks auf Elektrolytischem Wege." The latest advance* of the Siemens & Halske Co. in this field is the use of manganese peroxide anodes. The power consumption is 3.4 kw-hr. per kilogram Zn.

**220. Iron refining.** The **Burgess process** employs a solution of ferrous and ammonium sulphates with a cathodic current density of 6 to 10 amp. per sq. ft. and a slightly smaller anodic current density. The e.m.f. for each cell is slightly under 1 volt; the temperature of the electrolyte is about 30 deg. cent.; the anodes consist of ordinary grades of wrought iron and steel; the starting sheets for the cathode are of thin sheet-iron, previously cleaned of rust (*Electrochemical Industry*, Vol. II, p. 183). See also E. F. Kern, *Transactions*. Am. Electrochem. Soc., Vol. XIII.

As an electrolytic iron-refining process and as a plating operation may be considered the process of Cowper-Coles† for the production of iron sheets and tubes of nearly pure iron from anodes of pig iron. The electrolyte is a concentrated solution of ferrous chloride with addition agents.

**221. Tin refining.** According to the **Claus process** raw tin is electrolyzed in a 10 per cent. sodium sulphide solution at a temperature of more than 80 deg. cent. with a current density of 0.5 amp. per sq. dm. at a voltage at the electrodes below 0.2 volt. Pure tin plates or plates coated with pure tin must be used as cathodes. The anodes contain at least 90 per cent. tin: no circulation of electrolyte. Before introducing new tin anodes into the cell, it is necessary to dissolve in the electrolyte about 1 per cent. of its weight of sulphur, preferably in form of flowers of sulphur (O. Steiner, *Electrochemical and Metallurgical Industry*, Vol. V, p. 309).

**222. Bismuth refining.** The electrolyte is bismuth chloride containing free hydrochloric acid (7 per cent. Bi and 9 to 10 per cent. HCl). The cathodic current density is 20 amp. per sq. ft., the anodic current density is three times this amount, the voltage at the electrodes is 1.2. Silver and gold remain at the anode, but traces of the silver pass into the bismuth deposit. The anodes contain over 90 per cent. Bi, besides lead, silver, etc. The product is 99.8 per cent. pure, the chief impurity being silver. The arrangement of the cell is the same as in the Balbach silver-refining process. (A. Mohn, *Electrochemical and Metallurgical Industry*, Vol. V, p. 314.)

**223. Cadmium refining.** A cadmium sulphate solution containing free acid is electrolyzed with a current density of 0.005 to 0.02 amp. per sq. cm. (F. Mylius and R. Funk, *Zeit, f. Anorgan. Chemie*, Vol. 13, p. 157.)

**224. Miscellaneous refining processes. Cobalt** is stated to be deposited from its sulphate and chloride solutions with the same ease and under the same conditions as nickel. Concerning **thallium** see F. Foerster "*Zeit, f. Anorg. Chemie*," Vol. 15, p. 71. Concerning **chromium** see M. Le Blanc's "Production of Chromium," (English translation by J. W. Richards), also Carveth and Mott, and Carveth and Curry, *Jour. Physical Chemistry*, Vol. IX, pp. 231 and 353, Le Blanc, *Transactions* of the American Electrochemical Society, Vol. IX, p. 315.

## PRODUCTION OF HYDROGEN AND OXYGEN GASES BY ELECTROLYSIS OF WATER

**225. General theory.** In the electrolytic decomposition of water, as carried out on an industrial scale for the production of oxygen and hydrogen gases, instead of pure water which has too low an electric conductivity, either a 20 per cent. solution of sulphuric acid or a 15 per cent. solution of caustic soda is used as electrolyte, these concentrations corresponding to maximum conductivity. If sulphuric acid is used, the cathodic reaction is the dicharge of hydrogen ions and the setting free of hydrogen gas, while the anodic reaction may be written

$$SO_4'' + H_2O = H_2SO_4 + O, \qquad (35)$$

so that oxygen gas is set free and sulphuric acid is reformed. The quantity of sulphuric acid, therefore, remains constant and only water disappears.

* Engelhardt. *Met. & Chem. Eng'ing*, Vol. XI, p. 43.
† Palmaer and Brinell. *Met. & Chem; Eng'ing*, Vol. XI, p. 197.

Digitized by Google

In the same way with caustic soda, NaOH, as electrolyte, the cathodic reaction is

$$2Na^{\cdot} + 2H_2O = 2NaOH + H_2, \quad (36)$$

and the anodic reaction is

$$2OH = H_2O + O, \quad (37)$$

so that $H_2$ is set free at the cathode and O at the anode, water disappearing, while the quantity of caustic soda remains constant, since as much is formed at the cathode as is decomposed by the current. It is, therefore, necessary to add new water to the solution from time to time. The decomposition e.m.f. of water with polished platinum electrodes is about 1.7 volts.

**226. In a commercial electrolyzer** the e.m.f. is 3 volts or less. We will assume 3 volts, 100,000 coulombs evolve 1.04 g. of hydrogen gas, occupying 11.6 liters at 0 deg. cent. and atmospheric pressure, and 8.3 g. oxygen gas, occupying 5.8 liters. But the passage of 100,000 coulombs at 3 volts represents an energy consumption of $\frac{1}{3}$ kw-hr. so that the electrolytic production of 1 cu. m. of hydrogen gas (0 deg. cent. and atmospheric pressure) requires somewhat over 7 kw-hr. With an acid solution the electrodes may be made of lead, with an alkaline solution of iron. In the construction of the vats for electrolysis the chief problem is to keep the hydrogen and oxygen gases separate from each other by some such device as a diaphragm.*

**227. An important application of electrolytic hydrogen and oxygen** is the production of high temperatures by the **oxyhydrogen flame**† for welding, etc.

## ALKALINE CHLORIDE ELECTROLYSIS

**228. Products of alkaline chloride electrolysis.** If the solution of an alkaline chloride (say, sodium chloride) in water is electrolyzed, the products may be, according to the arrangement of the operation, either (a) caustic soda and chlorine, or (b) hypochlorite (bleaching liquor) or (c) chlorate.

**229. Caustic soda and chlorine.**‡ The total reaction is

$$NaCl + H_2O = NaOH + H + Cl. \quad (38)$$

At the cathode the Na cations discharge, react with water and form caustic soda and hydrogen gas. At the anode chlorine is liberated which is partly dissolved in the solution and partly evolved as gas. If the valuable products of the process are to be caustic soda and chlorine,§ the chief requirement is to keep the anodic and cathodic products separate from each other and to remove them as quickly as possible from the sphere of electrolytic action.

**230. Mercury cathode processes.** Of the mercury cathode processes, the Castner-Kellner process and the Solvay process first achieved large industrial importance. The sodium-mercury alloy formed at the cathode of the electrolytic cell is by some special means removed from the surface of contact with the electrolyte and carried off to a separate cell where the amalgam is decomposed in contact with water, caustic soda, NaOH, being formed with simultaneous evolution of hydrogen gas, $Na + H_2O = NaOH + H$. In some mercury-cathode processes this is simply a chemical reaction, heat being evolved in consequence of its taking place. In other processes, like the Castner-Kellner, it is made an electrolytic action, and the energy given out by this reaction is obtained in form of electrical energy so that less energy is required to decompose the NaCl solution in the other cell. As a matter of fact, we have in this case two electrolytic cells in series. In the series: carbon anode, NaCl solution, mercury, water, iron cathode, the mercury acts as a bipolar electrode, and the reaction in the first cell is $NaCl + Hg = Cl + Hg,Na$, that in the second cell $Hg,Na + H_2O = Hg + NaOH + H$; hence the total reaction $NaCl + H_2O = Cl + NaOH + H$. The

†Concerning this and oxy-acetylene welding see R. N. Hart, "Welding."

‡Billiter, "Die Electrochemischen Verfahren der Chemischen Gross-Industrie;" Brochet, "La Soude Electrolytique;" Lucion, "Electrolytische Alkalichloridzerlegung mit flüssigen Metall-kathoden;" Allmand, "Applied Electrochemistry, p. 342 to 385.

§The hydrogen gas evolved at the cathode is usually wasted, though it is employed in Germany to some extent for balloon filling.

Digitized by Google

first partial reaction consumes energy, hence it requires that a certain voltage be impressed on the cell from the outside. The second partial reaction evolves energy. Hence the total reaction requires energy equal to the difference of the energies of the two partial reactions. The voltage at the terminals of the whole is less than that required for the first partial reaction alone.

Newer mercury cathode cells are the Whiting cell and* the Wilderman cell.† The advantages of mercury cathode cells are high purity and high concentration of caustic soda with reduction of evaporation charges, and high ampere-hour efficiency. The drawbacks are comparatively high voltage and the first cost of the mercury.

**231. Fused-lead-cathode process.** While in the mercury-cathode cell an aqueous solution of sodium chloride is electrolyzed, the fused-lead-cathode process (C. E. Acker) employs an electrolyte of fused sodium chloride. The sodium alloys with the fused lead. This alloy is carried off and decomposed in another vessel by means of a jet of steam. The principle is exactly analogous to the mercury-cathode process (C. E. Acker, *Transactions* American Electrochemical Society, Vol. I, p. 165). The process is no longer in commercial operation.

**232. In the Glocken process** or bell-process or gravity-process the anode is contained in a bell-formed non-conducting receptacle, open at the bottom and thereby in connection with the outside cathode compartment surrounding the bell. By force of gravity the anodic and cathodic products are held automatically separate and prevented from mixing and are continually carried off. Fresh saturated NaCl solution is continually supplied to the anode compartment (bell) and passes downward and prevents the OH ions from reaching the anode (O. Steiner, *Electrochemical and Metallurgical Industry*, Vol. V, p. 171).

**233. In the Billiter-Leykam cell‡** the bell process has been modified by placing the cathodes (hooded to collect the hydrogen) immediately underneath the bell jar, and not around its sides.

**234. In the diaphragm processes§** which are the oldest ones and of which there are quite a number, the electrolytic cell is divided into an anode compartment and a cathode compartment by means of a porous diaphragm which prevents the mechanical mixing of the two solutions. If the chloride solution is supplied to the cathode compartment, the solution cannot be highly saturated with caustic without trouble being produced by the OH ions passing to the anode. The only large industrial process in which this arrangement is used is the Griesheim Elektron process‖ used in Germany.

In most **other diaphragm cells** saturated sodium chloride solution is introduced into the anode compartment so as to flow through the diaphragm toward the cathode and counteract the tendency of the OH ions to pass to the anode. This is the case, for instance, in the cells of LeSueur, McDonald and others. A comparatively very small cathode compartment of special construction is the feature of the Hargreaves-Bird cell. This principle is carried still further in the Townsend cell, in which the cathode compartment contains no electrolyte whatever, but liquid kerosene. The caustic as soon as formed is absorbed in the kerosene and carried off. (C. P. Townsend, *Transactions* American Electrochemical Society, Vol. VII, p. 63; L. Baekeland, *Electrochemical and Metallurgical Industry*, Vol. V, p. 209 and Vol. VII, p. 313.)

Almost all diaphragm cells use vertical diaphragms. An exception is the Billiter-Siemens & Halske cell¶ in which horizontal diaphragms are used.

**235. Data on alkali-chlorine cells.** Allmand ("Principles of Applied Electrochemistry," p. 383) gives the following comparative table of electrochemical data of different alkali-chlorine cells, which holds for those conditions under which the cell in question is normally worked. Concerning

| Finlay..... | 2n. | 98 | 3.0 | 75 | 2.0 |

**237. Anodes.** Artificial graphite anodes are exceedingly useful. Platinum anodes are occasionally used. Ferric oxide electrodes have been introduced in Germany. The construction of concrete tanks for chloride electrolysis is described by D. H. Browne, *Electrochemical Industry*, Vol. I, p. 273. Concerning the construction of diaphragms see Allmand's "Applied Electrochemistry," p. 154.

**238. Concerning the uses of electrolytic chlorine** see F. Winteler, *Electrochemical Industry*, Vol. II, p. 339; O. Nagel, *Electrochemical and Metallurgical Industry*, Vol. III, p. 16. The chief application of electrolytic chlorine is for the manufacture of chloride of lime (bleaching powder). Other applications are the detinning of tin scrap (with production of tin tetrachloride), manufacture of carbon tetrachloride, sulphur chloride, acetylene tetrachloride, hydrochloric acid (by combining the anodic chlorine with the cathodic hydrogen), etc. Concerning the uses of chlorine in metallurgy see Baker, *Transactions* American Electrochem. Soc., Vol. XII. As to the electrolytic production of bromine and iodine see the German monograph by M. Schloetter.

**239. Table of Hypochlorite Cells** (Allmand)

| Type | Brine used | Grams active chlorine per liter | Kw-hr. per kilo active chlorine | Kilos of salt per kilo active chlorine | Addition |
|---|---|---|---|---|---|
| | Per cent. | | | | |
| Kellner (vertical electrodes). | 15 | 12.0 | 6.5 | ..... | $K_2CrO_4$ |
| Haas-Oettel..... | 17 | 12.3 | 6.4 | 14 | ..... |
| Schuckert..... | 15 | 20 | 6.0 | 7.8–8 | Sodium resinate |
| Kellner (horisontal electrodes). | 15 | 25 | 6.0 | 4–6 | Sulphur compound |

**240. Hypochlorite (bleaching liquor).** While for the production of caustic and chlorine by electrolysis of sodium chloride the anodic and

Digitized by Google

cathodic products must be kept separate, the reverse requirement must be fulfilled for the electrolytic production of hypochlorites (bleaching liquors) by electrolysis of sodium chloride. Sodium hypochlorite is the result of the reaction of chlorine on caustic soda. To obtain the hypochlorite in the electrolytic cell itself, the electrodes are placed near together and the electrolyte is maintained in steady motion in order to mix the anodic and cathodic products together. For a description of commercial cells for the production of bleaching liquor see W. H. Walker, *Electrochemicol Industry*, Vol. I, p. 439; Engelhardt and Abel, "Hypochlorite and Elektrische Bleiche," 2 volumes; Allmand, "Applied Electrochemistry," pp. 318 335. Concerning cost of operation see Engelhardt, *Met. & Chem. Eng'ing*, Vol. IX, p. 489.

Allmand's table (Par. 239) gives typical results yielded by different electrolyzers. They cannot be very closely compared, owing to varying conditions, but give an idea of the relative capabilities of the different types.

Concerning the Digby hypochlorite cell see *Met. & Chem. Eng'ing*, Vol. IX, p. 328.

**241. Chlorate.** The production of chlorate by electrolysis of sodium chloride requires interaction between caustic soda and chlorine under the conditions of a moderately high temperature, above 40 deg. cent. and an absence of reducing conditions. For the latter purpose the addition of chromate has been found especially useful. No diaphragms are used in modern chlorate cells (see the German monograph by Kershaw and Huth; also Allmand, Applied Electrochemistry, pp. 335–341). As to the use of electrolytically produced acid and alkali (obtained by electrolysis of a solution of chlorate or perchlorate of sodium) for producing bichloric phosphate fertilizers see Palmaer, *Met. & Chem. Eng'ing*, Vol. X, p. 581.

## ELECTROLYSIS OF CHLORIDES OF COPPER, NICKEL AND ZINC

**242. Reduction of copper-nickel matte.** Besides the electrolysis of alkaline chlorides, which is now carried out on a very large industrial scale in the numerous processes, sketched above, chloride electrolysis has also been attempted in the metallurgy of copper, nickel and zinc. (Concerning the early work of Hoepfner in this field see Wm. Koehler, *Electrochemical*

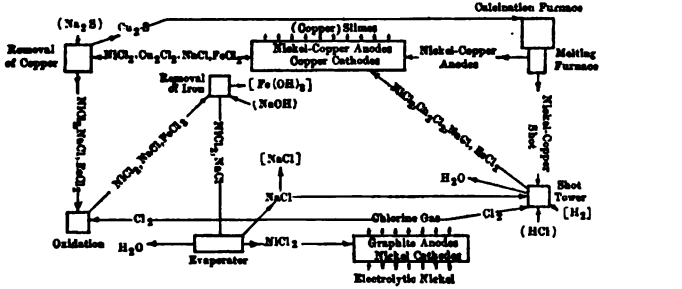

Fig. 9.—Separation of nickel and copper.

*Industry*, Vol. I, pp. 540, 568.) Success has been attained in this field by D. H. Browne for **separation of the nickel and copper from copper-nickel matte**, the scheme of the process being indicated in Fig. 9. The matte is roasted and melted and one-half of the fused copper-nickel is poured into anode form, the other half is poured into water, thus giving copper-nickel shot of a weight equal to that of the anodes. The anodes are placed in the nickel-copper chloride bath; the copper-nickel shot is brought into the shot tower in which the electrolyte for the copper-depositing baths is made. In these baths pure copper is deposited on the cathodes, nearly all the copper being separated from the nickel in solution. The small amount of copper remaining in solution is removed by means of sodium sulphide. The solution which is now a mixture of $NiCl_2$, NaCl, and a small amount of FeCl3

Digitized by Google

is then treated with some chlorine gas in order to oxidise the ferrous chloride to ferric chloride. By means of sodium hydroxide the iron is then removed from the solution; after removal of the ferric hydroxide, the solution is a mixture of $NiCl_2$ and NaCl and is then brought into the evaporator. The sodium chloride separates out, and the nickel chloride solution is subjected to electrolysis. As shown in the diagram, the process is nearly cyclic with respect to chlorine. (For details see F. Haber, *Electrochemical Industry*, Vol. I, p. 381.)

**243. Fused chloride electrolysis** is employed in the Swinburne-Ashcroft "chlorine-smelting" process for the treatment of mixed sulphide ores. The scheme is indicated in the diagram, Fig. 10, where the ore is assumed to be a mixture of zinc sulphide and the sulphides of two other metals, designated by M and N. The mixture of sulphides is first treated in the "transformer" with chlorine and changed into a mixture of chlorides. The second step of the process consists in substituting zinc for M and N. The zinc chloride is then electrolysed. The process is cyclic with respect to chlorine. (See Swinburne, *Electrochemical Industry*, Vol. I, p. 412; Vol. II, p. 404. See also Ashcroft's articles on experiments with fused electrolytes and handling of chlorine (pumping, etc.), *Electrochemical and Metallurgical Industry*, Vol. IV, pp. 91, 143, 178, 357.)

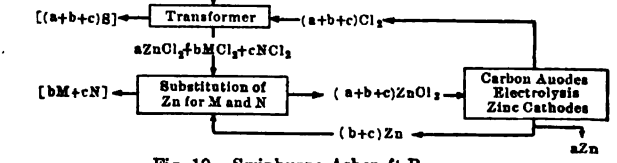

Fig. 10.—Swinburne-Ashcroft Process.

**244. Concerning electrolytic processes in zinc metallurgy**, see W. McA. Johnson, *Electrochem. & Met. Ind.*, Vol. V, p. 83; also *Transact.* Amer. Electrochem. Soc., Vol. II; and J. W. Richards, *Transact.* Amer. Electrochem. Soc., Vol. XXV. See also Günther's "Darstellung des Zinks auf Elektrolytischem Wege."

**245. In gold metallurgy** electrochemical processes have been tried or used in various ways. In the chlorination process electrolytic chlorine or electrolytically produced bleaching powder has been employed. In the cyanide process electrolytic precipitation of gold (as a substitute for zinc precipitation) by the Siemens & Halske process has been formerly employed on a large scale, especially in South Africa.* Clancy† has proposed the substitution of cyanamide (in combination with electrolysis) for cyanide, but has not achieved commercial success so far. Electrolytic amalgamation‡ has been experimented with repeatedly, but is not in use on a large scale at present; the principle is to make the mercury in the ordinary amalgamation process cathode in an electrolytic cell.

## ELECTROLYTIC REDUCTION OF ALUMINIUM, SODIUM, MAGNESIUM AND CALCIUM

**246. Aluminium.** Finally, various electrolytic processes must be mentioned which have resulted in the cheap production of certain metals which can be made by other means only at great expense. The classical example is the electrolytic production of aluminium which is now certainly

* Concerning this process and its later developments by Butters, Hamilton and Richmond see *Electrochem. & Met. Ind.*, Vol. II, pp. 55, 131, 207, 215, 372. B. Neumann, Vol. IV, p. 297. C. R. Richmond, *Eng. & Min. Jour.*, 1907 March 16. See also Walker, *Transact.* Amer. Electrochem. Soc., Vol. IV, p. 47 and two papers by Kern and by Clevenger and Hall in *Transact.* Amer. Electrochem. Soc., Vol. XXIV, pp. 241, 271.

† *Met. & Chem. Eng'ing*, Vol. VIII, pp. 608, 623; Vol. IX, pp. 21, 836,

Digitized by Google

the most important electrochemical industry. In the processes of Hall and Héroult the electrolyte is a fused solution of alumina (as solute) in the double fluoride of aluminium and sodium (as solvent). Carbon anodes are used, while the melted aluminium metal in the bottom of the pot forms the cathode. The temperature is 900 deg. cent. The alumina is decomposed by the current and fresh alumina is added at intervals to the bath. According to J. W. Richards the production of 1 kg. of aluminium requires 22 kw-hr. Aluminium is used for the manufacture of various utensils, for all purposes where lightness is an advantage, and especially for electric conductors as a substitute for copper. J. W. Richards' "Aluminium" is the standard book on this metal: concerning the theory of the process a different view is defended in the book by Minet, translated by L. Waldo.* According to the U. S. Geological Survey, the production of aluminium in the United States was 61,281 lb. in 1890; 920,000 lb. in 1895; 7,150,000 lb. in 1900; and 11,347,000 in 1905. It is estimated that the output in 1906 was 30 per cent. greater than the output in 1905, but a much greater rate of increase is expected in the future.

**247. Properties of aluminium cells.** The property of aluminium electrodes to let electricity pass in one direction (when the aluminium electrode is cathode), but not in the other, is made use of in **electrolytic rectifiers.** A. Nodon ("Transactions of the International Electrical Congress," St. Louis, 1904, Vol. I, p. 510) employs a neutral solution of ammonium phosphate in water as the electrolyte, with aluminium as one electrode and the other electrode of lead or polished steel. C. F. Burgess and Carl Hambuechen (*Transactions* American Electrochemical Society, Vol. I, p. 147) use a fused electrolyte of molten sodium nitrate with an aluminium and an iron electrode. If two aluminium electrodes are used, the system represents an **electrolytic condenser** (C. I. Zimmerman, *Transactions* of the American Electrochemical Society, Vol. VII, p. 309). This valve effect of the aluminium electrode is also made use of in the **electrolytic lightning-arrester** (see R. P. Jackson, *Electrical Journal*, August, 1907).

**248. Metallic sodium** is produced on a large scale by the **Castner process** from a fused NaOH electrolyte at a temperature not more than 10 or 15 deg. cent. above the melting point (which is at 308 deg. cent.). A gauze or screen is provided between the electrodes and a superposed dome for collecting the metallic sodium.

**249. The Ashcroft process** produces **sodium** from common salt in a double cell of the following construction. In the first half of the cell fused sodium chloride is electrolyzed with a carbon anode (at which chlorine is liberated) and a fused lead cathode (which absorbs the sodium). The same fused sodium-lead-alloy forms the anode in the second half of the cell, fused NaOH being the electrolyte and the cathodes consisting of iron or nickel. In this second half of the cell sodium passes from the sodium-lead alloy into the bath and is deposited at the cathode, the fused bath remaining of constant composition. The first half of the process is in principle analogous to the Acker process, the second half to the Castner process, but with the exception that as much NaOH is formed back at the fused sodium-lead anode as is decomposed. The total result of the process is given by the simple equation $NaCl = Na + Cl$ (*Electrochemical and Metallurgical Industry*, Vol. IV, p. 218). (A good summary of various sodium processes is given by C. F. Carrier, Jr., in *Electrochemical and Metallurgical Industry*, Vol. IV, pp. 442 and 475; also *Met. & Chem. Eng'ing*, Vol. VIII, p. 253.) The yearly production of sodium in the world (1906) is about 3,500 tons, of which 1,500 tons are used for making cyanide, 1,500 for peroxide and 500 are sold as metal.

**250. Magnesium** is produced by electrolysis from a fused dehydrated bath of carnalite, *i.e.*, a double chloride of potassium and magnesium or from a fused bath of magnesium chloride (Tucker and Jouard, Transact. Amer. Electrochem. Soc., Vol. XVII, p. 249).

**251. Calcium** is made by a process of the Allgemeine Elektricitats Gesellschaft by electrolysis of fused calcium chloride, the cathode being continually and slowly raised during process of electrolysis so that its end always just touches the surface of the bath (J. H. Goodwin, *Electro-*

## DISCHARGE THROUGH GASES

**253. Discharges through atmospheric air.** If an electric discharge is passed through a gas or a mixture of gases, different chemical reactions are produced according to the nature of the discharge. Thus, if a silent discharge is passed through atmospheric air the oxygen ($O_2$ molecules) in the air is changed into ozone ($O_3$ molecules). On the other hand, if a spark or arc discharge passes through air, the oxygen and nitrogen of the air are forced to combine; since the nitrogen in the air is thereby fixed in form of a useful compound, this process is spoken of as the fixation of atmospheric nitrogen.

**254. The rationale of ozone formation** by the silent discharge is not yet fully understood although considerable evidence has been produced to the effect that the reaction is essentially photo-electric, due to the ultraviolet radiation which accompanies the silent discharge. It is known that ultraviolet rays passing through oxygen gas change it into ozone. Commercial ozonisers are operated by high-tension alternating current and the chief feature of their design is the necessity to avoid any spark or arc discharges. In most forms of ozonisers this is accomplished by providing a dielectric (glass, mica, etc.) between the electrodes. In the Siemens & Halske ozoniser* a water-cooled metal tube is employed in a glass or mica tube wound with copper ribbon; the glass or mica tube forms the dielectric, while the inner metal tube and the outer copper ribbon form the two electrodes. Through the annular space between the two the air to be ozonised is passed. In the Vosmaer ozoniser no dielectric is used, but the production of sparks and arcs is prevented by purely electrical means, essentially with the aid of condensers.

**255. The main applications of ozone** are for bleaching, purifying and sterilising, and for the industrial manufacture of certain chemical compounds such as vanillin from iso-eugenol. The chief application is for the sterilisation of water; its effectiveness for this purpose is certain but the cost of the process has, so far, somewhat restricted its wider application on a commercial scale.† (Sec. 22.)

**256. Concerning other chemical effects of the silent discharge** see, for instance, J. N. Collie, *Transactions—Journal* of the Chemical Society, London, 1905, p. 154; Wiechmann, "Notes on Electrochemistry," p. 133. Concerning the fixation of atmospheric nitrogen by arc discharges see Par. **260** to **268**.

## FIXATION OF ATMOSPHERIC NITROGEN

**257. Atmospheric air is a mixture** of 80 per cent. by volume of **nitrogen** and 20 per cent. of **oxygen**, if the other gases which are present only in small quantities are neglected. Air is a mixture of gases, not a chemical compound. The importance of the problem of the fixation of atmospheric nitrogen rests in the fact that elementary nitrogen, as contained in the air, is inert and practically useless, while nitrogen compounds are of great commercial and industrial value, especially in the fertiliser industry and in the manufacture of explosives. The object of the "fixation" of atmospheric nitrogen is to change the elementary nitrogen in the air into some useful nitrogen compound. As there are various useful nitrogen compounds several fixation processes are possible. These will be discussed under the following three headings: nitric acid and nitrates; calcium cyanamide; nitrides and ammonia.

**258. Nitric acid and nitrates.** The simplest fixation process which suggests itself is to take the oxygen and the nitrogen in the air, as they are, and combine as large a portion of them as possible directly into nitrogen oxides (burning the atmospheric nitrogen) and then convert these oxides into nitric acid and nitrates. This is done in the processes of Bradley and

* The Siemens ozone plant for water purification in St. Petersburg is described by Erlwein in *Met. & Chem. Eng'ing*, Vol. IX, p. 213.

† An excellent serial, by A. Vosmaer, on the brush discharge, the production of ozone and its various uses, has been published in *Met. & Chem. Eng'ing*, Vols. XI and XII.

Digitized by Google

Lovejoy, Birkeland and Eyde, Schoenherr (Badische Company) and Pauling, all of which use electric discharges through air to produce a very high temperature. The object of the spark or arc is simply to produce the very high temperature required for the combination of the nitrogen with oxygen, which would go on in the same way if the same high temperature was produced by some other means. The gas mixture of air and nitrogen oxides thus produced is then treated with water or with alkaline solution (caustic soda, lime water, etc.) to give dilute nitric acid, nitrates, or a mixture of nitrates and nitrites.

The higher the temperature, the greater is the content of nitric oxide produced in the air and the quicker is the transformation. This is the reason why the electric arc is so effective. Besides the necessity of producing a high temperature, the second chief requirement is to remove the nitrogen oxide formed as quickly as possible from the high temperature zone and to cool it down as rapidly as possible; the reason is that with decreasing temperatures the opposite reaction takes place and the nitric oxide dissociates into nitrogen and oxygen, so that if the cooling of the mixture of air and nitric oxide is too slow the latter will break up into its constituents. Haber has shown, however, that at low temperatures the formation of nitrogen oxide by means of electric discharges cannot be considered as a purely thermal phenomenon; there seems to be a specific electric effect superposed upon it. At the temperature used in the commercial processes the thermal theory sketched above seems to hold strictly true.*

**259. In the Bradley-Lovejoy process**† mechanical means (rotation of a wheel carrying one set of electrodes which continually pass along an opposite and stationary set of electrodes) are employed to make and break continuously sparks (6,900 sparks per sec.) in the space through which the air is passed. While this process, which was tried for some years at Niagara Falls without attaining final commercial success, represents the era of the spark furnace, the desire to get larger units led to the construction of arc furnaces. The different types differ essentially in the way by which the produced gas mixture is quickly removed from the gas zone.

**260. In the Birkeland-Eyde process**‡ the arc is deviated magnetically by means of a single-phase magnet field, until the arc breaks; then a new arc is formed, etc. The Birkeland-Eyde process has been in successful commercial operation since 1905 in Norway (electric energy being very cheap at the plant, 0.094 cent per kw-hr.).

**261. The Schoenherr furnace.** The Badische Company used successfully for a time the Schoenherr furnace,§ the characteristic feature of which is the use of a very long alternating-current arc around which the air moves in a helical path. This plant has been taken over by the Birkeland-Eyde interests which now use exclusively the Birkeland-Eyde furnace as it has a higher efficiency in larger units.

**262. Pauling process.** Two plants in Tysol and in France employ the Pauling process,‖ using electric discharges quite similar to those obtained in a horn lightning arrestor. The results obtained in these three commercial processes were given in 1909 as follows (no later data being available):

| | Grams $HNO_3$ per kw-hr. | Concentration in per cent. NO |
|---|---|---|
| Schönherr | 75 | 2.5 |
| Birkeland-Eyde | 70 | 2 |
| Pauling | 60 | 1 to 1.5 |

**263. Calcium cyanamide,*** $CaCN_2$ (lime nitrogen; German: Kalkstickstoff: French: Chaux Azotee), is made from calcium carbide and nitrogen (Frank and Caro), the fundamental reaction being

$$CaC_2 + N_2 = CaCN_2 + C \qquad (39)$$

In this process the nitrogen must first be separated from the oxygen in the air (for instance, by fractional distillation of liquid air). Cyanamide may be used directly as a fertilizer, or as a starting material for making other compounds, like ammonia sulphide and nitric acid. Cyanamide may be used to make ammonia by blowing steam over cyanamide, $CaCN_2 + 3H_2O = CaCO_3 + 2NH_3$ and passing the ammonia so produced into sulphuric acid for the production of ammonium sulphate. Another development is the working up of the ammonia (produced from the cyanamide as just described) into nitric acid by the Ostwald contact process.†

**264. Nitrides and ammonia.** The most interesting of the processes for accomplishing the fixation of atmospheric nitrogen by means of nitrides is the Serpek process,‡ which is being tried on a large experimental stage in France. Its principle is first the production of aluminium nitride AlN from a mixture of alumina and carbon in an electrically heated kiln, in an atmosphere of nitrogen or producer gas ($Al_2O_3 + 3C + N_2 = 2AlN + 3CO$) at a temperature between 1,600 and 2,000 deg. cent.; this is followed by the decomposition of the aluminium nitride by water or caustic soda solution, thereby liberating the nitrogen as ammonia and producing an alkaline aluminate solution from which pure alumina can be obtained ($2AlN + 3H_2O = 2NH_3 + Al_2O_3$). The original intention was to use the alumina thus obtained for the production of fresh aluminium nitride so that the process would be cyclic with respect to alumina, and the net result would be the production of ammonia (by addition of the above two equations representing the two steps the net result is $3C + N_2 + 3H_2O = 3CO + 2NH_3$). However, the production of aluminium nitride does not work well with pure alumina. The intention is now to produce simultaneously pure alumina and ammonia and to use the pure alumina for the production of aluminium.

Another process for obtaining ammonia from atmospheric nitrogen is the Haber process§ for the synthesis of ammonia from its elements nitrogen and hydrogen. This process has no electrochemical features except possibly the production of hydrogen by the electrolysis of water.

A useful summary of the subject of utilisation of atmospheric nitrogen (covering proposals and accomplishments, unsuccessful and successful processes) is given by Thomas H. N. Norton in Dept. of Commerce & Labor, Special Agents Series, No. 52 ("Utilization of Atmospheric Nitrogen").

## ELECTROMAGNETIC AND ELECTROSTATIC PROCESSES

**265. Magnetic ore separators.** Although not strictly electrochemical the application of electricity and magnetism to ore dressing may here also be mentioned. There is no real chemical effect, but only a concentration or separation of a finely crushed ore-mixture into its constituents. The principle of magnetic separators is to pass the finely divided ore mixture through a strong magnetic field; the magnetic particles are thereby separated from the non-magnetic ones, since the latter are simply acted upon by gravity, while the former are attracted away from their path by the magnetic field. When they have been separated, they are called magnetic concentrates. A good summary of the practice of magnetic concentration, with description of magnetic separators and special reference to applications in zinc metallurgy may be found in W. R. Ingalls' "Report of the Commission Appointed to

[nvestigate the Zinc Resources of British Columbia" (Canadian Government publication, 1906, pp. 82 to 118) and in C. G. Gunther's book on "Electro-magnetic Ore Separation." See also Ruhoff, *Met. & Chem. Eng'ing*, Vol. X, p. 278.

**266. Electrostatic ore separators.** The action of electrostatic separators depends on the difference in electric conductivity of the constituents of the ore mixture. According to the conductivity, the electrostatic charge acquired by the different constituents from the same source of electric charge in the same time is different. If the mixture consists of a finely crushed non-conductor and a finely crushed conductor and is brought in contact with a charged surface, the latter will receive a charge while the former remains uncharged. Electrostatic repulsions of the charged particles from the charged surface will then result, while the uncharged particles are not repelled. (See paper by Blake in *Electrochemical and Metallurgical Industry*, Vol. III, p. 181; MacGregor, *Transact.* Am. Electrochem. Soc., Vol. XVIII, p. 267, and Vol. XXIV; Wentworth, *Met. & Chem. Eng'ing*, Vol. X, p. 167.)

**267. Dust precipitation by electrostatic means.** The Cottrell process* is based on the old familiar phenomenon of the "electric wind." If a metallic needle point is placed opposite a flat metallic plate and the needle is connected to one pole and the plate to the other pole of a high-voltage direct-current supply line, electricity streams out of the needle point and charges the gas molecules in the space between needle and plate. The gas molecules thus receive an electric charge of the same sign as the needle point, hence opposite to the sign of the charge of the plate. They are, therefore, attracted by the plate and move toward it. Now if the space between the needle point and the plate is filled with a gas or fume in which particles of dust, etc., are suspended, these dust particles will be immediately charged with electricity and will, therefore, move toward the plate, stick to it and give up their charges. The speed of movement of the particles is proportional to their charge and to the electrostatic field intensity in the space between point and plate. Cottrell uses this principle for the precipitation of dust particles from smelter fumes, etc. He employs ordinary commercial high-voltage alternating-current and converts it into intermittent direct-current by means of a specially designed synchronous converter. This intermittent direct-current is directly used for charging the system of electrodes (needles and plates) in the flues which carry the gas under treatment. Instead of using needle points he twists asbestos filaments or mica scales with wires. The electricity passes from the wires by surface leakage over the asbestos or mica, and the fine filaments of the asbestos or edges of the mica provide the required (very fine) discharge points. The process is in successful use in smelters,† cement plants,‡ etc.

**268. Smoke prevention.** The same principle has been proposed for the electric precipitation of smoke (A. F. Nesbit, Elec. Rev., Oct. 31, 1914, p. 877).

## BIBLIOGRAPHY

**269.** One of the best all-around books in English on industrial electrochemistry is Allmand's Principles of Applied Electrochemistry. Other general books are N. Monroe Hopkins, Experimental Electrochemistry; W. G. McMillan and W. R. Cooper, A Treatise on Electro-metallurgy; F. Mollwo Perkin, Applied Electrochemistry; M. de Kay Thompson, Applied Electrochemistry.

A very good general book on electric furnaces is Stansfield, The Electric Furnace. The application in the iron and steel industry is well treated in Rodenhauser and Schoenawa, The Electric Furnace in the Iron and Steel Industry (translated by vom Baur). Lyon, Keeney, and Cullen's, The Electric Furnace in Metallurgical Work (Bureau of Mines, Bull. 77) is very useful.

A standard work on the theory and practice of the electrolysis of aqueous solutions is Foerster's Elektrochemie wässeriger Lösungen. An equally excellent work on fused electrolytes is Lorenz's Elektrolyse geschmolsener Salze, 3 vols. Neither book is available in English.

The titles of the principal books on theoretical electrochemistry and on special fields of industrial electrochemistry are given in connection with their respective subjects.

# BATTERIES

## PRIMARY BATTERIES

### GENERAL

**1. Definitions.** An electric battery is a device for the direct transformation of chemical energy into electrical energy. The term is usually applied to an assembly of identical units or cells, connected in series. In a primary battery, the chemically reacting parts require renewal, whereas in a storage battery, the reactions being reversible to a high degree, the chemical conditions are restored after partial or complete discharge by reversing the current flow, *i.e.*, by electric charge. A primary cell is composed of a containing jar, plates or electrodes with suitable connecting terminals and the electrolytic solution. In certain types of cells, the two electrodes are in different electrolytes, separated by a porous cup.

**2. The poles of a cell are** the junctions of the external circuit with the plates or electrodes, *i.e.*, the terminals. The positive pole is that from which the current flows into the external circuit; the negative pole is the opposite terminal, and in the various practical primary cells, this is the zinc plate. Nevertheless, the zinc or **electrode** connected to the negative pole, is termed the positive plate or electrode. It is the electrode that furnishes positive ions in the action of the cell and it is also usually the more important source of the chemical energy.

**3. The e.m.f. of a cell** is understood to mean its total electric pressure. If current is permitted to flow, the terminal difference of potential or cell voltage is less than the e.m.f. by the amount of drop due to internal resistance, and also by the effects of polarization, and concentration changes in the electrolyte.

**4. The e.m.f. of polarization** is the amount by which the total e.m.f. of the cell is reduced, owing to secondary reactions or to concentration effects in the electrolyte. For example, if current is allowed to flow in the elementary zinc-dilute acid-copper cell, hydrogen appears at the copper electrode, the hydrogen-covered copper acting, as a hydrogen electrode, to reduce the initial pressure of the cell.

**5. Transition resistance.** With certain electrodes and electrolytes the action of the cell results in the deposition of a relatively insoluble or insulating substance on the electrode surface. The effect of this is to increase the internal resistance of the cell.

**6. Depolarizers.** The effect of polarization at an electrode surface may be partly or almost completely eliminated by depolarizing means, which may be either chemical (Par. 7), physical or mechanical. Mechanical depolarization arises from a relative motion of the electrolyte and the plates. It is not employed in practical forms of cells. Physical depolarization results from roughening the electrode surface in order to give it greater area, or it may result from the electro-deposition of a loose mass of metal on the electrode surface, such as platinum black on a smooth platinum surface, etc. The hydrogen escapes more easily from such a surface, and the polarization is considerably reduced.

**7. Chemical depolarizers.** These are of two general types. (a) The electrolyte contains the ion of the metal which constitutes the negative plate, so that, when current flows through the cell, additional metal is deposited on the negative with no escape of hydrogen gas. An example is

Digitized by Google

the copper sulphate in contact with the copper plate of a Daniell or gravity cell, or the slightly soluble mercurous-sulphate paste of the standard Clark or Weston cell.

(b) A chemical compound is present at the negative plate, which is capable of furnishing negative ions to the solution because of its metal constituent possessing different valencies. Examples are the manganese peroxide of the Leclanché or dry cell, and the chromic acid of the bichromate cell. It is of advantage that such depolarisers be relatively insoluble, in order that they do not come in contact with the zinc electrode and thereby suffer reduction.

**8. Measurement of internal resistance and polarization.** The true internal resistance of a cell is obtained from the formula

$$r = \frac{(E - E_p) - V}{I} \quad \text{(ohms)} \qquad (1)$$

in which $E$ is the total e.m.f. of the cell on open circuit, $E_p$ is the opposing polarization e.m.f. and $V$ is the voltage at the cell terminals. If immediately after breaking the current, the cell voltage is determined by the condenser-ballistic galvanometer method, or otherwise, then $E_p = E - V$.

Upon open circuit, after the delivery of current, the opposing e.m.f. of polarization decreases, at first rapidly and then more slowly, owing to the gradual diffusion of the polarizing substances. The curves, Fig. 1 are typical of a dry cell. The heavy curve shows the gradual drop in voltage, the cell being closed through a constant resistance, while the dotted curve (read in the opposite direction) shows the voltage recovery, with time, after the current ceases. The vertical portion of the recovery curve represents the voltage drop due to internal resistance, the further recovery being due to the gradual equalization of concentrations throughout the electrolyte, or in the pores of the electrodes.

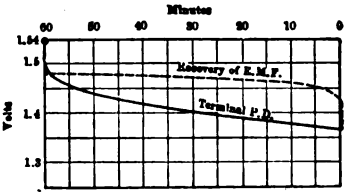

FIG. 1.—Polarization recovery.

**9. Local action.** In all practical forms of battery, the fundamental reactions are somewhat departed from. Local action takes place, resulting from impurities on one or both the electrodes; this action is of the nature of an elementary short-circuited cell. For example, a zinc electrode always contains impurities such as copper, iron and carbon. Zinc is dissolved, hydrogen gas comes off at the point of impurity, and current flows between the impurity and the point where the zinc enters into solution. This action is reduced by **amalgamating** the surface of the zinc with mercury; this forms a solution of zinc, uniformly covering the surface, and greatly reduces the local action.

**10. Electrochemical theory.** Two methods may be employed in the theoretical consideration of primary battery phenomena. One, the general thermodynamic method, the other, a mechanical method resulting from the osmotic-pressure theory of solutions. The e.m.f. of a reversible cell may be calculated from the relation

$$E = \frac{JH}{nq_c} + T\frac{dE}{dT} \quad \text{(volts)} \qquad (2)$$

Where $J$ = mechanical equivalent of heat; $H$ = heat of formation of resultant chemical compound in calories; $q_c$ = charge in C.G.S. units of 1 g. ion, *i.e.*, 9.654 units; $n$ = valency; $T$ = absolute temperature. The first quantity of the right side of the equation is the controlling one, the second usually having a small value. If a cell has a zero temperature coefficient, the e.m.f. can be directly calculated from the heat of formation of the resultant chemical compound of the reaction. The second term may be either positive or negative. The above equation is deduced on the assumption that the cell is reversible, but the voltage of any cell may be closely approximated by its use.

Digitized by Google

**11. Nernst's equation.** The osmotic pressure theory of solutions (see Sec. 19) leads to the equation

$$E = 0.0002T\left(\frac{1}{n}\log\frac{P}{p} - \frac{1}{n'}\log\frac{P}{p'}\right) \quad \text{(volts)} \qquad (3)$$

where $T$ = absolute temperature $n$ and $n'$ are the valencies of the two ions of the electrodes and $p$ and $p'$ the osmotic pressures of these ions in the electrolyte. $P$ and $P'$ are the solution tensions, *i.e.*, are the pressures immediately at the electrode surface. In this theory, which is essentially mechanical, the seat of conversion of the chemical to electrical energy is clearly at the electrode surfaces.

**12. Potential difference between electrode and electrolyte.** In the preceding equation the two terms on the right-hand side are the difference of potential between the corresponding electrode and the electrolyte, and it is at once apparent that the voltage of any cell depends on the concentration of the salts of the electrode metals present in the solution.

The absolute differences of potential of each element in a normal solution of one of its salts may be determined by means of a capillary electrometer, and the solution tension of that element may then be calculated. However the values of the solution tensions thus determined are open to some question.

**13. Reference electrodes.** In Sec. 19, Par. 174, the normal hydrogen and calomel electrodes are defined; they may be used as reference electrodes and the differences of the potential of the various elements in normal solutions of their salts have been observed.

**14. Electrochemical series.** The various elements in normal solutions of their salts may be arranged in a series with reference to their potentials against the normal hydrogen electrode (see Sec. 19, Par. 175). It should be noted that the tabulated values and the order of the potential differences are dependent upon a normal strength of solution. If the elements are immersed in other electrolytes, the values will be quite different. The reader is referred to Le Blanc: *Electrochemie*, 1911, for a complete treatment of this subject. The series is not to be confused with the "Voltaic series" nor with the "Peltier effect."

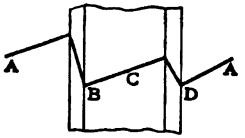

FIG. 2.—Potential diagram.

**15. Potential fall in a cell.** The potential of the various parts of the current path in a cell may be represented diagrammatically as in Fig. 2 in which the lines $A$ are supposed to join at their outer extremities. The section $A$ represents the drop in the external circuit, $B$ is the potential fall in the exceedingly thin film of electrolyte adjacent to the positive electrode, $C$ is that which takes place in the electrolyte and $D$ that in the electrolyte film adjacent to the negative electrode. The thickness of these films in which the potential drops occur, is exceedingly small, as calculated from the osmotic pressure theory.

**16. Concentration cells.** An effect which is small, but which cannot be neglected is the difference of potential which exists at the boundary surface of two solutions of different concentrations. This arises through diffusion of the various ions tending toward equalization of the concentrations on either side of the boundary and the fact that the different ions have different mobilities, that is, under unit force they move at different rates. See Sec. 19, Par. 145 et seq. This effect does not, however, lead to cell constructions of a practically valuable difference of potential.

**17. Classification.** Primary cells may be classified as wet and dry. They are further classified as to their depolarizing means and whether they are single or two fluid. The various applications of primary batteries impose special conditions which the different types in general use possess in very different degree. Dry cells or storage batteries have displaced the other forms of battery to a great extent, although the gravity battery and the Edison Lalande battery have a wide application.

## WET CELLS

**18. The Daniell cell.** The container is usually a glass jar in which is a porous cup. A sheet of copper partly surrounds the outside of the porous

Digitized by Google

cup and is in a saturated solution of copper sulphate containing excess crystals. The zinc (usually amalgamated) is in the porous cup, which contains sulphuric acid and zinc sulphate solution. The e.m.f. of the cell depends on the concentration of the zinc sulphate in the porous pot, the maximum initial value being about 1.14 volts. The cell may be set up with zinc sulphate solution only in the porous cup in which case the e.m.f. is approximately 1.07 volts and has a very small temperature coefficient. The chemical reaction is $Zn+CuSO_4=ZnSO_4+Cu$. The cell is not adapted to stand on open circuit. When placed out of service the liquids should be poured out and the porous cup should be thoroughly washed in running water until all the zinc sulphate is removed, otherwise the cup will crack on drying.

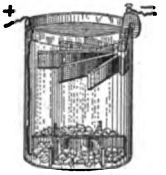

FIG. 3.—Gravity cell.

**19. Gravity battery.** This cell is the usual modification of the Daniell cell, and is shown in Fig. 3. The porous pot is omitted and gravity is depended upon to keep the heavier copper sulphate solution in the bottom of the cell. The zinc is frequently cast in the form of a "crowfoot" and hangs from the edge of the jar. The copper electrode is made of two or three strips of sheet copper, riveted together and spread out in the bottom of the jar. A rubber-covered wire is fastened to the copper and leads upward out of the cell. Copper-sulphate crystals are placed in the bottom of the jar and zinc sulphate solution is added to cover the zinc. The solution should be poured in carefully, so as not to bring copper sulphate solution in contact with the zinc, as copper would be immediately precipitated on the zinc.

**20. Care of gravity battery.** The cell should be kept on closed circuit in order to prevent copper from diffusing upward and precipitating upon the zinc. The edge of the jar should be coated with paraffin to prevent creepage of the zinc sulphate solution. As the top solution becomes saturated with zinc sulphate some of it should be drawn off and carefully replaced with water. The copper sulphate solution must not be stirred up. Evaporation may be reduced by covering the solution with a thin layer of mineral oil. If a heavy copper precipitate is present on the zinc, it should be scraped off. A sharp dividing line should be maintained between the two solutions. This can be noted by color difference. At the top should be a light solution, while the copper sulphate is very dark blue. For each ampere hour, the following amounts of materials are theoretically used up or formed—0.042 oz. copper deposited, 0.043 oz. zinc is dissolved, and 0.164 oz. copper sulphate used up. Local action will require at least a 10 per cent. greater amount of zinc and copper sulphate. Note that the increased copper weight should be credited to the cost of upkeep.

**21. Bunsen or Grove cell.** In the Bunsen cell the zinc plate is in a sulphuric acid solution, while the negative plate is a carbon rod immersed in strong nitric acid, contained in a porous cup. The Grove cell differs from the Bunsen cell only in the use of platinum instead of the carbon. The e.m.f. of this type of cell is about 1.9 to 2 volts and the internal resistance quite low. The cell is adapted for laboratory purposes and can be used for heavy currents. It must not be allowed to stand on open circuit for any considerable time, and must be set up freshly each time it is used.

Vapors of nitric peroxide are given off from the cell and provision must be made for their removal. The chemical reaction of the cell is presented by the equation $Zn+H_2SO_4+2HNO_3=ZnSO_4+2H_2O+2NO_2$.

**22. Chromic-acid cell.** This cell is in wide use for laboratory purposes. It may be used as a single-fluid cell but the porous-cup form is preferable. The Grenet or plunger type is shown in Fig. 4. Two carbon plates are immersed in a solution of potassium or sodium bichromate, sulphuric acid and water. Potassium permanganate is a fairly satisfactory equivalent to the chromic-acid salt. The zinc plate is between the two carbons when lowered for use. The usual solution is made up as follows: water, 12 lb. concentrated sulphuric acid, 2½ lb. and potassium bichromate, 1 lb. Potassium bichromate gives rise to insoluble crystals of chrome alum and the sodium salt is preferable. Chromic acid, on account of its great solubility is to be preferred over either of the above salts, and the quantity used need be but two-thirds of the weight of either of the salts, required for the same

Digitized by Google

effect. The cost of the equivalent weight of the chromic acid is not appreciably greater than the salts. The e.m.f. of the cell is about 2 volts, and the internal resistance extremely low. It can therefore be used for high currents, and, by raising the zinc, can be open circuited. The chemical reaction is represented by the formula $3Zn+2CrO_3+6H_2SO_4=Cr_2(SO_4)_3+3ZnSO_4+6H_2O$.

FIG. 4.—Grenet chromic-acid cell.

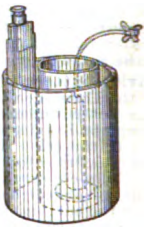

FIG. 5.—Fuller cell.

**23. Two-fluid chromic-acid cell.** In the single-fluid type there is some local action between the zinc, and the chromic acid and a waste of both these materials even when the zinc is amalgamated. It is preferable, therefore, to immerse the amalgamated zinc in a sulphuric-acid solution contained in a porous pot, the chromic-acid solution and carbons being in the outer chamber. The **Fuller cell**, Fig. 5, is of this type and has a restricted use in telephone practice for small local exchanges.

**24. Discharge curves.** In Fig. 6 are discharge curves which illustrate the advantage of the porous cup.

**25. Leclanché cells.** There are many forms of this cell in practical use. In the original form the carbon rod was contained in a porous cup filled with crushed carbon and manganese dioxide, the mixture being tamped to obtain intimate contact. In the later forms, the manganese dioxide and carbon are moulded by the use of a binder into a cylindrical form, the zinc rod being suspended centrally, as in Fig. 7. The electrolyte is a solution

Digitized by Google

of salammoniac. The e.m.f. is about 1.5 volts but the terminal voltage drops rapidly with high currents. The cell is suitable for open-circuit or closed-circuit work, if large currents are used intermittently and for short periods of time. The continuous current demand on closed circuit must not exceed a few hundredths of an ampere, as otherwise the terminal voltage is too greatly reduced by polarization. The chemical reaction is $Zn+2NH_4Cl+2MnO_2 = ZnCl_2+2NH_3+H_2O+Mn_2O_3$. The dry battery, which is a modification of the Leclanché cell, has largely replaced the latter in practical use.

**26. Edison Lalande.** The usual form of this cell comprises a plate of compressed copper oxide on either side of which is a zinc plate with ribs. These ribs serve to hold the plate together until it is worn out. The copper-oxide plate is superficially reduced to cover it with a very thin layer of metallic copper for conductivity. The electrolyte is caustic soda solution covered with a layer of mineral oil to prevent evaporation and the formation of sodium carbonate from the carbon dioxide of the air. The construction of these cells is shown in Fig. 8. The chemical reaction is $Zn+2NaOH+CuO = Na_2ZnO_2+H_2O+Cu$. The e.m.f. of the cell is 0.95 volts and the terminal voltage drops to less than two-thirds of this value when furnishing heavy currents. Its internal resistance is low. It is adapted for both closed and open-circuit work and does not depreciate materially, excepting from the using up of the chemicals corresponding to the ampere-hour output. These cells are available in sizes from 100 to 600 amp-hr. On account of the low voltage, the initial cost of a battery of these cells is relatively high.

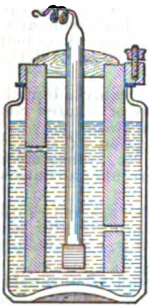

FIG. 7.—Leclanché cell.

FIG. 8.—Edison-Lalande cell.

**27. Carbon cells.** A great deal of effort has been expended to develop a cell which would permit the conversion of the chemical energy of coal and the oxygen of the air directly into electric energy. The difficulties at the present time seem insurmountable on account of the high temperature which must obtain in order for the carbon to enter into a suitable reaction, and because the $CO_2$ necessarily formed, unites with the fused caustic soda electrolyte, which has been proposed. The difficulties in the way of an oxygen electrode are also great.

**28. Standard cells.** The **Clark cell** comprises an electrode of mercury, containing metallic zinc, an electrolyte of zinc sulphate and a depolarizing electrode of metallic mercury, covered with a paste of difficultly soluble mercurous sulphate. The chemical reaction is $Zn+Hg_2SO_4 = ZnSO_4 +2Hg$. In the **Weston cell**, cadmium is substituted for the zinc. Very elaborate preparation of all the materials used in these cells is imperative, and the reader is referred to the extensive literature on this subject. The variation of the e.m.f. with temperature of the practical forms of these cells is given in Sec. 3. These cells are not adapted for closed-circuit work, although they quickly recover their voltage after an appreciable discharge.

## DRY CELLS

**29. Definition.** The only "dry battery" in commercial use is a modification of the Leclanché cell, in which the sal ammoniac solution is held by capillary action in a porous medium separating the zinc from the opposite electrode also in the pores of the carbon-depolarizer electrode.

Digitized by Google

**30. Construction.** In the usual form, the zinc of the negative pole takes a cylindrical shape and constitutes the containing vessel. An absorbent separating medium of pulp, plaster of Paris or paste covers the walls and bottom of the zinc cylinder, and a rod or flat plate of carbon is placed axially inside. A mixture of crushed coke, graphite and manganese dioxide is tamped about the carbon rod to within about 1 in. of the top edge of the zinc cylinder. The whole is mounted in a pasteboard container and the filling mass saturated with a solution of zinc chloride and sal ammoniac. The top is then flooded with an asphaltum sealing compound. The stud of the positive binding post is fixed in a vertical hole in the carbon by running in an expanding bismuth alloy, the hole in the rod being enlarged at the bottom.

**31. The internal resistance** of various makes of dry cells depends slightly upon the absorbent material between the plates, but is principally determined by the fineness of the crushed carbon and manganese dioxide and the degree to which it is tamped when new. The internal resistance is usually less than 0.1 ohm but increases to several times the initial value with age.

**32. The open-circuit voltage** of a new cell is approximately 1.5 volts and is but slightly influenced by temperature. With age the voltage gradually drops, whether the cell is used or not. The terminal voltage on closed circuit is about 1 volt, the greater portion of the drop being due to polarisation. For this reason it is not usually important to determine the internal resistance.

**33. Dry-cell applications.** Dry cells are admirably adapted for such purposes as require minute currents continuously or limited amounts of current intermittently. Among the various applications, may be cited the following: intermittent gas-engine ignition; operation of relay-controlled mechanisms; telephone work; pocket flash-lamps; etc. They are not suited for heavy discharges nor to furnish appreciable currents on continued closed circuit.

**34. Life.** Dry cells continuously depreciate with age and caution should be exercised when purchasing to see that cells are recently made. The better makes become worthless after 12 to 14 months, even on open circuit. A gage as to their condition is therefore desirable.

**35. Dry-cell tests.** Cells for any particular application should be tested under conditions which approximate actual service. The usual method for a large consumer, is to place a number of cells in a rack and by means of resistances and switch contacts operated by a clock mechanism, subject the cells to intermittent discharge at the desired rates and for the desired intervals. A committee of the American Electrochemical Society on dry-cell testing has had this subject under consideration for several years, and its reports in the transactions of this society since 1912 should be consulted.

**36. Qualitative tests.** It is desirable to apply rough selective tests if dry cells are purchased from any but reliable concerns. The best test of this nature is to connect a cell momentarily through an ammeter whose needle is properly damped; for this test the resistance of the outside circuit, including the ammeter shunt, should not exceed 0.01 ohms. According to Ordway (Trans. Am. Elec. Chem. Soc., 1910) a 2½-in.×6-in. dry cell when freshly made should give between 18 and 25 amp. at a temperature of about 70 deg. Fahr. If the cell gives less than 18 amp., age or inferior materials are indicated.

**37. Shelf test.** The user of a considerable number of dry cells should select a few at random for shelf test. This consists in determining the number of months the cells will last before the short-circuit current, taken at monthly intervals, falls to a certain arbitrary value which is customarily taken at 10 amp. Such test cells should be continuously kept at about 70 deg. Fahr., as the shelf life is favorably influenced by lower temperatures. Dry cells depreciate rapidly at high temperatures. Voltage readings on open circuit have little or no value in determining the merits of a cell.

**38. Capacity.** The capacity of a freshly made standard 2½-in.×6-in. dry cell, closed through a circuit of 16 ohms resistance, averages about 25 amp-hr. before the terminal voltage falls below 0.5 volts. Individual cells may show considerably better capacity than this. Considerable data on capacities under various conditions are given by Ordway in the Trans. Am. Elec. Chem. Soc., 1910.

Digitized by Google

**39. Service tests.** The committee on dry cell tests of the Am. El. Chem. Society (Transactions 1912) has recomended the tests described in Par. 40 to 42.

**40. For telephone work.** Connect 3 cells in series through a resistance of 20 ohms for a period of 2 min. during each hour until the terminal voltage falls to 0.93 volt per cell at the end of the 2-min. period. The tests are to continue 24 hr. per day and 7 days per week, and the number of days elapsing until the above limiting voltage is reached is to be noted.

**41. For gas-engine ignition.** Connect 6 cells in series through 16 ohms resistance for two periods of 1 hr. each during each day, 7 days per week. The first discharge may be made during the morning, and the second, late in the afternoon. At the end of each twelfth of the above discharges, shunt the 16-ohm resistance with a 0.5-ohm resistance connected to an ammeter and note the current. The test is considered complete when the current shunted through the ammeter falls below 4 amp., and the total number of hours of actual discharge to this limiting value of 4 amp. is noted.

**42. For flash-lamp service.** Discharge the battery through a resistance of 4 ohms for each cell connected in series for a period of 5 min. once each day, and determine the total number of minutes of actual discharge, the terminal voltage of the last discharge being limited to 0.75 volt per cell.

## STORAGE BATTERIES

**43. Definitions.** Cells which are reversible to a high degree, *i.e.*, those in which the chemical conditions after discharge are brought back to the original condition simply by causing current to flow in the opposite direction, or "charge," may be used as storage batteries. Storage batteries are sometimes termed **electric accumulators.**

**44. Reversibility.** In all the practical forms of storage batteries, both the electrode materials and the products of the chemical reaction are relatively insoluble. The form of the electrodes is practically unchanged with use, or at least it changes but slightly. Many of the cells in which the reaction products are soluble and which are ordinarily used as primary batteries can be used as storage batteries. For example, the Daniell or gravity cell and also the Edison-Lalande cell are reversible to a high degree, but have practical disadvantages contributing against their use as storage batteries.

**45. Classification.** The storage battery which is in widest commercial use, for various purposes, is the lead-sulphuric acid type. The only other type which is of any prominence is the nickel-iron-potash battery, apparently first proposed by Darrieus, then by Jungner and developed in commercial form by Edison. The use of cadmium instead of iron as a negative plate, the battery otherwise being quite similar to the Edison, is due to Hubbell and his battery is in extensive use for miner's lamps.

**46. Positive and negative plates.** The positive terminal or pole of a battery is that one from which the current flows into the external circuit. In storage battery practice, a positive plate is one which is connected to the positive pole, and the negative plate, the one which is connected to the negative pole. It should be specially noted that this is the reverse of primary-battery terminology. The U. S. Patent Office has attempted to avoid confusion in this regard by insisting on the use of the terms, **"positive-pole plate"** and **"negative-pole plate,"** but this has not come into general use.

**47. The e.m.f. or open-circuit voltage** of any storage cell depends wholly upon its chemical constituents and not in any way upon the number or total area of its plates. It varies further with the strength of the solution, or electrolyte, and its temperature, and to a minor extent, upon the state of charge of the plates. Upon charge, the terminal voltage of the cell rises, and, upon discharge, it falls, due to the internal resistance and to a number of more or less obscure causes, such as polarisation, acid-concentration effects, etc.

**48. The capacity of a cell** with a definite type and thickness of plate is in proportion to the plate area. The size of a cell is usually stated in terms of its ampere-hour capacity at a standard temperature of 70 deg. fahr., but it is necessary, also, to state the discharge rate, as the capacity of all practical forms of batteries is lower with increasing discharge rates.

**49. Battery voltage.** The voltage of a battery is that of each cell multiplied by the number of cells connected in series.

# LEAD STORAGE BATTERIES

## GENERAL

**50. Theory.** The active material of the lead storage battery is lead peroxide ($PbO_2$) on the positive plate or electrode and finely divided, or sponge lead (Pb), on the negative plate. The plates are immersed in a solution of sulphuric acid and water ($H_2SO_4+H_2O$) called electrolyte. On discharge of the battery, both these active materials are quantitatively converted into lead sulphate, ($PbSO_4$) at the expense of the acid radical of the electrolyte and with the formation of water. Precisely the reverse action takes place upon charge of the battery and these reactions may be represented by the following chemical equations:

Reaction at positive plate:

$$PbO_2+H_2SO_4=PbSO_4+H_2O+O \qquad (4)$$

Reaction at negative plate:

$$Pb+H_2SO_4=PbSO_4+2H \qquad (5)$$

Combined reaction at positive and negative plates:

$$PbO_2+Pb+2H_2SO_4=2PbSO_4+2H_2O \qquad (6)$$

Eq. (6), read from left to right, is the equation of discharge; read from right to left shows the reactions during charge. The above reactions are those which normally take place. If impurities are present either in the plates themselves or in the electrolyte, these normal reactions may be departed from.

**51. The active materials,** lead peroxide on the positive plate and spongy lead on the negative plate, are crystalline in structure, the masses being held together by the intergrowth of the crystals. The positive active material probably exists in the cell as a hydrated peroxide of lead; when fully charged it has a very dark brownish-black color, but the color of the positive plate as a whole may be somewhat masked by the presence of loose particles of white lead sulphate which have become detached from the active mass. The positive plate becomes reddish brown in color with proceeding discharge. The color of the negative active material is that of metallic lead after it has been exposed to air, and is somewhat darker when the plate is discharged. These active materials are supported on the plates in either of two ways. With Planté plates, they form rather dense, thin layers, formed from a massive lead blank with a highly developed surface and cohere to the surface. With pasted plates the active materials are cemented masses supported in a grid, usually of lattice form.

**52. The capacity of a cell** is stated in ampere-hours, at some normal rate of discharge. The 8-hr. rate is standard with lead cells of the stationary type. No standard rate has been adopted for the other types.* The capacity of a plate varies with the amount of active material, but not directly, because its mass initially does not hold enough acid to convert it to lead sulphate. Diffusion of acid into the mass is quite slow, so that the higher the discharge rate, the more nearly is the plate surface the determining factor. The capacity of a cell at the higher rates of discharge depends, therefore, on the area of its plates, their number, and, to a minor extent, on the thickness of plates. With low discharge rates, a sufficient amount of acid diffuses into the interior of the active material to permit this portion to be acted upon.

**53. The amount of active material converted into lead sulphate per ampere-hour of discharge,** is 0.135 oz. (avoirdupois) of sponge lead, and 0.156 oz. of lead peroxide, independent of the discharge rate. Reduction of capacity with high rates is the result of using up the acid in the pores of the active material, and lack of time for fresh acid to diffuse from the electrolyte to replace it. Diffusion is also hindered by the reduction of porosity on the surface of the active materials, due to the formation of lead sulphate, which occupies a greater volume than either the sponge lead or lead peroxide. The amount of active material actually present in a plate, is some three to six times that converted into lead sulphate, part of this excess being present for the life of the plates.

* For standard rate proposed by Standards Committee, Soc. Automobile Engineers, for gas-car batteries, see Sec. 22.

Digitized by Google

**54. The open-circuit voltage** of a lead cell varies between 2.06 to 2.14, according to the strength of electrolyte and temperature and is independent of the size of a cell. Charge and discharge characteristics are given under descriptions of the various types.

**55. The variation of voltage** is approximated by the following formula, due to Streintz:

$$E = 1.850 + 0.917(G - g) \qquad \text{(volts)} \qquad (7)$$

in which $E$ = e.m.f. in volts; $G$ = specific gravity of electrolyte, and $g$ = specific gravity of water at the cell temperature.

**56. Test or reference electrode.** It is often desirable to determine the relative performance of the positive and negative plate groups in a cell and this may be done by taking the voltage between either group and a reference electrode of zinc, spongy lead or, preferably, cadmium.

**57. A typical discharge curve** for a stationary type of cell is shown in Fig. 9, also the curves for both positive and negative groups with reference to cadmium. Curve (1) shows the cell voltage, curve (2) the voltage of the positive group and cadmium, while curve (3) represents the voltage for the negative group and cadmium. Fig. 10 shows the corresponding curves for charge.

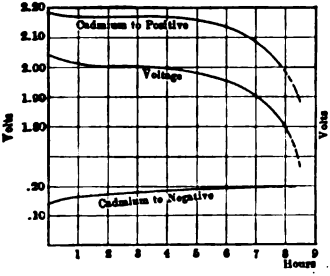

FIG. 9.—Discharge curves.

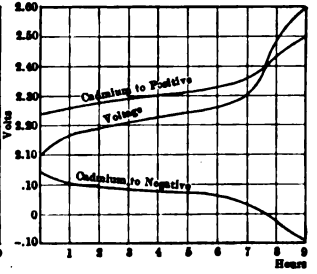

FIG. 10.—Charge curves.

**58. Cadmium tests.** The cell voltage is the difference between the positive-cadmium and the negative-cadmium voltages. In Fig. 9 the discharge curves are continued in dotted lines and, the greater portion of the final voltage drop occurring with the positives, show that the capacity of the cell, in this instance, is limited by the positive group. This is a desirable condition, as most negatives suffer from overdischarge more than do the positives.

**59. Lead battery plates are classified** thus: Planté plates (Par. **60**) and pasted plates (Par. **62**).

**60. Planté plates** comprise a mass of lead, usually of flat form with a highly developed surface. The increased surface is obtained by casting a cellular structure, or by scoring or cutting a blank of heavy sheet lead. The active material is electrochemically formed as a coherent layer of lead peroxide at the expense of a film of the underlying lead. Such plates are always formed as positives, but Planté negative plates are obtained from the positives by connecting them as negatives in a cell, and charging whereby the active material is reduced to sponge lead.

**61. The original Planté process of formation** consists of charging the plates alternately in opposite directions; each successive reversal under proper conditions of temperature, strength of electrolyte and current increases the capacity of the plates. This method is extremely wasteful of current and requires a long time; it has been abandoned in favor of accelerated forming processes which consist of making the plate to be formed an anode in an electrolyte of dilute sulphuric acid containing a small amount of nitric, perchloric or other acid which dissolves lead. The current density,

Digitized by Google

strength of acids and temperature must be properly related to obtain a successful result.

**62. Pasted plates** take the form of a flat basket-like frame or grid, pasted with a mass of lead oxide under cementing conditions. After the mass is thoroughly cemented, the plates are assembled in a dilute sulphuric-acid electrolyte and charged. The oxide mass becomes lead peroxide on the positives and sponge lead on the negatives.

**63. Processes in paste manufacture.** There are many ways of making paste masses which have been proposed and great merits have been claimed for special processes. All the practical paste processes, however, depend in principle on the cementing action resulting from the formation of lead sulphate. Plates can be pasted with a stiff mixture of lead oxide and water and then immersed in dilute sulphuric acid solution. The resultant sulphating hardens the mass. Another method is to mix the oxide with dilute sulphuric acid or a solution of ammonium sulphate and stir to a uniform thick paste, which is then smeared into the grids quickly and before much sulphating has had time to take place.

**64. Combination of Planté and pasted plates.** Pasted plates of one polarity can be used with Planté plates of the opposite polarity and *vice versa*, but plates of different design or age should not be assembled together in any single positive or negative group in a cell. If this is attempted, local action takes place between the different plates.

**65. Depreciation of Planté plates.** Planté positive plates wear in service, by gradually shedding their active material and, as fast as this occurs, new lead automatically is corroded and formed to lead peroxide at the expense of the original reserve of metallic lead of the plate. The life of these plates is at an end when the lead becomes so corroded that the plate is mechanically weak. A good positive Planté plate is capable of giving 1,800 to 2,400 cycles of complete charge and discharge at the 8-hr. rate.

Planté negative plates in use show a physical shrinkage of their active material, and, associated with this, a shrinkage of capacity. Good Planté negatives have a capacity of 75 per cent. to 100 per cent. in excess of their rated capacity to provide against this factor. They should give 2,500 to 3,000 cycles of charge and discharge at the normal rate before falling to 80 per cent. of their rated capacity.

**66. Depreciation of pasted plates.** Pasted positive plates lose their active material by gradual shedding which, however, should not begin until after 60 to 70 cycles of charge and discharge. The capacity is maintained so long as there is sufficient remaining active material. Plates 0.25 in. thick should give 600 to 800 complete cycles of charge and discharge at the 8-hr. rate, before falling to 80 per cent. of their rated capacity. Plates 0.125 in. thick should give some 300 or more complete cycles of charge and discharge.

Pasted negative plates would show the same physical shrinkage of active material as Planté negatives, if it were not for the incorporation of materials such as lamp-black, barium sulphate or kaolin, termed **expanders**, into the oxide pastes. Pasted negatives can be somewhat thinner than pasted positives to show the same life.

**67. Permanizing process.** Instead of mixing expanders (Par. **66**) with the paste, certain substances can be deposited in the pores of the active material to produce a like result, after the plates are formed. Jos. Bijur perfected a process of soaking negatives in sugar solution and subsequently carbonising the sugar. He also brought forward a process of precipitating barium sulphate in the pores of the spongy lead. The process is specially applicable to Planté negatives.

**68. Growth of Planté plates.** All Planté positives show the characteristic of growth in service. The lead peroxide occupies more volume than the lead from which it is formed, and this action finally causes the lead to stretch. For this reason, they are usually made of smaller dimensions than the negative plates with which they are used. In some cases, the growth takes place unequally on the two sides of the plate, this causing a deformation or **buckling**. As the positives grow their capacity usually increases very appreciably.

Attempts have been made to reduce buckling of Planté positives by subdividing them and allowing for growth of individual sections. These

Digitized by Google

methods have not proved very successful in practice and have largely been abandoned.

**69. Tudor Positive.** Fig. 11 is a "Tudor" positive. It is a cellular casting of pure lead. It has claimed for it the characteristic of remaining straighter in service than other Planté types and that it shows a minimum of buckling. No centre web is employed, an open type of construction being adopted.

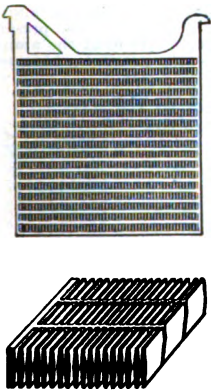

FIG. 11.—Tudor positive and section.

**70. Centre-web positives.** Figs. 12 and 13 show Planté positives made from a sheet-lead blank, the surface being increased by plowing leaves in the first

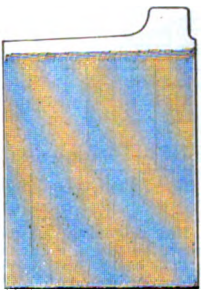

FIG. 12.—Willard "plowed" plate.

instance, and by "**spinning**" with rotating circular discs in the latter. A section of the latter plate is shown in Fig. 14.

**71. Manchester positive.** Fig. 15 shows a Manchester positive, comprising a casting of lead antimony with a number of round holes symmetrically spaced. Into these holes are inserted spiral coils of corrugated lead ribbon. The plate as a whole is electrochemically formed, but the frame

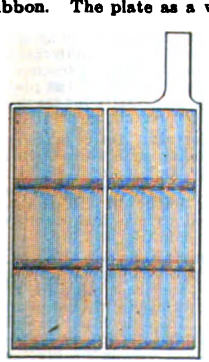

FIG. 13.—Gould "spun" plate.

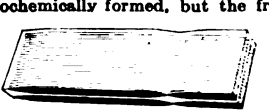

FIG. 14.—Section of Gould "spun" plate.

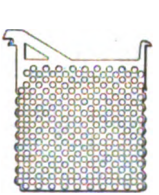

FIG. 15.—Manchester positive.

work is but slightly corroded. This makes a very rugged plate. It will not show as good a life in possible number of cycles of charge and discharge as the pure-lead Planté plates, but this is largely counterbalanced by its rigidity. The plate is, however, much more sensitive to overcharge than are the other Planté plates.

Digitized by Google

**72. Planté negatives.** Any of the foregoing Planté positives can be used as negatives by reversal, but the general form of Planté negative is that shown in Figs. 12 and 13, since these can most readily be given the required excess capacity.

**73. Paste-plate grids.** A section of the usual pasted-plate grid termed the shelf type is shown in Fig. 16 and a modification which is in considerable use in Fig. 17. The grids are cast of an antimony-lead alloy, the antimony content being sufficient to make the grids stiff. The presence of the antimony also serves, to a considerable degree, to limit the amount of corrosion which would otherwise take place on the positive grid in service.

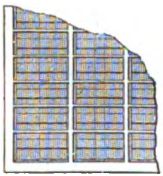

FIG. 16.—"Shelf type" grid.

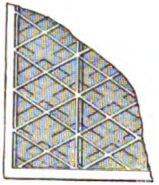

FIG. 17.—"Diamond" grid.

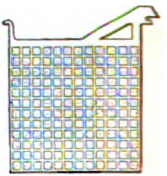

FIG. 18.—Box negative.

**74. Box negative.** A pasted plate which is in wide commercial use in stationary batteries, is the box negative of the Electric Storage Battery Co. The grid is cast in two halves, the outside of each half grid consisting of a very thin perforated sheet lead. Loose pellets of oxide paste are dropped into one-half, the other half grid then being placed on top and both are riveted together. This plate is shown in Fig. 18.

**75. Ironclad positive.** Another type of pasted plate which is considerably used is the positive of the "Exide Ironclad" battery. This plate, Fig. 19, comprises a number of vertical pencils or units supported in a frame of lead-antimony alloy. Each pencil or unit has a central core of lead-antimony alloy of somewhat irregular section. A layer of lead peroxide surrounds this core and is retained by a slotted cylindrical casing of hard rubber. The slots are so small that the particles of active material do not readily fall out. It is claimed that the presence of the casing greatly increases the useful life of the plate. The Ironclad battery is used principally for traction purposes.

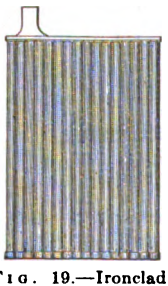

FIG. 19.—Ironclad positive.

**76. Quality of paste materials.** Active materials of pasted plates vary in quality with the chemical purity of the oxides partly, but it is of equal or greater importance that the physical properties meet rigid specifications. A high degree of skill and accurate information is required to produce an active material having the requisite capacity and life.

**77. The essential differences between the practical forms of Planté and pasted plates** are the following: Planté plates are heavier, more bulky and cost more for the same capacity. They will give a greater number of cycles of charge and discharge than can be obtained from pasted plates. In many cases, weight and space are the controlling requirements to be met and in this case pasted plates are used. If a battery is required for insurance of power supply, and is used only in rare emergencies, pasted plates can be used. If a battery is required to withstand continued heavy service, and weight and space are not an important consideration, Planté plates are used.

**78. Electrolyte variations.** When a lead battery discharges, the amount of sulphuric acid which combines with the active materials is in quantitative proportion to the number of ampere hours discharged. The

Digitized by Google

density of the electrolyte varies with its acid content, and the change in density may be used as a measure of the state of charge of the battery, if the initial and final specific gravities are known.

**79. The quantity of electrolyte required** for 100 amp-hr. discharge is calculated from the following formula.

$$G_o = \frac{1290 - 10.53d}{D - d} \quad \text{(oz.)} \qquad (8)$$

in which $G_o$ = number of ounces of electrolyte per 100 amp-hr. of discharge; $D$ = per cent. of $H_2SO_4$ in the electrolyte at the beginning of discharge; and $d$ = per cent. of $H_2SO_4$ at the end of discharge. For a capacity $G$ other than 100 amp-hr. multiply $G_o$ by $G \div 100$.

When the value of $G_o$ for 100 amp-hr. and either the initial or final density of the electrolyte are known, then that density, which is unknown, can be determined from the following:

$$D = \frac{1290 + d(G_o - 10.53)}{G_o} \qquad (9)$$

and

$$d = \frac{1290 - G_o D}{10.53 - G_o} \qquad (10)$$

**80. The change in acid strength is not immediate;** it lags behind the values determined in Par. **79** on account of the fact that time is required for the strong acid to diffuse into the plate on discharge, and for the strong acid to diffuse out of the pores of the active material on charge.

Fig. 20. —Hydrometer.

**81. Separation.** It is essential that plates of opposite polarity be kept from coming in contact with each other. This is insured by the use of ribbed perforated sheets of hard rubber, glass spacing tubes or, more frequently, wood **separators.** The wood used is selected for a minimum content of such constituents as would be injurious to the plates and it is usually subjected to a treatment to reduce such constituents still further.

**82. Lead burning of joints.** The use of solder must be avoided in storage-battery construction. Joints are made by lead burning, by which is meant the melting together of the lead parts by a hydrogen flame. This flame deoxidizes the melted lead, and the two parts readily flux together.

Fig. 21.—Syringe hydrometer.

## ELECTROLYTE AND WATER

**83. The electrolyte** used in lead storage batteries is a solution of sulphuric acid and water. The sulphuric-acid content determines the density of the solution, *i.e.*, its specific gravity (sp. gr.)or the ratio of its weight to that of an equal volume of water.

**84. Hydrometer.** The specific gravity of electrolyte is practically determined by the use of an hydrometer which comprises a weighted glass bulb with a graduated stem. In strong acid the stem protrudes further above the surface of the solution, and the point at which the top of the meniscus touches the scale is read off directly in degrees of specific gravity.

With stationary types of cells there is usually space enough between plates or at the end of the tank to float a flat bulb hydrometer directly in the acid of the cell. This type of hydrometer is illustrated in Fig. 20.

**85. Syringe hydrometer.** With vehicle and other types of batteries with small separation between plates, a convenient method to determine the acid density is to employ a syringe hydrometer as illustrated in Fig. 21; the hydrometer floats within the enlarged portion of the glass barrel when acid is sucked into it by means of the rubber bulb.

**86. Table of Sulphuric-acid Solutions**
(Based on one part acid of 1.835 sp. gr. at 60 deg. Fahr.)

| Specific gravity of solution (70 deg. Fahr.) | Parts of water to one part acid | | Percentage of sulphuric acid in solution |
|---|---|---|---|
| | By volume | By weight | |
| 1.100 | 9.8 | 5.4 | 14.65 |
| 1.110 | 8.8 | 4.84 | 16.0 |
| 1.120 | 8.0 | 4.4 | 17.4 |
| 1.130 | 7.28 | 3.98 | 18.8 |
| 1.140 | 6.68 | 3.63 | 20.1 |
| 1.150 | 6.15 | 3.35 | 21.4 |
| 1.160 | 5.7 | 3.11 | 22.7 |
| 1.170 | 5.3 | 2.9 | 24.0 |
| 1.180 | 4.95 | 2.7 | 25.2 |
| 1.190 | 4.62 | 2.52 | 26.5 |
| 1.200 | 4.33 | 2.36 | 27.7 |
| 1.210 | 4.07 | 2.22 | 29.0 |
| 1.220 | 3.84 | 2.09 | 30.2 |
| 1.230 | 3.6 | 1.97 | 31.4 |
| 1.240 | 3.4 | 1.86 | 32.5 |
| 1.250 | 3.22 | 1.76 | 33.7 |
| 1.260 | 3.05 | 1.66 | 35.0 |
| 1.270 | 2.9 | 1.57 | 36.1 |
| 1.280 | 2.75 | 1.49 | 37.3 |
| 1.290 | 2.6 | 1.41 | 38.5 |
| 1.300 | 2.47 | 1.34 | 39.65 |
| 1.320 | 2.24 | 1.22 | 42.0 |
| 1.340 | 2.04 | 1.11 | 44.1 |
| 1.360 | 1.86 | 1.01 | 46.3 |
| 1.380 | 1.7 | 0.92 | 48.4 |
| 1.400 | 1.56 | 0.84 | 50.5 |
| 1.500 | 1.0 | 0.55 | 60.15 |
| 1.600 | 0.639 | 0.348 | 69.12 |
| 1.700 | 0.369 | 0.201 | 77.6 |
| 1.800 | 0.1192 | 0.0646 | 87.5 |
| 1.835 | 0.0 | 0.0 | 93.19 |

**87. Mixing electrolytes.** If concentrated sulphuric acid and water are mixed a great amount of heat is generated. If electrolyte is prepared from concentrated acid, the acid should be added to the water. Never add water to concentrated sulphuric acid. Mixing should be done in a glass or earthenware vessel or a hard rubber jar.

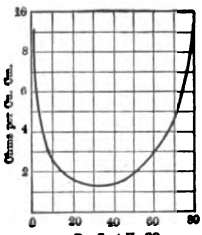

FIG. 22.—Electrolyte resistance.

**88. Temperature.** The density of electrolyte decreases with increased temperature on account of expansion, although the actual strength remains the same. A temperature of 70 deg. Fahr. is taken as standard and since the specific gravity of electrolyte varies approximately 0.001 for each 3 deg. Fahr. difference in temperature, the specific gravity at any temperature within practical limits is reduced to that at standard temperature by adding or subtracting 0.00033 for each degree Fahr. above or below 70 deg.

**89.** The **resistance of the electrolyte varies with its specific gravity** and with temperature. The curve shown in Fig. 22 indicates that at the extremes of dilution or concentration the resistance is highest and is a minimum at a specific gravity of 1.224, or when the proportion of acid is 31 per cent. Its temperature coefficient is negative, the resistance reducing with increase of temperature. Table (**90**) gives the resistance in ohms of 1 c.c. of electrolyte of varying densities and at different temperatures. It will be seen that the decrease of resistance with increase in temperature is very marked.

Digitized by Google

**90. Table of Resistance of Electrolyte for Various Temperatures and Specific Gravities**

| Spec. grav. at temps. given | 32 F. | 47 F. | 61 F. | 75 F. |
|---|---|---|---|---|
| 1100 | 1.43 | 1.122 | 1.00 | 0.91 |
| 1200 | 1.33 | 0.900 | 0.73 | 0.62 |
| 1300 | 1.35 | 1.000 | 0.79 | 0.43 |
| 1400 | 1.89 | 1.425 | 1.05 | 0.82 |

**91. Freezing point of electrolyte.** The freezing point of the electrolyte of fully charged batteries is quite low; however, the electrolyte of partly or fully discharged batteries will freeze at low temperatures. If batteries are to be subjected to such temperatures, it should be seen to that they are fully charged. The freezing point of sulphuric acid solutions is given in the following table:

| Sp. gr. | Temp. (deg. Fahr.) | Sp. gr. | Temp. (deg. Fahr.) |
|---|---|---|---|
| 1.060 | 25 | 1.220 | −31 |
| 1.080 | 22 | 1.240 | −51 |
| 1.100 | 18 | 1.260 | −75 |
| 1.120 | 14 | 1.280 | −90 |
| 1.140 | 8 | 1.300 | −95 |
| 1.160 | 2 | 1.320 | −80 |
| 1.180 | −6 | | |
| 1.200 | −16 | | |

**92. New electrolyte.** The presence of impurities in a cell is objectionable (Par. 97). In acid used for the first filling of cells they should not exceed the limits cited in Par. 93.

**93. Maximum allowable impurities in electrolyte for first filling (initial charge).**

| | |
|---|---|
| Color | Colorless |
| Suspended matter | Trace |
| Platinum | Trace |
| Antimony and arsenic | Trace |
| Manganese | 0.0025 per cent. |
| Iron | 0.005 per cent. |
| Copper | 0.0025 per cent. |
| Nitrogen in any form | Trace |
| Chlorine | 0.001 per cent. |
| Organic matter | None |

**94. Maximum allowable impurities in water used for replacing evaporation.** In the operation of a battery, the electrolyte loses water by evaporation, also some water is electrolytically decomposed. Water must be added to the cells, and any impurities it might contain would be cumulative. The maximum limits of impurities in water for storage-battery purposes are given in the following table:

| | |
|---|---|
| Color | Colorless |
| Suspended matter | Trace |
| Total solids | 10 parts per 100,000 |
| Calcium and magnesium oxides | 4 parts per 100,000 |
| Iron | 0.05 parts per 100,000 |
| Ammonia as $NH_4$ | 0.8 parts per 100,000 |
| Organic matter | 0.1 parts per 100,000 |
| Nitrates as $NO_3$ | 1.0 parts per 100,000 |
| Nitrates as $NO_2$ | 0.5 parts per 100,000 |
| Chlorine | 1.0 parts per 100,000 |

Digitized by Google

**96. Water supply and storage.** The use of distilled water is preferable, but frequently local sources of supply will meet the requirements. The different battery makers are usually glad to report on the suitability of waters from different sources if samples are submitted by users of their batteries. Otherwise, an analysis should be obtained from a competent chemist, if any doubt exists. A 2-quart sample in an absolutely clean glass or rubber-stoppered bottle should be submitted for this purpose. Well water is nearly always to be rejected, and hot well water from condensers usually contains impurities arising from cylinder oils or boiler compounds. Rain water is suitable if taken from clean roofs. Water should be stored so that it is not contaminated by dust or foreign matter, and, if chemical or ice factories are in the neighborhood, the possibility of absorption of acid or ammonia vapors must be guarded against.

**96. Replacement of electrolyte.** If the battery has been in service a long period and impurities have been accumulated through the use of impure water or otherwise, the electrolyte may require renewal. The table in Par. **97** will determine if this is required.

**97. Maximum allowable impurities in electrolyte for batteries in service.**

| | |
|---|---|
| Color | Colorless |
| Suspended matter | None other than lead compounds |
| Platinum | Trace |
| Antimony and arsenic | Trace |
| Manganese | 0.005 per cent. |
| Iron | 0.01 per cent. |
| Copper | 0.005 per cent. |
| Nitrogen in any form | Traces |
| Chlorine | 0.002 per cent. |
| Organic matter | Trace |

**98. Effects of impurities.** Of the impurities mentioned in Par. **96**, those which are metallic will be precipitated at once upon the negative plates if they are less electronegative than lead, and the electrolyte of a cell will not show anything more than traces of such impurities. Their presence is indicated, if, on open circuit, the negative plates of a cell gas continuously. Platinum is the worst of these metals in this respect.

The presence of iron and manganese compounds in electrolyte is decidedly injurious, as they are reduced to lower states of oxidation when in contact with the negative plates, and reoxidize when in contact with the positive plates—in both cases with the formation of lead sulphate from the active materials of the plates. The presence of nitrous or nitric acid or its compounds, or any chlorine compounds, is especially injurious, as these tend to corrode the unformed lead of the positive plates. Organic acid or organic matter which may readily be oxidized to acids, will act in the same manner.

The possible injuries resulting from the presence of iron, chlorine or nitric acid, are of much greater consequence in giving a battery its initial or developing charge. A high degree of purity of the electrolyte must, therefore, be assured before using it in new cells, if obtained from any other source than the battery manufacturer. Old cells will withstand much greater quantities of foreign substances.

**99. Rough qualitative tests for the presence of iron** or chlorine which are the more frequent impurities may be carried out as follows: Fill a test-tube to approximately one-third of its capacity with electrolyte, add one or two drops of dilute nitric acid and heat to the boiling point. Then allow the contents to cool and add ammonia solution until the acid is thoroughly neutralized. As soon as the solution does become netural, a light brown, loose, flocculent precipitate of iron hydrate will indicate the presence of an appreciable amount of iron, in which case the electrolyte should be carefully examined for its iron content.

**100. The qualitative test for chlorine** is to fill a test-tube approximately one-third full of electrolyte, and add a few drops of a very dilute solution of

Digitized by Google

silver nitrate. If the solution becomes opalescent, the electrolyte should be examined carefully for chlorine content. A great excess of chlorine will be indicated by the test solution becoming curdy.

## TESTING

**101. Preliminary.** Before starting a test on a lead-acid type of storage battery, see that it is fully charged and in good condition. The acid should be pure and its strength adjusted to that which is recommended by the maker as standard for the type. If the battery is new, insure that it is fully developed by taking several preliminary discharges; the capacity of a battery increases very considerably with the first few cycles of charge and discharge. Before starting tests for capacity or efficiency, continue the charge at the normal or 8-hr. current rate for a stationary type of battery, or at the "finishing" rate (usually about one-half of the normal rate) for pasted plate batteries, until neither cell voltage nor acid density show a further increase for four 15-min. intervals, which will indicate that the battery is fully charged.

**102. Capacity tests.** Since the capacity depends on the rate of discharge, it will be advisable, with stationary types of batteries, to obtain test discharges at several different rates; in particular, those most nearly approximating the desired service conditions. Nearly all the makes of storage batteries will perform the higher discharge rate if they will give full capacity at the normal or 8-hr. rate. In conducting the usual tests, the charges should preferably take place at the normal rate. When the discharge is started, the current should be maintained as steady as possible and should continue until the cell voltage has reached its limiting value. Voltage readings should be taken at stated intervals and the strength of acid, temperatures and possibly also cadmium readings should be taken at the same time. The same readings should be taken on the subsequent charge. It is advisable to plot these readings, as any discrepancies will then be apparent. The ampere-hour capacity of the cell will be the average amperes multiplied by the time of discharge in hours. The watt-hour capacity will be the ampere-hours multiplied by the average voltage of discharge, provided the current is maintained reasonably steady.

**103. Characteristic performance.** A complete series of tests as outlined in Par. **102**, carefully plotted, will give the battery characteristics. With a set of these curves, the performance of a battery can be quite definitely determined. It is of little value, from an engineering standpoint, to know the internal resistance of a cell, except for highly special applications, as the drop in voltage due to polarization, usually greatly exceeds the resistance drop. The expression of "**virtual internal resistance,**" which is an attempt to include polarization effects is also of no value, as it contains no time factor, and the time the discharge is to last is of extreme importance.

**104. An approximate way of determining the internal resistance of a cell** is to proceed as follows: momentarily interrupt the current and note the instantaneous increase in cell voltage, preferably by the condenser, ballistic galvanometer method. The difference between the terminal voltages with and without the current flow is the resistance drop; dividing this difference by the current will give the approximate value of the internal resistance. Values determined by the wheatstone bridge method with alternating current will be in error on account of the capacity effect which any electrode shows in an electrolyte.

**105. Efficiency tests.** The efficiency of a storage battery is the ratio of watt-hours of discharge to watt-hours of charge and should be determined as the mean of several charges and discharges, as there is no absolutely definite point to terminate either the charge or discharge. The condition to be met is simply that the battery must have received sufficient charge each time, to insure full capacity on the succeeding discharge. The efficiency should be taken as the ratio of the total watt-hours of discharge to the total watt-hours of charge, for all the charges and discharges. For efficiency tests, the end point of charge should be taken as the point when both positives and negatives are gassing uniformly, the voltage showing the same value for two read-

Digitized by Google

ings taken 15 min. apart, and the acid density having reached a value within 0.003 deg. sp. gr. of the maximum value reached on the thorough overcharge before starting the test. The terminating point of discharge should be taken as that at which the battery has discharged the desired number of ampere-hours; the specific gravity of the acid, corrected for temperature, if necessary, should show approximately equal values at the end of each discharge. Failure to observe the above points, especially temperature effects, may cause serious errors in the determination. The room temperature should be maintained as nearly constant as practicable.

## BATTERIES FOR STATIONARY PURPOSES

**106. Batteries for power-plant purposes** are usually designed with the idea that combined capital and maintenance charges shall be a minimum. For this reason, if a battery is in constant active service, Planté plates are used, but if the main consideration is insurance of continuous power supply, or "stand-by" service, pasted-plate batteries will usually prove to be the more economical. Pasted-plate batteries are lighter, require less room, cost less, and, if but a limited number of discharges are required, will be equally long lived as the Planté-plate batteries. Considerable attention is given to the details of stationary batteries in order to insure reliability and life.

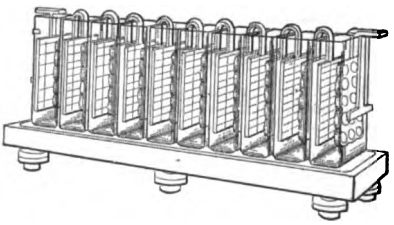

FIG. 23.—Couple type cells.

**107. Plate sizes.** For small requirements the **couple types** are applicable, the construction details being apparent from Fig. 23. The capacities available in this type are the following:

| Size of plate (in.)..... | 3 by 4 | 4 by 4 | 5 by 5 | 6 by 6 | 5 by 8½ | 7½ by 7½ |
|---|---|---|---|---|---|---|
| 8-hour capacity (ampere-hours)..... | 7 | 10 | 15 | 20 | 24 | 40 |

For greater capacities with the regular cell constructions the following sizes of plates are used:

| Size of plate (in.)..... | 7½ by 7½ | 10½ by 10½ | 15½ by 15½ | 18½ by 18½ | 15½ by 31 |
|---|---|---|---|---|---|
| 8-hour capacity (ampere hours)..... | 40 | 80 | 160 | 240 | 320 |

**108. Choice of plate size.** As a general rule the smallest size of plate should be chosen which does not make the width of the cell prohibitive. It is also well to choose either of the first two sizes of the latter table if possible, as they may be mounted in glass jars, these being cheaper and more durable than the lead-lined tanks used with the larger sizes. Glass jars for thirteen-plate cells are readily obtained, but the larger sizes are imported.

**109. The standard glass jar mounting** is shown in Fig. 24. The plates are provided with support lugs which rest on the edges of the glass jar and the plates of like polarity are "lead burned" to a cross bar with connector straps for connecting adjacent cells. The connector straps are joined either by bolt connectors consisting of a brass stud with lead-covered brass nuts or are "lead burned." The plates of opposite polarity are intermeshed and are spaced apart by **separators,** comprising diaphragms of wood

Digitized by Google

veneer threaded through slotted wood dowels, both the veneer and the dowels being first treated to remove injurious substances. The veneers are fairly durable in the electrolyte but require renewal in 2 to 4 years. They prevent particles of active material bridging across the space between plates, which otherwise would cause internal short-circuits. The separators are kept from floating by pieces of glass called **separator hold-downs**. The cells are set in a layer of sand contained in a wood sand tray thoroughly coated with asphaltum paint, and the sand trays are mounted on glass insulators. The use of porcelain insulators is to be avoided, as the glaze is attacked by acid spray and the insulating properties are lost. Glass sand trays with integral insulating feet are often used instead of the wood trays and insulators. They are not satisfactory with the larger sizes on account of liability to breakage.

**110. Lead-lined tank construction.** Plates 15¼ in. × 15¼ in. and larger are always mounted in lead-lined tanks, the construction being shown in Fig. 25. The wood tanks are preferably of long-leaf yellow pine, with dovetail joints and dowels and without metal fastenings. The tanks should be painted both inside and outside with three coats of acid-resisting paint, and lined with 4-lb. sheet lead, the lining projecting outside the wood tank in order to prevent acid falling onto the tank. Tanks should have liberal mud space to take the accumulation of sediment. The sediment space should exceed one-third of the length of the plate. The tanks should be supported on glass insulators, the oil-filled type with a protecting cover being preferred. Lead footings are placed in the bottom of the tanks, upon which rest the glass support plates. The support plates are about ¾ in. thick, and have the upper edges, which support the plate lugs, ground smooth. The plates are lead-burned to bus bars of extruded lead and wood separators with dowels are used to space the plates, as with the glass-jar cells. A few installations of large cells have been made in special acid-proof stoneware tanks, but this construction has not come into general use.

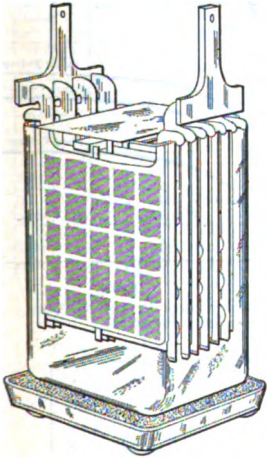

FIG. 24.—Cell in glass jar.

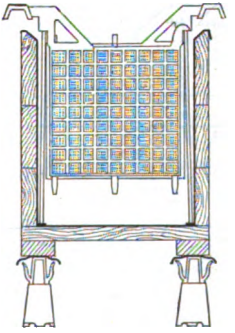

FIG. 25.—Cell in lead-lined tank.

**111. Erection.** Glass-jar cells are mounted on wood stringers, or two tier racks if space is limited, these being thoroughly coated with acid-resisting paint. The insulators for lead-lined tanks usually rest upon acid-resisting tile, the tiles being brought to a level by supporting them on pillars of sulphur-sand cement. These piers are made by supporting the tile on a ball of stiff cement and pouring melted sulphur, into which sand has been stirred. Another method of insulator support is to use heavy earthenware truncated cones in place of the sulphur piers.

**112. The strength of electrolyte** at full charge in stationary types of batteries, is usually limited to 1.200 to 1.215 sp. gr., and a sufficient volume of electrolyte is usually present in the cells so that its strength does not fall below 1.150 to 1.160 sp. gr. at the end of discharge.

**113. Typical charge and discharge curves of Planté stationary-type cells** are shown in Fig. 26. The upper charge curve is for the normal or 8-hr. rate, subsequent to a complete discharge at the like rate. The main part of the charge curve is similar for plates of different standard make

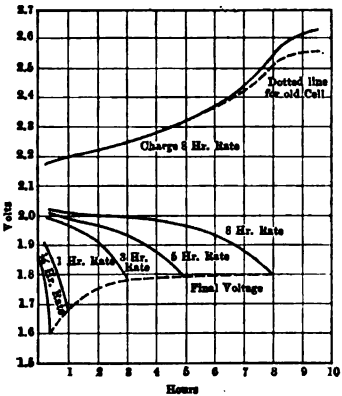

FIG. 26.—Charge and discharge curves.

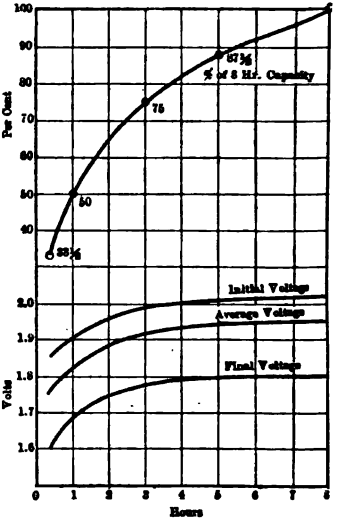

FIG. 27.—Capacity and voltage characteristics.

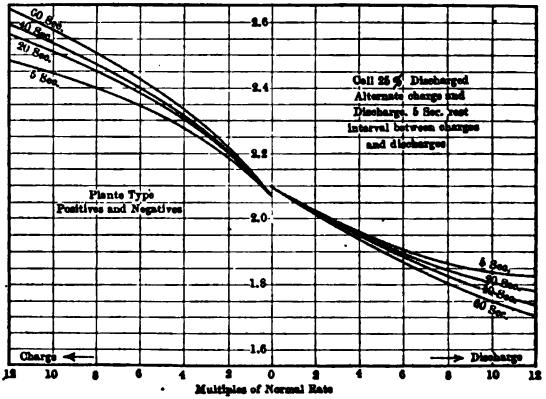

FIG. 28.

Digitized by Google

or design, but the latter part of the curve will show wide variations with plate design and age of plates. The factor which seems to be of greatest importance in determining the maximum voltage value reached on charge, is the condition of the negative plates with reference to a possible deposit of impurities on their surfaces. The maximum value reached with continued charge at the normal rate, may be as high as 2.65 volts with the cell at 70 deg. Fahr., and as low as 2.45 volts. All commercial lead contains a small percentage of impurities such as copper, antimony, etc., and these are eventually deposited from the positives, with their proceeding corrosion, onto the negative-plate surfaces. The result of these deposits is generally to reduce the final charge voltage. If a positive-plate grid contains antimony, the effect is quite marked. Antimony, artificially introduced into a cell, will produce this effect.

**114. The point of discharge termination** is determined arbitrarily, the main condition being that the cell voltage drops with increasing rapidity, toward the end. The capacity decreases with increasing discharge rates, as shown in the curves of Fig. 27, and the initial, average, and final voltages are also indicated. The decrease in capacity, as previously stated, results from lack of time for acid to diffuse into the active material.

**115. Voltage variations on intermittent charges and discharges.** Stationary types of lead batteries are capable of charging and discharging at high rates for short intervals, with a relatively small variation of voltage. The curves of Fig. 28 show voltages at the end of charge and discharge for the times indicated on the different curves. These curves are of importance in determining the variation of line voltage with a "floating battery," or that amount of work necessary to be done by a booster generator in series with a battery, in order to maintain a constant line voltage.

**116. Variation of capacity with temperature.** The rate of diffusion of acid into the pores of the plates varies markedly with temperature, and, in consequence, there is a marked decrease in capacity with lower temperatures. Temperature coefficients for different rates of discharge are as shown in the curve of Fig. 29.

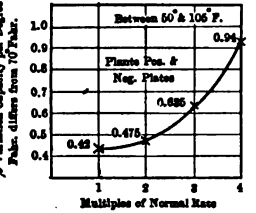

FIG. 29.—Temperature coefficients.

**117. Nominal battery ratings.** Frequently a stationary battery is referred to as having a kilowatt-hour capacity. By this is meant the 8-hr. or normal ampere-hour capacity multiplied by the number of cells and by the open-circuit voltage per cell which is approximately 2.1 volts.

## ELECTRIC VEHICLE BATTERIES

**118. Adaptable types.** Pasted plates are universally used in vehicle batteries at the present time, although there is no reason why a battery with Planté positives and pasted negatives should not be successful on account of its greater capability to withstand "boosting" charges. By a boosting charge is meant a partial charge at a high current rate, such a charge taking place at the noon hour or other rest period after the battery is partly discharged. The Planté positive, even with a pasted negative, may be charged at enormously high rates without the injurious heating which develops in the Edison battery.

If in a particular service, the capability of a battery to withstand boosting at high rates is of importance, this combination should receive consideration.

The prime reason for the use of pasted plates is their relative lightness, since a reduction in weight of battery results in a reduced current consumption for the vehicle and a reduction in the expense of tire upkeep. For these reasons, battery-plate life is often deliberately sacrificed by using thin plates and a small separation between plates. Small separation makes it necessary to employ strong acid and this reduces the life of the separators as well as the life of the plates. There is already a strong tendency toward the use of thicker separators and a reduced acid strength.

Digitized by Google

**119. Plate dimensions.** The size of plate in general use for vehicle purposes is 5¼ in. × 8¼ in. Standard positive plates vary from 0.22 in. to 0.13 in. in thickness, negative plates from 0.19 in. to 0.11 in. Several other sizes of plates are in occasional use than the one above stated, but they are gradually being abandoned.

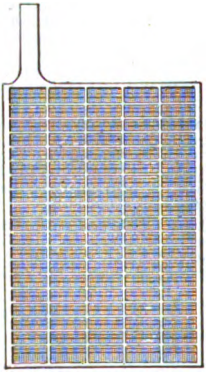

FIG. 30.—Vehicle plate grid "shelf type."

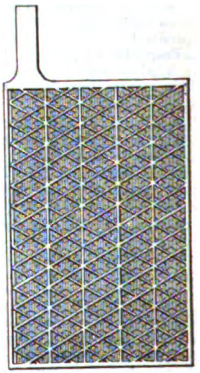

FIG. 31.—Vehicle plate grid "diamond type."

Negatives are usually thinner than the positives with which they are used by several hundredths of an inch, so that the plates of each polarity will have approximately equal life. Each battery manufacturer makes several thicknesses of plates, the proper thickness to use under any condition being dependent on the ampere-hour capacity required and the space and weight limitations. In a definite size of jar, a greater capacity can be obtained with a larger number of thin plates at high discharge rates. The cost of the thin-plate battery in the same size jar is somewhat greater, and the ampere-hour life is slightly less. The ratios as obtained from bench tests, under exaggerated charging conditions, are shown in Par. **122**.

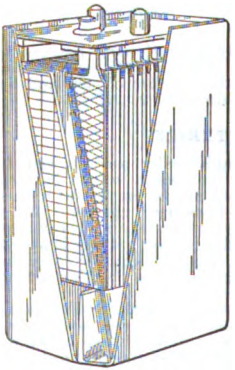

FIG. 32.—Vehicle cell construction.

**120. Choice of plate thickness.** In the examples cited in Par. **122**, the prices and, also, the "probable life" are to be considered as comparative. The ratios hold for several makes of battery. Where maximum mileage radius of a vehicle is necessary, the thinner plates will be chosen. The best all-round results will be obtained, in the judgment of many, from using the intermediate plate thicknesses.

**121. Grid types.** The only two grid designs in general use with the ordinary plates are those illustrated in Figs. 30 and 31.

**122. Vehicle battery construction** is illustrated in Fig. 32. Jars are universally of hard rubber. Celluloid is not suitable for vehicle batteries on account of its inflammability. It also oxidizes in contact with positive plates and becomes worthless. The bottoms of jars contain supporting ribs or bridges, upon which

Digitized by Google

the plates rest; these bridges provide a space beneath the plates to take the sediment which is gradually thrown off from the plates in service.

**123. Relative Attributes of Plates of Various Thicknesses**

| Size of Jar 6.125 in. wide, 4.25 in. long, outside | | | | |
|---|---|---|---|---|
| Type of plate | Weight per cell (lb.) | Capacity at 6-hr. disch. rate (amp. hr.) | List price per cell | Average life (amp-hr.) |
| Thick | 34½ | 155 | $16.70 | 77,500 |
| Medium | 33½ | 171 | 17.75 | 71,800 |
| Thin | 35 | 189 | 19.00 | 71,000 |
| Extra thin | 37 | 204 | 20.10 | 61,200 |

| Size of jar 6.125 in. wide, 8 in. long, outside | | | | |
|---|---|---|---|---|
| Type of plate | Weight per cell (lb.) | Capacity at 6-hr. disch. rate (amp. hr.) | List price per cell | Average life (amp-hr.) |
| Thick | 64 | 309.0 | $30.00 | 154,000 |
| Medium | 65½ | 343.0 | 32.20 | 144,000 |
| Thin | 65½ | 378.0 | 34.95 | 143,000 |
| Extra thin* | 67½ | 382.5 | 35.10 | 115,000 |

**124. Separators.** The plates are insulated from each other by thin sheets of corrugated wood veneer, grooved on one side, the wood used being either naturally free from such organic substances as would injure the plates, or else treated to remove such impurities. These veneers are usually kept away from the positive plate by inserting a thin sheet of perforated hard rubber. The smooth side of the veneer is placed against the negative plate. The life of these wood separators is unfavorably influenced by very strong acid also by an excessive amount of overcharge. If batteries are properly operated, the separators will last as long as will the plates of a thin-plate battery, that is, 12 to 15 months in commercial service and 18 to 24 months in pleasure-vehicle service.

Thick plates will generally have a longer life than the wood separators, so that, in order to obtain the best possible life of the plates, the separators will require renewal. If the separators and the plates are to give approximately equal lives, sufficient space should be provided in the jars to take all the sediment which will be thrown off in the life of the plates, *i.e.*, high-bridge jars should be used. Otherwise the space should be ample to take the sediment which will be deposited during the interval of separator renewals.

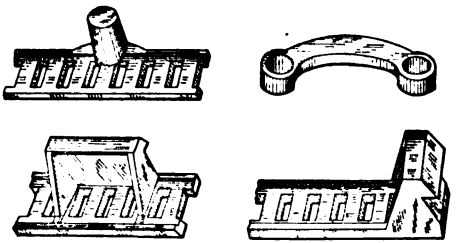

FIG. 33.—Vehicle type straps and connector.

**125. The straps to which the plates are burned** are of several types, as shown in Fig. 33. The pillar-post strap, used with connector links, is

* Length of standard jar for this size is 7¼ in.

Digitized by Google

generally considered to be the best design. Several kinds of bolted connections are on the market, but most of them are unsatisfactory. A burned connection is preferable.

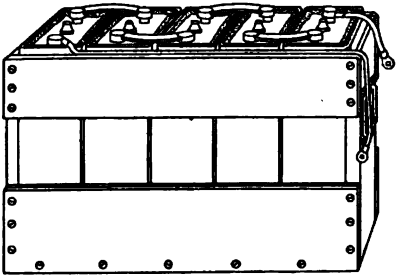

FIG. 34.—Vehicle battery assembly.

**126. Covers.** The cells are preferably provided with covers of hard rubber, sealed with an acid-resisting compound, to prevent slopping of the electrolyte, although frequently a tight-fitting cover is relied upon to prevent this. If the covers are sealed, **vent caps** of either hard or soft rubber are used.

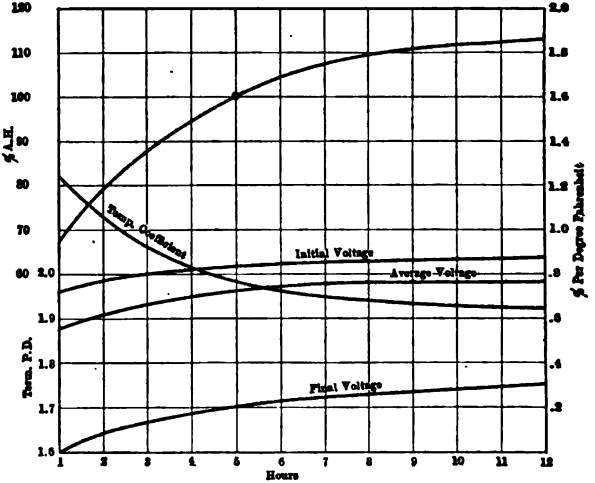

FIG. 35.—Capacity voltage and temperature characteristics.

**127. Degrees of separation of plates.** As it is desirable to reduce weight and space required, as far as possible, with vehicle batteries, separation between plates and the volume of electrolyte are limited; on this account the range of acid strength between the states of full charge and full

Digitized by Google

discharge is great. In extreme cases, acid of 1.300 sp. gr. at full charge is used, and only sufficient volume employed to give a final acid density of 1.100. A better life of plates and separators will result, however, if a wide enough separation between plates is used to permit a full charge density of 1.260 to 1.280 sp. gr.

**128. Crates.** The method of assembling vehicle cells into crates is shown in Fig. 34. The crates are of hard wood, painted thoroughly with asphaltum acid-resisting paint or else soaked in hot paraffin oil, then subsequently dipped into melted paraffin. The practice of fastening crate terminals onto the crates is to be thoroughly condemned, as when the crates become acid-soaked, there is current leakage between them, and the positive terminal corrodes seriously. Crate ends are charred from this cause, and the current leakage is of a magnitude not to be neglected.

**129. Performance of thin-plate batteries.** The variation of capacity of a thin-plate vehicle-type battery in wide commercial use, is shown in

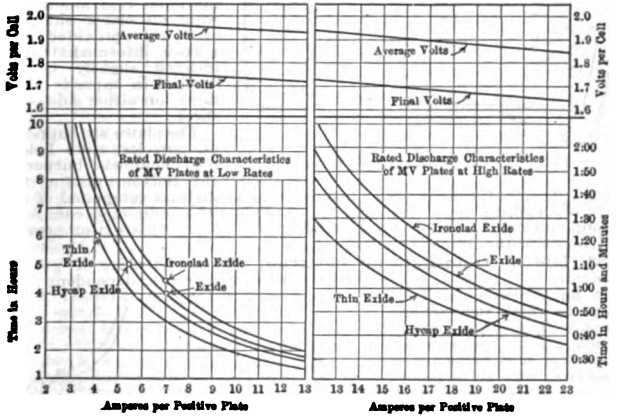

FIG. 36.—Exide plate characteristics.

Fig. 35 and the average and final voltages are also given. The Electric Storage Battery Co. has devised an ingenious chart showing the characteristics of their "Exide" batteries which is reproduced in Fig. 36.

## TRAIN-LIGHTING BATTERIES

**130. Capacity.** A special type of battery has been developed for the lighting of steam railroad trains. The standard battery comprises 16 cells of 300 amp-hr. rated capacity, and this size is used in most cases for coaches, parlor cars, and sleeping cars. For dining cars, 32 cells are frequently used. Batteries of smaller capacity are often used for lighting baggage and postal cars.

**131. These batteries are charged** either from an outside source at terminal yards, or, especially where the cars run over several different lines, are operated in conjunction with an automatically controlled axle-driven generator. The "head end system," with a steam-driven generator in the baggage car is sometimes used, though it is not so popular as formerly. (See Railway Train Lighting, Sec. 22.)

**132. Design.** Batteries for train lighting have been standardized, the construction being shown in Fig. 37. The cells are mounted in pairs in

Digitized by Google

double-compartment wood tanks, with lead linings. The tanks are provided with insulating porcelain rollers or skids on the bottom; also with insulating side and end buffers of porcelain or paraffined wood. The covers are sealed in with a suitable asphaltum compound, the covers being of lead-antimony or hard rubber. Soft-rubber bushings surround the terminal posts where they emerge from the covers, in order to absorb the shock incidental to the service.

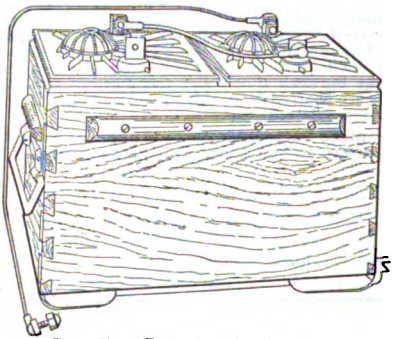

FIG. 37.—Train-lighting battery.

The elements usually comprise Planté plates, both positive and negative, although pasted plates are sometimes used. With Planté plates, the separators are perforated hard-rubber sheets with marginal ribs about ⅛ in. wide on either side, and also are provided with narrow intermediate ribs, inclined slightly to the vertical in opposite directions, on either side of the sheet.

The plates are supported on porcelain rests held in lead channels burned to the bottom of the tank lining. The tank linings are embedded in an asphaltum compound of relatively low melting point (about 135 deg. Fahr.) the compound completely surrounding the lining on sides and bottom. This construction prevents electrolysis of the linings to a large degree.

**133. Life of train-lighting batteries.** These batteries if properly cared for, will have a life of from 4 to 8 or 9 years, dependent somewhat on the amount of discharge to which they are subjected. They are usually opened up for inspection 2 years after first being placed in service, and subsequently once a year. Any sediment accumulation is then removed and the plates straightened, if this be required.

**134. Voltage characteristics** of train-lighting batteries are practically the same as for cells of the stationary type (see Par. **113**).

## BATTERIES FOR MISCELLANEOUS PURPOSES

**135. Automobile starting, lighting and ignition batteries.** Batteries for this service have been specially designed to meet the large current demands required for engine starting. Normal voltages of 6 and 12 volts are usual, although there are a number of 16-, 18- and 24-volt systems. The lower voltages are preferable on account of the better durability of the low voltage lamps. (See "Electric Equipment for Gas Automobiles," Sec. 22.)

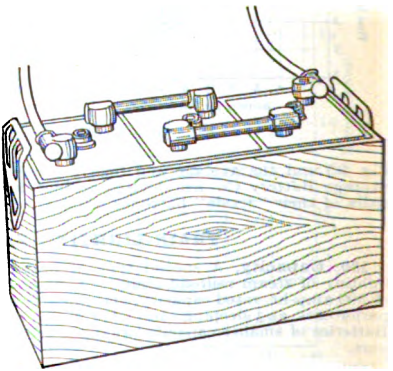

FIG. 38.—Motor starting and lighting battery.

The battery elements are made up of a large number of thin plates, usually with thin corrugated wood veneer separators, and without perforated hard-

Digitized by Google

rubber sheets, the latter being omitted to reduce the voltage drop on the very high discharge rates for starting. The initial current value is frequently three times the rated ampere-hour capacity of the battery, and, in order to reduce the voltage drop, cell connectors and terminals have copper cores. Plate grids are also usually provided with reinforcing diagonal members for the same purpose. Fig. 38 shows a standard battery design for motor starting and lighting.

**136. The voltage characteristics** of these batteries, as furnished by several manufacturers, is shown in Fig. 39.

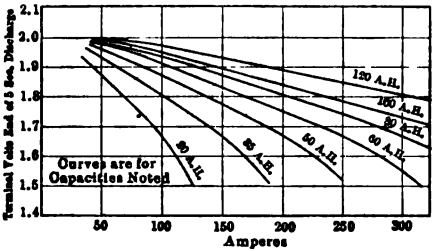

FIG. 39.—Motor starting battery characteristics.

**137. Batteries for ignition alone.** The current required for ignition rarely exceeds an average value of from ½ to 1 amp. For this reason, batteries for ignition alone usually have thick plate elements, the discharge rates being so low that the full plate thickness is efficiently used. Standard batteries for this service are 4 and 6 volts, that is, two and three cells.

## BATTERY ROOMS

**138. General rules.** It is desirable to install stationary batteries in rooms which have good ventilation and are well lighted. Direct sunlight should not, however, be permitted to fall on the cells; it is well, therefore, to coat windows with an opalescent paint, in order to avoid this possibility and also to cause the illumination of the entire room to be more equally diffused. Where natural illumination is not possible or convenient, a liberal number of electric lamps should be provided. Open flames and fires in stoves must not be permitted, as the cells give off hydrogen and oxygen on overcharge and the mixture of these gases, if sufficiently concentrated, is explosive.

**139. Temperature.** A battery room should be maintained at as nearly 70 deg. as possible. Higher temperatures than 95 deg. to 100 deg. Fahr., excepting during rare intervals, must be avoided. Low temperatures temporarily reduce the battery capacity, but do no injury.

**140. Cleanliness of location.** Batteries should not be installed adjacent to an ice plant, or to a stable, as ammonia gas is absorbed with great avidity by the electrolyte and eventually, crystals of ammonium sulphate collecting on the containing tank, may cause the electrolyte to syphon off by capillary action. The capacity of negative plates is reduced by the presence of ammonia. Corrosive gases or vapors from other manufacturing processes should also be avoided. Iron ore dust is also objectionable.

**141. Ventilation.** If large batteries are to be installed in the immediate vicinity of dwellings, forced ventilation may have to be provided, during the completion of charge, by means of an exhaust fan. The acid vapors may be removed from the exhaust by sucking it through several layers of bronze screen or thin perforated sheets of lead. Exhaust ventilation is much preferable to direct, as air currents are more uniform and there are fewer eddies. The acid spray in the first method does not so readily precipitate upon the tanks and insulators.

**142. Protection to iron work and walls.** There should be a minimum of exposed piping and iron work in a battery room, especially near the floor.

Digitized by Google

If radiators or coils are present, they should be as high from the floor as possible and kept painted with asphaltum paint. At the floor level and for the first 4 or 5 ft., it is especially desirable that the iron work be protected. On ceilings and on walls above the top level of the cells, a good white-lead, linseed-oil paint should be used. The white walls and ceiling will materially assist in the illumination of the room.

**143. The floor of a battery room** should receive particular consideration, especially if, as frequently occurs in large cities, a large battery is erected in an upper story of a building containing iron or steelwork in its floor. A good floor specification in this case is the following: A layer of concrete is spread over the floor, the surface being "floated"—not trowelled. This surface is thoroughly mopped with hot "Hydrex" compound (a pure grade of Trinidad asphaltum) and a layer of "Hydrex" felt is then laid, the edges being flashed on the walls and other uprights about 3 in. Three layers of this felt are laid, the surface of each being thoroughly mopped with hot Hydrex compound and at the same time seeing that the abutting joints of the sheets of one layer do not match with those of the lower layer. Two-inch tile, of a grade which is not porous and which is not attacked by acid, are then laid, a space of ½ in. being left between the tile. Hot Hydrex compound is then poured in these spaces. The floor should be pitched toward drains, the pitch being at least ¼ in. per ft. Drains should comprise a sheet-lead catch basin, all joints in which should be lead burned, and lead pipe should be used for the drains. Covers to drains should be of bronze, which withstands sulphuric acid to a satisfactory degree for this purpose. Such a floor construction is quite expensive and is only warranted for the conditions above stated.

If a battery is installed on a ground floor and the room can be kept fairly dry, a concrete floor will be quite satisfactory. The floor must, however, be flushed at frequent intervals and acid must not be slopped on the floor. Any leaky cells must be promptly repaired and the spilled acid promptly neutralized with washing soda. A concrete floor can be protected to a satisfactory degree (in the absence of ironwork in its construction) by mopping with very hot paraffin, applied with a heavy brush to prevent too rapid cooling. In those cases where an expensive construction is not warranted fair results can be obtained by keeping sawdust on the floor to absorb the acid spray from overcharge or any spilled acid.

**144. Arrangement of wiring.** Conductors to terminals and between rows of large batteries should be of bare copper, supported on glass insulators and horizontal runs should be at least 4 ft. above the tops of the cells. The copper should be liberally smeared with vaseline. Lead-covered copper cable makes a very good conductor for running in a battery room. Rubber-covered cable, without braid, is also satisfactory if the rubber covering is high grade.

**145. Location of switchboard.** Switchboards and end-cell switches should not be installed in a battery room on account of the presence of acid-containing vapors given off during charge. It is well to provide a separate room for these parts.

**146. General layout.** In laying out a battery room, liberal aisle spaces should be provided if possible. There should be at least 6 in. space between walls and a row of cells. With glass-jar installations, 30-in. aisles are satisfactory for passage ways, and, if the battery is installed in double rows, there should be a clear space of at least 4 and preferably 6 in. between adjacent rows. With lead-lined tank installations, sufficient aisle space must be provided to remove tanks, if necessary, by up-ending.

## REGULATING EQUIPMENT

**147. Voltage regulation.** Since the voltage of a battery falls on discharge and rises on charge, it is necessary to compensate for these variations in some way, if a constant line voltage is to be maintained. With small batteries on steady charge or discharge, regulation for constant voltage is sometimes effected by means of an adjustable resistance in series with the battery, the battery either being split in two halves in parallel for charge or a shunt charging booster is used to add sufficiently to the line voltage in order to charge the cells in a single series. Another method of voltage regulation sometimes used, is to absorb the excess voltage at the beginning of discharge by means of "counter e.m.f. cells" (Par. 148). With larger

Digitized by Google

batteries, the losses of the preceding methods are avoided by the use of automatic regulating boosters (Par. 150) or end cells with end-cell switches (Par. 158).

**148. Counter-e.m.f. cells.** These are simply cells with unformed plates. When current flows through such cells, they oppose the main battery voltage by approximately 2.8 volts for each counter-e.m.f. cell in series. They are so connected in a circuit that current always flows through them in the same direction, as otherwise they would gradually attain a considerable capacity.

**149. Shunt charging booster.** This consists of a generator, usually motor-driven, whose field is excited from the line; actually, therefore, the designation is misleading. A variable resistance in series with the field permits the adjustment of the booster voltage to the desired value. These boosters are connected as shown in Figs. 47 and 48.

**150. Automatic regulating booster.** The charge and discharge of a battery may be made responsive to the variations of any desired means by placing a motor-driven generator in series with the battery, the field of the generator being excited in accordance with such variations. Automatic boosters usually regulate for constant current or for constant voltage. Current regulation is the more frequent application. Regulating boosters are usually driven at practically constant speed. They are used when rapid variations of battery charge and discharge are required.

**151. Ents booster.** Mailloux proposed the use of two opposing field coils on the booster generator, one a shunt field excited from the line voltage, the other carrying the total current. The Ents modification of this scheme, formerly in wide use, is shown in Fig. 40, in which the coil *A* carries the current from the generator, *B* carries the external load, while the shunt coil *C*, excited at line voltage, carries a practically constant current opposed to *A* and *B*. The coils are so determined that the resultant booster field is zero when both the outside load and the generator load have a certain definite value. Any increase in the outside load then causes a resultant field, and consequently a resultant booster voltage, in the direction forcing the battery to discharge. Any portion of the increased load falling on the generator would tend still further to increase the booster field and result in additional battery discharge. The resultant booster voltage would be in the opposite direction if the outside load decreased and the battery would be forced to charge. Regulation tending toward constant generator current, therefore, results from this scheme. A practical defect of the Ents booster is that, the field being the resultant of two opposing fields, the field structure must carry much more than the normal amount of winding and a highly special machine results.

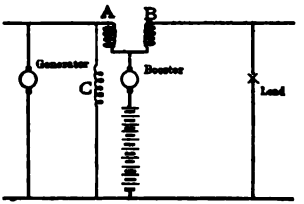

FIG. 40.—Ents booster.

**152. Separately-excited booster.** The modern boosters have fields of normal dimensions with a single winding excited from a separate machine for this purpose. The excitation schemes in practical use are of two types described below.

**153. Carbon-pile regulator.** This regulator is shown diagrammatically in Fig. 41 in which two piles of carbon discs are under but a slight compression when the lever arm is in the horizontal position. The lever arm is operated by a solenoid plunger whose coil carries the current to be regulated. The pull of the solenoid is balanced by a spring whose tension is such as to equal the solenoid for normal average current. The bottoms of these two piles are connected, one to the positive and the other to the negative of the battery, and the two tops of the piles connected together. One terminal of the booster field is connected to the junction of the two piles, the other to the middle point of the battery. With the two piles under equal compression, no current flows through the booster field. An increase of current from the main generator causes the solenoid to compress

Digitized by Google

one of the carbon piles and release the pressure in the other; in consequence of the reduction of resistance of the carbon piles under pressure, current flows from the middle point of the battery through the booster field and the pile under greater compression, the current being in the direction which will cause the battery to discharge. A reduction of the main generator current causes the field to reverse and the battery to charge. The regulator is adjusted for various average values of main generator current simply by changing the spring tension. The amount of current that can be handled by the carbon piles is limited, so that, for large boosters, the carbon-pile regulator acts as the field control of an exciter for the booster generator. These regulators are supplied by the Electric Storage Battery Co.

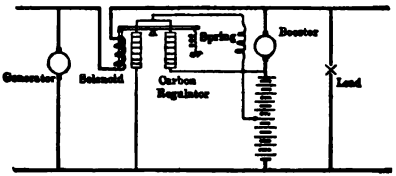

FIG. 41.—Carbon-pile regulator.

**154. Counter-E.M.F. booster regulator.** This scheme is due to A. S. Hubbard and is furnished by the Gould Storage Battery Co. Referring to Fig. 42, the main booster field is across the line, but there is an exciter machine, E, included in the field circuit. The latter is usually mounted upon the same shaft with the main booster set and its field is either the whole or shunted portion of the main generator current. When the current in the field of the exciter machine has its normal average value, the exciter machine is designed to give the full line voltage and in this case zero voltage is applied to the main booster field. With a reduction in value of the main generator current and consequently in the field of the exciter machine, the voltage of the latter is reduced, so that current flows in the main booster field in a direction causing the battery to receive charge. If the main generator current increases above the average value, the voltage of the exciter machine is in excess of the line voltage and current flows in the booster field coil in a direction causing the battery to discharge. Shunting any portion of the current from the field

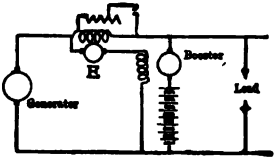

FIG. 42.—C.E.M.F. booster.

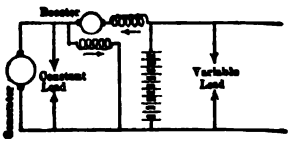

FIG. 43.—Constant current booster.

of the exciter machine increases the main generator current; for example, a shunt across the exciter-machine field of equal carrying capacity and resistance means that the value of the main generator current must be twice as great in order that the exciter-machine voltage may be equal to the line voltage (the point at which the battery will neither charge or discharge). Adjustment for any desired average generator load is made by variable shunts on the exciter field.

**155. Differential booster.** When boosters are connected as shown in the two preceding diagrams, they are designated as differential boosters as distinguished from those of the succeeding paragraph.

**156. Constant current boosters.** In many instances, a portion of the plant load, such as that of incandescent lamps, requires steady voltage, while the remaining load is satisfactorily supplied at a voltage which may vary by, say, plus or minus 10 per cent. from the generator voltage. In this event, the booster capacity can be reduced, under certain conditions as explained below, by connecting it in circuit as shown in Fig. 43 where the constant load circuits such as lamps, for motors, etc., have an electrical position between the main generator and the booster, and the variable load cir-

Digitized by Google

cuits, such as result from hoists, elevator operation, etc., are taken off the opposite side of the booster and are subjected to the battery voltage variation. If the average value of the variable load is less than the difference between the maximum current and the average load, it may be possible to reduce greatly the booster capacity by so connecting it as to realise constant current.

**157. Electrical position of booster regulator.** Where a portion of the station load is steady and another portion variable, the regulating coil should in general be so placed as to be affected by the variable load only, if this is conveniently possible. This can be done by grouping the constant and the variable loads separately, the coil then being placed between the two groups of circuits. The position indicated will result in closer regulation, since all the practical regulating schemes provide that the current to be regulated shall not depart from its average value by more than a given percentage. This rule holds for both constant current and differential boosters.

**158. End-cell switches.** An end-cell switch is a device for cutting in or cutting out cells of a series and thereby compensating for battery voltage variation. The contacts of the smaller size switches are usually arranged in the arc of a circle, while with larger sizes the contacts are arranged in a straight row and a heavy laminated copper brush is moved over these contacts by means of a motor-driven worm. In switching from one point to the next, the circuit must not be opened, and the blade must not touch two adjacent contact points, as this would short-circuit a cell having its terminals connected to these points. End-cell switches are therefore provided with an auxiliary contact, either on the moving blade as shown in *B*, Fig. 44, or, in some instances, fixed adjacent to each main contact. The main and auxiliary contacts are joined by a resistance as shown at *C*, but otherwise insulated from each other. The auxiliary contact touches one of the switch points, while the main contact touches the adjacent point. The circuit is, therefore, not interrupted, being completed through the resistance, *C*, which has too low a value to affect the line voltage appreciably. Its resistance, however, is sufficiently great to prevent short-circuiting the cells connected across the two points. The larger sizes of end-cell switches are motor-driven, and are very elaborately designed. The reader is referred to the literature of the various manufacturing companies for full particulars of these switches.

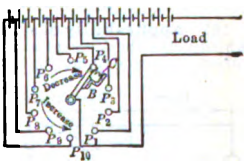

FIG. 44.—End-cell switch.

**159. Load-limit devices.** It is sometimes desirable to limit the load on the battery. This may be accomplished by providing an adjustable stop to limit the travel of the lever arm of the carbon-pile regulator, and thus limit the amount of current which will flow through the booster field. This, in turn, will limit the amount of battery charge and discharge. An equivalent device for the same purpose can be applied to the Hubbard booster.

**160. Average adjuster.** It is often desirable to limit the work which a battery does, to taking simply those heavy variations of current which persist for short times, and to allow the main generator to follow the load averaged over relatively long intervals. A device which accomplishes this object is furnished by the Electric Storage Battery Co., and its design is dependent upon the following principle: the armature of a small motor is connected to the adjusting screw which controls the tension of the spring of the carbon pile regulator, through a suitable train of reducing gears. The armature of this motor carries a practically constant current, as it is connected across the line in series with a fixed resistance. The field of the motor is connected across the terminals of the booster. The effect of this arrangement is to permit the battery to absorb momentary fluctuations, while the main generator current follows the load averaged over a relatively longer interval.

## OPERATING EQUIPMENT

**161. Pilot cells.** The specific gravity of the electrolyte of a cell in which the acid level is kept constant by adding water to replace evaporation, is

Digitized by Google

the best means of determining the state of charge of a battery. One or two cells of a battery should be selected for this purpose; these will be known as "pilot cells," and records should be kept of their acid density. With stationary batteries, an automatic cell filler should be provided and maintained. In other cases, the evaporation should be replaced daily, preferably before starting the charge.

**162. Auxiliary operating apparatus.** To follow the operation of a battery the following apparatus should be available: (a) **low-reading voltmeter**, with a scale of 0.3–0–3.0 volts, with **"stabbers"** (to make contact with the cell terminals). (b) **Cadmium test electrode**, comprising a cadmium rod covered with perforated rubber. This is suitably combined with this previously mentioned "stabbers" and is used to determine the relative condition of the positives and negatives. (c) **Examination lamps**; these are bulbs at the end of a flat hard-rubber or glass tube so that they may be inserted between plates in lead-lined tanks. The lamps are for low voltage (2 or 3 cells), and enable the interior at the cell to be examined. (d) **Compensating hydrometer**; either an hydrometer which automatically compensates for temperature differences should be supplied or a thermometer should be kept in the pilot cell and the hydrometer readings corrected for temperature. Many consider the latter course preferable. (e) **Ampere-hour meter**; these instruments also are frequently used to determine the state of charge of a battery, but they should be checked from time to time with the acid readings of the pilot cells. An ampere-hour meter will not determine the amount of local action which takes place in a battery. It is usually assumed that a certain percentage of overcharge will be required, but the accurate check is the pilot-cell reading.

## STORAGE-BATTERY APPLICATIONS

**163. Applicability of stationary types.** The characteristics of batteries which make them essentially valuable with reference to their practical application in power plant work are, (a) they do not contain moving parts and are capable instantaneously of furnishing current; and, (b) they will absorb and give out current at high rates and at high efficiencies. Because of their voltage variation on charge and discharge, auxiliary apparatus (Par. 147–160) must be used if the line voltage is to be maintained constant.

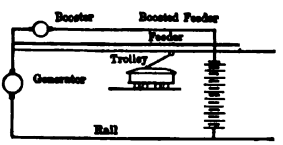

FIG. 45.—Line battery with boosted feeder.

**164. Line or floating batteries.** If a battery is connected directly across a line whose voltage varies, then the battery will discharge when the applied voltage is reduced below its open-circuit or floating voltage, and it will charge when the applied voltage rises. The amount of voltage variation necessary to make the battery charge and discharge at various rates may be determined from the curves, Fig. 28. A battery of the stationary type will neither charge at appreciable rates unless the voltage exceeds 2.14 volts per cell, nor discharge unless the voltage is below 2.04 volts per cell (if the battery is of the stationary type). A battery may therefore be practically floated at any voltage per cell between the limits just stated, although the value 2.08 volts per cell is usually taken as the best point. If a number of cells equal to the average voltage, divided by 2.08, is placed across a line, therefore, the voltage variations will be limited to those of the battery when charging and discharging at the rates necessary to furnish the current demand. The capacity of the battery is determined from the condition that frequent discharges should not exceed twice the 1-hr. rate and frequent charges should not exceed the 1-hr. rate.

Battery installations of this nature may be installed at points distant from a power source, in order to maintain a more constant line voltage under heavy fluctuating loads such as may result from the operation of cars on interurban railways or unloading machines at docks, etc., etc. Batteries may also be floated directly across the terminals of heavily under-compounded generators.

**165. Railway line batteries with boosted feeder.** The voltage at the

Digitized by Google

distant ends of long lines with infrequent service, can be satisfactorily maintained by connecting a battery as shown in Fig. 45. The feeder can be tapped into the trolley at a short distance from the battery in the direction of the power-house. It is necessary to provide a reverse-current circuit-breaker in circuit with the generator.

**166. Load-regulating batteries.** Batteries may be installed to absorb momentary fluctuations above or below the average load, or any desired percentage of these fluctuations. In this connection it is usual practice to employ an automatic regulating booster (Par. 149) to force the battery to charge and discharge in accordance with the load variations. The number of cells usually installed is equal to the line voltage divided by 2.08, and the size of the battery is generally determined by the condition that frequently recurring discharges should not exceed twice the 1-hr. discharge rate of the battery. Under these conditions, the main battery voltage will not fall below 1.6 volts per cell nor exceed 2.6 volts per cell under regular operating conditions. A limiting voltage of 2.65 volts per cell must, however, be available to complete the regular charge of the battery and to give it the necessary overcharge which occasionally should take place. The booster must, therefore, have a voltage range equal to approximately 0.48 volts times the number of cells, for regulation service. Provision must be made either by increasing the speed of the booster, or else by forcing the booster field to reach the extreme voltage (for booster and generator together) of 2.65 volts per cell in order to give the battery its periodic overcharge. Fig. 46 is a diagram of connections, showing how batteries are applied for this purpose. Regulating battery plants are installed in connection with generators, motor-generator sets or rotary converters, supplying railroad, rolling-mill, elevator and other widely varying loads.

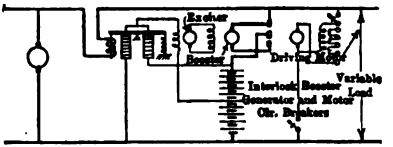

FIG. 46.—Regulating battery.

**167. Alternating-current regulation.** If there is a reversible means of converting alternating to direct current on an alternating-current source of supply, and it is desired to equalize the load variations on the latter, the battery may be made to do this by exciting the booster field in accordance with these variations. The lever of the carbon-pile regulator (Par. 153) would then be subjected to a pull in proportion to the load in watts, or the power component of the load. A solenoid coil carrying the current only will not effect the desired result unless the power-factor remains constant.

Another method of securing equalization of alternating-current variations is to rectify the secondary current from series transformers in the line in such a way that the output of the rectifier is proportional to the power component of the load. The latter may then be the excitation of the c.e.m.f. exciter of the Hubbard booster. The literature of the Gould and Electric Storage Battery Companies should be consulted for details of this method.

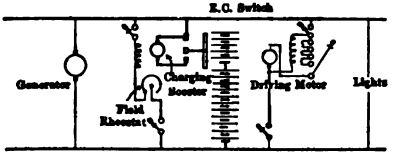

FIG. 47.—Peak load battery.

**168. Peak-load batteries.** If a battery is to supply a discharge of relatively long duration and at constant voltage, it is usual to effect the voltage regulation by means of an end-cell switch. A diagram of connections for a direct-current two-wire system is shown in Fig. 47. The charging booster is employed for the purpose of adding to the line voltage a sufficient amount to complete the charge of all the cells of the battery. Plants of this nature are used to supply hotel and residence lighting and motor circuits, but are infrequently used for regular operation with large plants, except for emergency reserve.

Digitized by Google

**169. Isolated-plant batteries in hotels and office buildings.** Batteries with means for appropriate regulation are quite frequently installed in connection with the generating apparatus in such buildings, for the purposes of eliminating the voltage variations which would result from variable elevator loads, and in order to reduce the capacity requirements of the generating equipment. In many instances the battery is also called upon to furnish energy during the night, when the generators are shut down. The battery capacity will be determined by that requirement which preponderates, whether it be the momentary-discharge capacity for regulating, or the continuous-discharge capacity when carrying all the load after the generators are shut down. The booster is usually of the constant-current type, and end cells are added to the battery to maintain the proper voltage on continued discharge without the generator in operation. The elevator circuits may be taken off the main portion of the battery, inside the end cells; the booster, however, is so connected that the end cells are in its circuit, through the end-cell switch, until these end cells are charged.

**170. Batteries for exciter and oil-switch reserve.** It is important, in large plants, that current be always available for the operation of oil switches and, temporarily, for excitation to prevent a shut-down, or in starting up. Battery current is frequently provided for oil-switch operation and also for excitation when it is of advantage to start quickly after a shut-down. If oil switches only are to be provided for, the vehicle types of battery will offer the cheapest and most convenient means for the purpose. A separate battery room is not then necessary. The diagram of connections for an exciter and oil-switch battery is the same as that of Fig. 47.

**171. Stand-by batteries.** Batteries to insure continuous power supply on direct-current three-wire networks, are in wide use in the most important cities of the country. In fact, it may be said that one of the advantages of the direct-current three-wire distribution is that storage batteries may be floated on such a distribution, so that, in case of an interruption of the power supply, the voltage is still maintained on the network and the annoyances and dangers of light failure in theatres and crowded streets are eliminated. The general practice of applying such batteries is illustrated in Fig. 48. On a three-wire system with a minimum bus pressure of 230 volts maintained between the outside wires, it is usual to float a battery of 150 cells between the outside wires, that is, 75 cells on either side of the system. Connection to the proper cell, to insure that the battery neither charges nor discharges, when "floating, and to regulate the voltage on discharge is effected by means of end-cell switches. It is usual to connect cells No. 55 to 59 inclusive, on both the positive and negative sides of the system, to the end-cell switches, while the balance of the cells are connected, first in groups of two and then in groups of three, to the remaining points of the end-cell switch. The first single-cell intervals are provided so that the battery may float without charge or discharge under the usual range of bus-pressure variation. The remaining intervals of two and three cells make it possible to reduce the heavy copper runs which would be necessary with single-cell intervals.

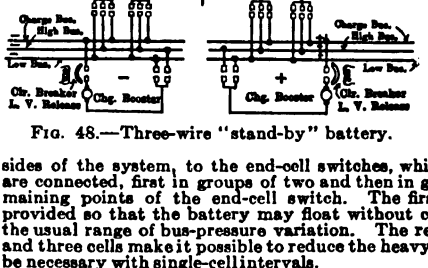

FIG. 48.—Three-wire "stand-by" battery.

A shunt charging booster is usually employed for charging stand-by batteries, and, during the charge, the battery, in standard practice, is not immediately available for emergency discharge, except in the reverse direction through the booster. However, the battery is always charged at times of relatively light load when there is little danger of disturbance to the system; also, when a momentary failure would not be of vital importance.

It is usual practice to install two end-cell switches on either side of the battery and this permits floating the battery simultaneously across the high and low bus. The possibility of doing this is not usually taken advantage of

Digitized by Google

in regular operating practice, and the end-cell switches are usually installed in pairs for the sake of limiting the amount of current to be carried by a single contact. Provision is not made in the majority of cases for floating the battery on the bus during charge, for the reason that a greater number of end-cell points would be required, and because of the heavy expense of the copper runs to the additional number of end cells. The capacity of a battery for stand-by service is frequently determined by the requirement that it should carry the maximum station peak for a period of 5 or 6 min., and that the usual 150 cells will maintain a voltage of about 115 volts per side during this period.

**172. Batteries for telephone exchanges.** The batteries of the larger offices are either 11-cell or 22-cell installations, and are floated directly across the power circuit without any special regulating means. The capacity of these batteries is usually such that they will carry the entire station load for a period of 24 hr. or longer. The internal resistance of the batteries is extremely low, owing to the relatively large size of the battery. A low internal battery resistance is especially desirable for telephone service, in order to eliminate the possiblity of "cross talk" (Sec. 21). It is desirable, with these batteries, to select a type that will permit completion of charge at relatively low rates in order to avoid excessive voltages and resultant interference with relay operation and lamp signals.

Planté type batteries are usually used for the purpose on account of their long life. Pure-lead Planté negative plates show high voltages on the completion of overcharge, especially when new, and this fact should receive consideration.

The loads on telephone-office power plants in business districts usually show decided morning and afternoon peaks, and it is usual to operate the charging generator in parallel with the battery during the periods of higher load. The battery alone usually carries the load excepting from, say, 9 A.M. to 4 P.M. in the typical exchange in business districts.

**173. Residence and farm lighting plants.** A great number of these plants are in service, and they vary in elaboration from a simple battery without voltage regulation (the battery being taken off the lighting service when charging) to the more complete plants previously described. The usual low-voltage plants are 8 and 16 cells, *i.e.*, furnishing 15 and 30 volt lamps. The small plants frequently use vehicle or motor starting and lighting batteries, as these are cheaper for the same capacity and may be readily shipped to a service station for repairs when necessary. The couple-types (Par. 107) of stationary batteries are also frequently used. The regular stationary types will give longer and somewhat more reliable service. Diagrams of connection are given in Figs. 49 and 50, the former without voltage regulation while, in the latter, voltage regulation is effected by counter-e.m.f. cells.

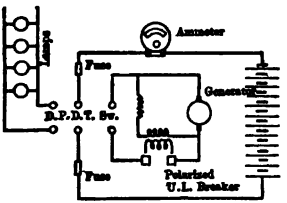

FIG. 49.—Farm lighting plant without voltage regulation.

**174. Electric-vehicle battery applications.** The use of vehicle batteries in electric-truck service is fully covered in Sec. 17. Additional applications are covered in Par. **175–177.**

**175. Storage-battery street cars.** A large number of these are in service in New York City and elsewhere. The field for the battery car is limited to those cases where the traffic is not great enough to justify electrification in the ordinary manner, or where for special reasons, the overhead trolley is not permissible. In New York City, battery cars are in operation on such of the cross-town lines in the metropolitan district as do not carry an extremely heavy traffic, and the expense of the prescribed underground trolley would be entirely unwarranted. In a number of smaller towns or cities, storage-battery cars are operated because the investment for equipment is much less than it would be for the regular overhead trolley, and the expense of continuous power-plant operation under poor load conditions is thus avoided. In these cases the batteries are charged from the local power service between midnight and early morning, that is, at a time when the stations are willing to supply the energy at a moderate charge. The majority of battery cars now in service, have 18-ft. bodies and are 28 ft. long over-all. They seat 28 passengers and their weight, fully-equipped, is approximately 14,000 lb. The battery equipment comprises 58 cells of approximately 385 amp. hr. rated capacity, and the current consumption varies from 3.8 to 6 amp. hr. per. car mile. The cars are capable of making in daily operation 75 to 100 miles or more on a single charge of the battery. With a current cost per kw-hr. of about 2 cents, the entire cost of operation is between 7½ cents and 8 cents per car mile, exclusive of platform expenses, but including car and battery maintenance.

The early battery cars were failures, and the success of the modern battery car is due to the use of ball-bearing motors and axles, high-efficiency motors and proper design.

**176. Storage-battery locomotives.** These are employed in shops for handling heavy castings, moving freight cars through short distances, etc., and also in tunnel excavations and for gathering cars in coal mines. Such are wide and growing applications for storage batteries.

**177. Freight and baggage-handling trucks.** The larger passenger terminals have placed a great many of these trucks in service for handling baggage, express and mail. The standard truck for this purpose is capable of carrying about 4,000 lb., and their maximum speed is limited to 4 or 5 miles per hr. A 12-cell battery of 195 amp-hr. capacity is the one most usually employed for this service. A number of these trucks are also in operation on steamship piers and in freight warehouses. Smaller trucks are widely used in manufacturing plants, for the transfer of work from one department to another.

## OPERATION

**178. Operation.** In order to obtain satisfactory battery life, a few simple instructions should be carefully followed. It is frequent practice for the battery manufacturer to guarantee his battery, and, in this event, he will not, of course, accept responsibility for damage to the battery unless his operating instructions are followed. The characteristics of plates as furnished by the different manufacturers, vary somewhat and therefore any special instructions given by the manufacturer should take precedence. The following general rules should be followed:

**179. Batteries should not be overdischarged,** and after the completion of a discharge they should be recharged within a reasonable time.

**180. Determining the charge** of a battery should be differentiated as follows: (a) the completion of regular charge; (b) the completion of overcharge (Par. **181**). The determination of completion of regular charge is that all cells are gassing uniformly, both from positives and negatives; that with the current maintained at a constant value there is no further increase of voltage as determined by successive 15-min. readings; that the acid density corrected for temperature is within 0.003 sp. gr. of the maximum reached on the last preceding overcharge. It is good practice to maintain one or two pilot cells (Par. **181**) in the battery and to note the acid readings of these cells as determining the state of charge of the whole battery. Batteries which are operated in this way will show a slight formation of sulphate in the plates, and this, for a limited time, is not injurious but beneficial.

Digitized by Google

If the sulphate formation is allowed to continue indefinitely, large insoluble crystals of lead sulphate are formed, and the plates will become *injuriously sulphated.*

**181. To reduce fully or oxidize the sulphate, the battery should receive a periodic overcharge** at intervals of at least once a week if the battery is called on for heavy service, or once every 2 weeks if the service is light. The overcharge is simply a continuation of the regular charge until the battery voltage at constant current input has remained constant and also until the acid density, corrected for temperature, has reached a maximum value as indicated by three successive acid-density determinations, at half-hourly intervals, having the same value.

If any cell or cells are late in gassing or become warm during charge, or if the specific gravity of the electrolyte is markedly lower than in the remaining cells, they should be investigated for short-circuits. Short-circuits will also be made evident if any cell falls materially behind the others in voltage on discharge. An excessive amount of charge should be avoided, as the resultant gassing will throw off some of the active material, especially from the positive plates.

**182. Removal of separators.** If for any reason it is necessary to remove wood separators from a cell, they should be kept covered with water. If allowed to dry out they will shrink, also the resulting concentration of acid in the wood will ruin them. Wood separators which have been in acid for several months will have so little strength that they cannot be handled without danger of breaking. New separators should be kept damp to prevent their shrinkage.

**183. Evaporation of the electrolyte should be replaced** by adding pure water. Keep the level of the electrolyte well above the tops of the plates. Do not add acid to the electrolyte unless it is clearly established that the removal of possible short-circuits and the subsequent overcharges will not restore the density of the electrolyte. Both water and electrolyte should be pure. It is preferable to add water before an overcharge; as the gassing will serve thoroughly to stir up the acid and equalize any differences in specific gravity between the tops and bottoms of the cells.

**184. Operating temperatures.** It is best not to allow the temperature of a battery to exceed 100 deg. Fahr.; a temperature above 105 deg. should positively be avoided.

**185. It is well to note the color of the plates** from time to time and to see that the colors of the plates in different cells are uniform.

**186. If the battery is low in capacity,** the relative condition of the positive and negative plates should be determined by taking voltage readings between both the positive and negative groups and a cadmium test electrode. This should be done toward the end of the discharge and will determine which of the groups are at fault.

**187. If any cell shows low voltage or low acid-density by reason of short-circuits,** it should be separately charged after the short-circuits have been removed. In large installations a **milker set** is usually provided for this purpose. This comprises a motor-generator supplying energy at from 3 to 6 volts. Another method is to cut-out the cell on discharge and replace it in the series on charge.

**188. The strength of the acid** to be used in various types of cells should be that prescribed by the manufacturer. It will depend entirely upon the battery design. The usual practice is to use electrolyte of 1.210 sp. gr. with stationary types of cells, while with vehicle types and with motor-starting and lighting batteries, maximum densities of 1.300 sp. gr. are sometimes used.

**189. Be sure that sediment does not accumulate** to such an extent as to touch the bottoms of the plates, as this would cause internal short-circuits in the cells. Separators must be kept in place and in good order. The entire battery should be kept clean and free from dirt. Condensed moisture or acid vapors should be wiped off from time to time, and the insulation kept dry. Raw linseed oil should be applied to the wood of lead-lined tanks as occasion demands.

**190. Charging rates.** The recommendations of the various manufacturers differ widely as to the proper charging current values. The following

Digitized by Google

is general practice, although the manufacturer of the battery should always be consulted on this point.

With Planté positive plates having centre webs, it is desirable to start the charge of the battery at as high as the 3-hr. rate, and to finish the charge at not less than the 8-hr. rate. Tudor-type positives may be charged at lower current rates than these, but at not less than one-half the preceding values. Batteries with Manchester-type positive plates should not be allowed to gas when charged at a rate above the normal 8-hr. charging rate, and an excessive amount of gassing should be positively avoided.

With pasted plate batteries, best results will be obtained by charging at low rates. With stationary types, the charge should be started at about the 8-hr normal rate and finished at one-half this value. With pasted vehicle-type batteries, the charge may begin at as high as 6 amp. per positive plate, but the completion of charge should be carried out at not more than 2 amp. per positive plate. These values hold for the standard size of plates, (5¾ by 8¾ in.) and should be varied in proportion to the plate area for other sizes. As the cells begin to gas on charge, the charging current should be reduced to the minimum values just given.

The constant potential method of charge wherein a battery is connected, without resistance, directly across a charging source having a voltage maintained at a value equal to the number of cells multiplied by 2.3, is advocated by many operators of vehicle batteries. This method insures a rapid charge of a battery without either gassing or overheating. For this method the line voltage, if too high, can be reduced by inserting counter e.m.f. cells in series with the battery, each counter e.m.f. cell reducing the voltage by approximately 3 volts. In applying this method, the literature of the battery manufacturers should be consulted. The constant potential method of charge is particularly adapted for the "boosting" of batteries.

**191. Fires, or flames must not be permitted in battery rooms,** unless the rooms are well ventilated; they must especially be prohibited when cells are gassing. Never bring a flame near a sealed-type cell.

**192. The usual troubles to which a storage battery is subjected,** result either from overcharge or undercharge, or from allowing short circuits to occur in cells. If the trouble has not been of too long duration, in practically all cases the battery can be brought into good condition by proper charge, presuming that, with the short-circuited cells, the shorts first have been removed and the separators put in good condition. Planté-plate batteries which have become sulphated should have their remedial charge started at about twice the 8-hr. or normal rate, which is to be reduced to normal when vigorous gassing ensues. Any of the methods of "rejuvenating" battery plates should not be carried out without having obtained the advice of the battery manufacturer or a qualified storage-battery expert. The methods which have been proposed for charging the battery in electrolyte containing sodium, potassium or magnesium sulphate, are to be condemned as impracticable, excepting on an experimental scale.

**193. The initial or developing charge** should be very carefully carried out in accordance with the directions of the manufacturer of the battery. Practice varies considerably in this regard, and the manufacturer will not accept responsibility for injury to the battery if his directions have not been followed. Points which should receive consideration are the following:

(a) Be sure that the positive pole of the battery is connected to the positive pole of the charging source.

(b) Always, in pouring electrolyte into cells containing dry plates, there is a certain amount of chemical reaction between the acid and the plates, especially the negatives. If the electrolyte becomes warm, it is well to allow sufficient time, before starting the initial charge, to allow the cells to cool down. A few hours, also, are required for the absorption of electrolyte in the pores of the plate.

(c) With Planté-plate batteries, the current at beginning of charge should be well above the normal rate, and should be reduced to the normal rate when vigorous gassing takes place at the positive. With pasted plates, lower rates are employed.

(d) If the cells reach a temperature of from 103 to 105 deg. Fahr., the charging current must be interrupted and the cells allowed to cool. If it is

Digitized by Google

found necessary thus to interrupt the charging current, the number of ampere-hours of initial charge must be increased.

(e) The initial or developing charge is to be considered complete only when both positives and negatives are gassing uniformly in all the cells, and when there has been no increase in voltage or specific gravity of electrolyte (the latter corrected for temperature) for a period of 5 or 6 hr. The battery should then be open circuited for an hour or so and, subsequently, the current applied again; in this charge, the cells should begin to gas from both positives and negatives within a minute or two.

(f) The battery should not be allowed to discharge until it has been fully developed as above. The color of the positives should be a very deep brown, and the negatives a light lead color.

**194. Placing batteries out of commission.** If a battery is not to be used for several months it should receive a very thorough charge before allowing it to stand idle. It is desirable, though not absolutely necessary, to give it a freshening charge of an hour or so once a month. If glass-jar batteries are to be left over winter and low temperatures will be met, it may be necessary to remove the acid, see Par. 100.

If a battery is to remain out of service an indefinitely long time, it will be advisable to remove the acid. Before doing this, it should be given a thorough overcharge. If the plates are to remain in the cells, syphon off the acid and remove the wood separators. Watch cells carefully and when the negatives become hot sprinkle with water. If the plates are to be removed from the cells, keep the positives apart and simply let them dry out. Do not rinse in water. The negative plates must be carefully kept apart, and sprinkled with water as soon as they become hot.

## DEPRECIATION AND MAINTENANCE OF LEAD STORAGE BATTERIES

### STATIONARY BATTERIES

**195. General considerations.** As with generating machinery, obsolescence, due principally to changes in service requirements, is the important factor of depreciation. A stationary battery may be maintained indefinitely by replacing worn out parts, but a renewal of tanks or the replacement of a battery room floor is a considerable item of expense. In these events it will frequently be advisable to reconsider the entire installation. Many floating batteries on interurban lines have given ten to twelve years of service with a single renewal of positive plates. The same result has often been obtained with regulating batteries.

**196. Actual maintenance costs.** A case of five large railway regulating batteries which are called upon daily excepting Sundays, for peak discharges each morning and afternoon, the ampere-hours of discharge aggregating quite approximately the equivalent of one 8-hr. discharge per day, may be cited. A blanket contract to furnish and install all the maintenance material required to maintain the five batteries in efficient operating condition for a second term of 10 years was entered into, the contractor undertaking to do this for approximately 8 per cent. per annum of the initial cost of the installation. The foregoing are among the hardest-worked batteries installed in the United States. Stand-by batteries can be maintained for a period of 10 to 15 years at within 3 per cent. per annum of the cost of installation.

**197. Life of plates.** Planté positive plates in regulating or line batteries will have lives of from 4 to 6 or more years if they are in hard service, and should last longer in light service. Planté negative plates should outlast two sets of positives within a period of 12 to 14 years. Paste positives in stand-by service show every indication of being good for 10 years of service, negatives being good for a somewhat longer period. The scrap lead of plates, to be replaced, has a considerable value and the cost of plate replacements should be credited with this value. Manufacturers will usually guarantee a minimum life of plates if they know the service conditions.

**198. Life of tanks.** Glass jars are good until broken and a few jars, especially with the larger sizes, will break from time to time outside of accidental causes. This breakage is usually a consequence of imperfect

Digitized by Google

annealing of such jars, and should not aggregate more than 5 to 7 per cent of the total number. The life of lead-lined tanks will depend on the care with which insulation is maintained and whether the wood is kept protected from acid by painting. If the insulators are kept clean, if the battery is not allowed to gas from excessive charge, if tanks are kept covered, and if the tanks are occasionally oiled and painted they will last from 10 to 15 years. The largest item in the depreciation of tanks is the pitting of their lead linings through electrolysis. This is a minimum if the insulation is maintained.

**199. Acid and water.** These are small items and properly come under the head of operating expense.

**200. Wood separators.** Wood separators should have a life of from 2 to 5 years, depending largely on the amount of overcharge to which the battery is subjected. They rapidly lose their strength after installation but if it is not necessary to disturb them when removing plates for straightening or for other causes, they will act as efficient diaphragms for the above mentioned times.

**201. Other parts.** Glass covers will be broken from time to time; the number will depend entirely on the care of the attendant. Glass support plates will be broken occasionally but the number should be small. Bus bars and copper should not require renewal during the life of the battery. Wood sand trays will require renewal at intervals depending on the care with which they are kept dry and free from acid when filling cells with water.

**202. Sediment removal.** Modern practice is to install tanks with a liberal space below the plates for sediment accumulation. The cost of cleaning between intervals of plate renewals is great enough to warrent the slight extra cost of a battery installation when such space is provided. The injury to the battery insulation and battery-room floor from slopping of acid is another justification for deep tanks.

## VEHICLE BATTERIES

**203. General considerations.** Batteries in pleasure vehicles, on account of the limited use to which they are subjected, frequently last 2 to 3 years. Batteries in truck service should last at least 1 year if of the thin-plate type and longer with thicker plates.

**204. Life of plates.** Thin plate batteries of the better makes in commercial service should give 12 to 15 months of service. Thick plate batteries should have a plate life of 18 to 24 months, the vehicle supposedly in operation each week day. Plate life will be increased by avoiding overcharge especially at high rates, also by employing as wide a plate separation as possible to avoid the necessity of strong acid.

**205. Life of wood separators.** If the acid strength is not excessive and overcharge is avoided, wood separators will last normally 12 to 15 months. With thick-plate batteries, it will usually be necessary to renew the separators once.

**206. Life of jars and hard-rubber sheets.** The compound of the usual jar and perforated sheet is not rich in rubber, and its constituents harden with age. They become especially brittle if the battery is permitted to overheat on charge. Unless jars are of good material a large number will be broken when plates are renewed.

**207. Life of other parts.** Battery crates usually require renewal when the plates wear out. If the crates are kept dry however they will frequently be in good enough condition to warrant their use with a new set of plates. Negative crate terminals will in most cases be intact but the positive terminals if not kept well covered with vaseline will require renewal when plates are replaced. Hard-rubber covers for cells will usually be in good condition, but a few will be broken in removing sealing compound. Soft-rubber vent plugs depreciate considerably, but these are quite inexpensive. Cell connectors and straps have a high scrap value and it will usually be cheaper to replace old ones with new.

## TRAIN-LIGHTING BATTERIES

**208. Effect of overcharge.** The maintenance of train-lighting batteries has varied widely under different operating conditions. Some of the earlier

Digitized by Google

batteries were serviceable for 9 or 10 years with negligible replacements. The best results have been obtained with batteries which were not overcharged. The increased capacity of axle-generator equipments of recent years has resulted in greatly overcharging batteries, with a serious shortening of their life.

Overcharge of these batteries requires that water be added frequently, and if this is not carefully done the insulation of the tanks is injured. Overcharge also results in a greater deposition of sediment from positive plates and a shortening of their lives.

**209. Frequency of cleaning.** Train-lighting batteries which are properly charged can be kept in operating condition for 3 years without being opened up for cleaning. After cleaning the first time such batteries should be cleaned at intervals of 2 years. With many railroads the practice is to make the first cleaning 2 years after placing in service, with subsequent intervals of 1 year between cleanings.

## ALKALINE STORAGE BATTERIES

**210. Classification.** There are but two practical types of alkaline storage batteries in commercial use: one is the Hubbell, used in the miners' lamps of the Portable Electric Safety Light Co.; the other is the Edison storage battery.

**211. The Hubbell battery** differs from the Edison in principle, only in using a negative plate of cadmium instead of the iron of the Edison battery. Hubbell apparently was the first to use nickel threads incorporated in the nickel-oxide active material, and this is one of the essential steps in the production of a practicable battery plate with this active material. The nickel oxide of the original Edison battery, contained flake graphite to increase the conductivity; the graphite was seriously affected by electrolyte action, and these plates were short lived. In the present type of Edison battery, flake nickel replaces the graphite of the earlier type. In December, 1914, the first few of these batteries had completed 5 years of service.

**212. Theory of the Edison battery.** The active materials of the Edison battery consist of nickel peroxide for the positive plate and finely divided iron for the negative plate. The electrolyte is a 21 per cent. solution of potassium hydrate in water to which is added a small amount of lithium hydrate. To overcome the passivity of iron a certain amount of mercury is incorporated with the iron of the negative plate; a suitable compound is also incorporated with the nickel hydrate which is the salt from which the nickel peroxide is electrolytically formed. The nickel oxide is a relatively poor electrical conductor and, for this reason, layers of flake nickel are added in the mass to increase its conductivity. Catalysis plays a large rôle in the action of the Edison battery. A complete and correct theory of these reactions has probably not yet been given. Essentially, however, it is the following:

$$8OH + 3Fe = Fe_3O_4 + 4H_2O \quad \text{(Negative Plate)} \quad (11)$$

$$8K + 6NiO_2 = 3Ni_2O_4 + 4K_2O \quad \text{(Positive Plate)} \quad (12)$$

$$8KOH + 6NiO_2 + 3Fe = Fe_3O_4 + 2Ni_2O_4 + 8KOH \quad \text{(Both Plates)} \quad (13)$$

or,

$$6NiO_2 + 3Fe = Fe_3O_4 + 2Ni_2O_4 \quad (14)$$

The above formula, read from left to right, indicates discharge; read in the reverse direction, it indicates charge.

Both the iron and nickel oxides probably do not exist as such, in the electrolyte, but are hydrated. In the charge of the battery, potassium is not deposited, and there are none but concentration changes in the electrolyte in the pores of the active materials. There is no appreciable change in electrolyte density from the charged to discharged state of the Edison battery. At the latter end of charge a higher oxide of nickel is formed, which is unstable on standing. This oxide decomposes to $NiO_2$ with time. A freshly charged Edison battery shows a higher voltage on discharge than one which has been standing.

**213. Positive-plate construction.** The positive plate consists of a nickel-plated steel frame into which are pressed perforated tubes filled with alternate layers of nickel hydrate and metallic nickel in very thin flakes. The tube is formed from a thin sheet of steel, nickel plated and perforated, and has a spirally lapped joint. The active material is tamped into the tubes, nickel hydrate and nickel flake being fed alternately and the tubes when

Digitized by Google

filled have their ends pressed together in such a way to permit them to be mounted in the frames. The tubes have small steel bands slipped over them

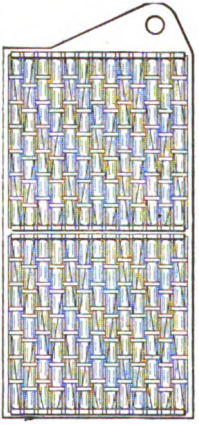

FIG. 51.—Edison positive plate.

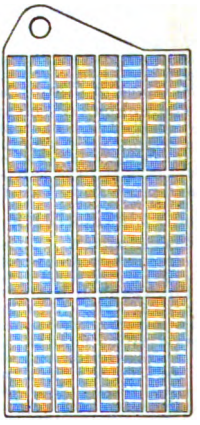

FIG. 52.—Edison negative plate.

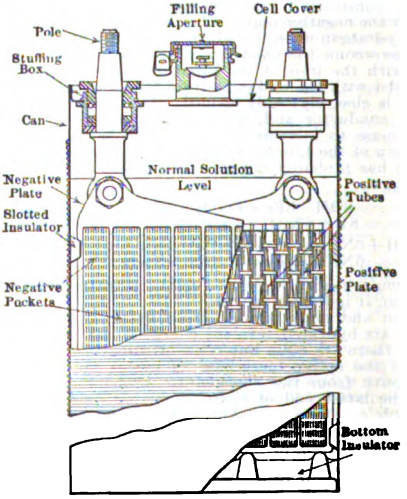

FIG. 53.—Edison cell construction.

to prevent expansion away from the active material. Such a plate is shown in Fig. 51.

| Watt-hr. per lb. of cell | 10.4 | 13.0 | 13.7 | 13.3 | 13.4 | 14.1 | 13.1 | 13.2 | 13.2 |

**215. Negative-plate construction.** The negative plate comprises a grid of nickeled steel with oblong openings into which are placed perforated steel boxes or pockets containing finely divided iron with mercury. See Fig. 52. These boxes are assembled in the grid and subjected to pressure to weld the joints and to corrugate their surfaces. The iron is precipitated as a chemical compound and the nickel hydrate and this iron compound are converted electrolytically to nickel peroxide and metallic iron respectively, in the forming of plates.

**216. The assembly of the cell** is shown in Fig. 53. The plates are supported on hard-rubber spacing and insulating pieces. The lugs of the plates are punched and are mounted upon a steel pin with a terminal post. The ends of the pins are threaded and the plates, separated by washers, are held together by steel nuts. The elements are contained in a nickel-plated sheet-steel case, the walls of which are corrugated to add stiffness and also to assist in cooling the cells in action. The cover also is of

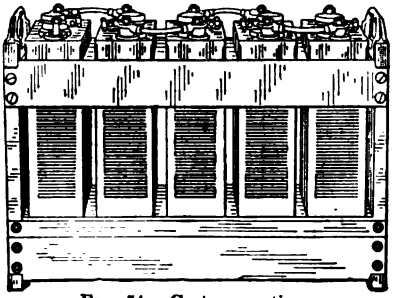

FIG. 54.—Crate mounting.

sheet steel with three openings; two for the terminal bushings, which are provided with stuffing boxes, and the third for the gas vent and for the filling of the cell with water.

The cells are assembled in wood crates as shown in Fig. 54, usually with the bottom left open to secure a circulation of air sufficient to keep the cells cool.

With the Edison battery the discharge rate which has been taken as the normal or standard, is that which would discharge the battery in 5 hr.

The numerals of the type designations indicate the number of positive plates in a cell, and each positive plate of the vehicle size is capable of giving 7.5 amp. for 5 hr.

**217. Charge and discharge curves.** The characteristic normal charge and discharge curves for an Edison battery are given in Fig. 55. It will be noted that the average voltage on discharge is approximately 1.2 volts; the initial open-circuit voltage is approximately 1.5

Digitized by Google

volts, and the final voltage at the end of discharge is approximately 1 volt. The first part of charge shows a characteristic voltage rise, and there is a subsequent decrease in voltage with continued charge, followed by another rise. There is no extremely sharp rise in the final voltage of the Edison cell, and it is therefore somewhat difficult to determine the end of

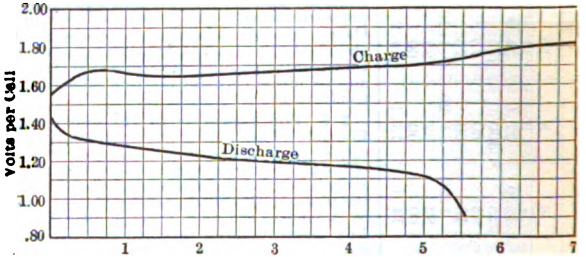

FIG. 55.—Normal charge and discharge curves.

charge. If an Edison cell is known to have been considerably discharged, it is always well to continue the charging current for the full 7-hr. period, as the battery is not injured by overcharge unless the temperature passes a critical point.

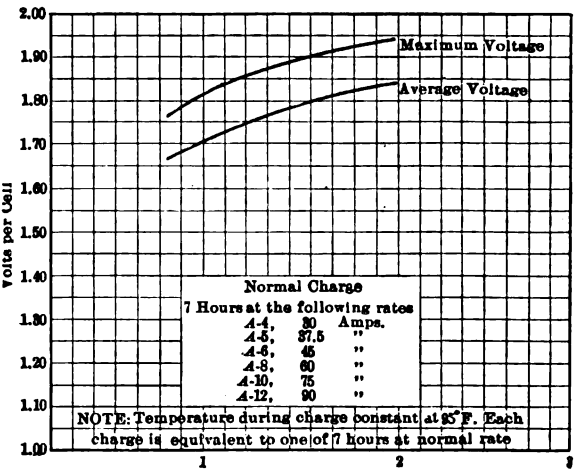

FIG. 56.—Temperature influence on charging voltage.

**218. Charging curves.** Maximum and average voltages of charge as influenced by charging rate, are shown in Fig. 56. In these curves, the cell is presumed to have a constant temperature of 95 deg. Fahr. and the duration of charge is 7 hr. The voltage on charge decreases considerably with increasing temperatures.

Digitized by Google

**219. Characteristic discharging curves.** Characteristic discharge curves for Edison type "*A*" cells are given in Fig. 57. It will be noted that the ampere-hour capacity of an Edison cell does not suffer very greatly with increasing discharge rates, if the terminal voltage be carried low enough. For practical purposes, however, the last portion of the discharge at high rates would have no value because of its great falling off from the open-circuit voltage.

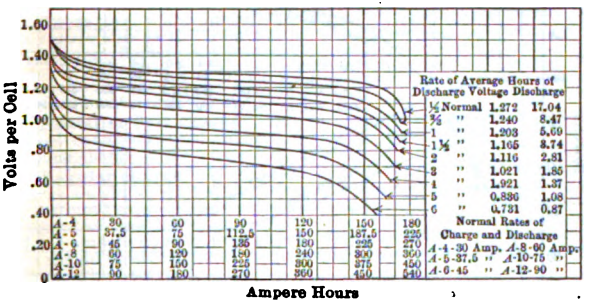

FIG. 57.—Typical discharge curves, type "*A*" cells.

**220. Standing discharged.** No injury is done to the Edison battery if it is completely discharged and allowed to stand in this condition. This is one of the principal distinguishing features of the Edison battery. The cell, however, loses in capacity by standing as shown in Fig. 58, and is most easily brought back to its condition of full capacity by giving it a very considerable overcharge. The usual practice is to ship the Edison battery in a discharged condition, and it requires several cycles of charge and discharge to bring it to its full capacity.

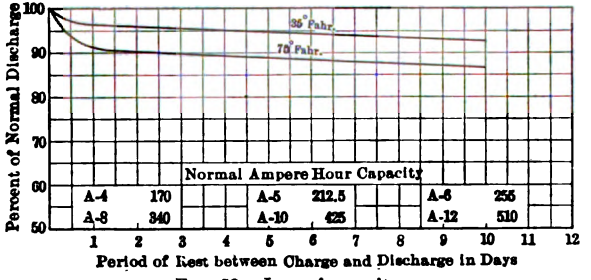

FIG. 58.—Loss of capacity.

**221. Overcharge.** The Edison battery is not injured by overcharging unless its temperature exceeds 105 to 110 deg. Fahr. High temperatures seriously affect the capacity and life of Edison negative plates, and the manufacturer's guarantee does not hold for overheating from this cause. A continuance of overcharge increases the capacity on the subsequent discharge, but this increase in capacity is obtained at the expense of efficiency. The effect of continued charge is shown in Fig. 59.

**222. Effect of temperature.** There is a marked falling off in capacity of the Edison battery with low temperature, especially at high discharge

Digitized by Google

rates. For this reason the battery compartments of electric vehicles using these batteries must be carefully insulated against cold, if low temperatures are to be met. If the battery has attained a low temperature from long standing, it will tend to heat up on discharge, because of the high internal resistance, and if this heat is retained by the insulation, a fairly complete discharge can be obtained.

FIG. 59.—Influence of overcharge.

**223. Deterioration of electrolyte.** Water must be frequently added to the electrolyte of an Edison battery, to replace that lost by decomposition and evaporation. The amount of water required for this purpose is considerably greater than with a lead battery, because of the poor ampere-hour efficiency and the higher temperatures reached on charge. Distilled water must be used for this purpose, but even with its use, the electrolyte becomes gradually converted to potassium carbonate through the absorption of carbon dioxide from the air. For this reason also, it is perferable to use water which has been freshly distilled. As the electrolyte deteriorates from the above

FIG. 60.—Log of life test.

mentioned cause, the capacity of the battery falls off, and, after about 250 cycles of charge and discharge, the electrolyte should be renewed. After each electrolyte renewal there is a temporary increase in capacity as shown in Fig. 60.

**224. Testing.** Tests on Edison batteries should be carried out as described in Par. **101** to **105**, with certain obvious changes. There is no appreciable variation of electrolyte density, and the end point of charge is also determined with greater difficulty than with the lead battery. A

Digitized by Google

suitable neutral or test electrolyte for an Edison battery is a nickel-oxide hydrate, such as those used in the standard positive plates.

**225. Application.** The "*B*" type cells are used for ignition and lighting of gasoline motor cars; they are not commercially used for motor starting on account of the high internal resistance. The vehicle-type cells are used for electric vehicle propulsion, storage battery street cars, mining locomotives and industrial trucks; they are not used for load regulation on account of the heavy drop in voltage at high discharge rates, this factor also limiting their use in other power applications.

**226. Operation.** The life of the Edison battery is guaranteed under certain restrictions as to its operation. The operating instructions of the Edison Storage Battery Co. should be carefully followed if the battery company is to be held to its guarantee. A temperature of 115 deg. Fahr. should not be exceeded under any circumstances, as high temperatures will seriously injure the negative plates.

**227. Initial or first charge.** Edison batteries are usually shipped in a discharged condition. Before placing them in service they should receive a continued charge at the normal or 5-hr. rate, for a period of 12 hr. or more.

**228. Regular charge.** If the battery has received a complete discharge, the charge should be started at the normal rate and continued for a period of 7 hr., or until each cell, under normal temperature conditions, has reached a voltage of at least 1.8 volts per cell. The ampere-hours of charge should exceed the ampere-hours of discharge by approximately 40 per cent., and the battery should receive in addition, an overcharge of several hours at the end of each month of service.

**229. Replacing evaporation.** The electrolyte must be kept well above the plates by adding water whenever necessary, to maintain the level. Always use distilled water for this purpose.

**230. The outside of the cells and the trays must be kept clean and dry.** Dampness under certain conditions will cause the containers to pit under electrolytic action.

**231. Standing idle.** If an Edison battery is to be placed out of commission it need not receive any special attention, other than to see that the electrolyte is brought to the proper level. The battery can stand either charged or discharged equally well. To obtain the full capacity, however, after a long period of standing it is necessary to overcharge the battery.

**232. Life of Edison battery.** A log of a life test as published by the Edison Storage Battery Co. is shown in Fig. 60, the statement is made that the conditions of the test are harder than would normally be met in service. The battery is more durable than the vehicle types of lead battery. It is doubtful if it approaches the durability of the heavy Planté types of lead cells.

# SECTION 21

## TELEPHONY AND TELEGRAPHY

BY

**FRANK F. FOWLE, S.B.**

*Consulting Electrical Engineer, Member American Institute of Electrical Engineers*

### DEFINITIONS

1. **The scope of this section** is confined to the needs of electrical engineers who encounter telephone or telegraph problems only in the sense of an adjunct to a major operation, or subsidiary to the main work in hand. Therefore the section deals exclusively with those applications of telephony and telegraphy which may be termed **private-line systems**, as found in connection with steam and electric railways, transmission and distribution systems, industrial plants, etc.

2. **Telephone systems** may be classified, according to their commercial uses, as follows:

*Telephone Systems* { *Public* { *Exchange*; *Toll* }; *Private* }

3. **Public telephone systems** are those operated for commercial profit, under some fixed schedule of tariffs or rates. Such systems must serve all who apply, and are usually subject to some form of regulation as to rates and service by the public authorities. Any public system might be broadly defined as a common carrier of intelligence or communication.

4. **Telegraph systems** may be classified, according to their uses, as follows:

*Telegraph Systems* { *Public*; *Fire Alarm*; *Police*; *Private* }

5. **Public telegraph systems** may be defined in general the same as public telephone systems, in Par. 3, with the exception that the mode of communication of course is different.

6. **Private telephone and telegraph systems** are those operated as auxiliaries to some other form of business or enterprise (Par. 1), but not directly for commercial profit. Private systems are sometimes interconnected with public systems, and in other cases are completely isolated. Any private system which is operated under especially hazardous conditions, such as long parallel exposure under a high-tension transmission line or close proximity to a single-phase traction system, should be connected to a public system, if at all, only through elaborate protective apparatus designed to reduce to an absolute minimum the probability that dangerous potentials or currents will penetrate beyond the protection to any part of the public system.

7. **Private systems may be classified**, according to their uses, as follows:

*Private Systems* { *Train Dispatching*; *Load Dispatching*; *Line Patrol*; *General communication*; *Intercommunicating* }

Digitized by Google

**8. Train dispatching systems** are those employed on steam or electric railways in connection with the control of train movements by one or more train dispatchers.

**9. Load dispatching systems** are those employed in large central station systems, or in large transmission and distribution systems, in connection with the centralised control of the distribution system by one or more load dispatchers.

**10. Line patrol systems** are used in connection with the patrol of transmission lines, to enable patrolmen to communicate quickly with headquarters; they are used also by the U. S. Life-Saving Service.

**11. Private systems for general communication** have numerous and extensive applications on steam and electric railways, and in connection with central stations, transmission and distribution systems, etc.

**12. Intercommunicating systems** are designed for isolated local service, usually without attendance, in factories, mills, shops, residences, etc.

## STANDARD TELEPHONE INSTRUMENTS

**13. Speech is transmitted electrically** by means of three supplementary elements, termed the transmitter, the line, and the receiver. The sound waves of the voice impinge upon the diaphragm of the transmitter and cause it to vibrate in substantial synchronism with the impressed disturbance. The diaphragm forms part of an electromechanism which establishes in the line circuit an alternating current of variable frequency, amplitude and wave form, but substantially proportional at any instant to the pitch, intensity and quality, respectively, of the impressed sound. The line current in its passage over the line suffers both loss of intensity, or attenuation, and change of wave shape, or distortion. If not too greatly enfeebled or distorted by its passage over the line, the transmitted energy enters the receiver and is there converted again into sound waves, approaching in pitch, intensity and quality the impressed sound waves at the transmitter. The receiver is an electromechanism whose function is the reverse of that performed by the transmitter.

The alternating line current, in certain instances, is superimposed on a continuous current, the resultant being a pulsating current. The two currents are separable either by means of a transformer, known in telephony as a repeating coil, or by a combination of reactance (choke) coils and condensers.

**14. Transmitters** of the variable-resistance, granular-carbon type are almost universally employed. This type consists essentially of two parallel circular electrodes, usually of carbon, one of which is attached to the diaphragm, the other being rigidly mounted. Between the electrodes is a loose mass of finely granulated carbon. Vibration of the diaphragm causes simultaneous variations of pressure on the granular carbon, with accompanying changes in total resistance from electrode to electrode; the resistance decreases with increase of pressure, and *vice versa*.

**15. High-resistance transmitters,** having about 30 to 60 ohms average resistance, are ordinarily employed for both common-battery and local-battery (magneto) sets. High resistance is particularly desirable in common-battery sets, with central energy supply; it also has the advantage, in local-battery sets, of being economical in energy consumption.

**16. Low-resistance transmitters,** having about 10 to 15 ohms average resistance, are used in special service (local battery) where the transmission requirements are severe, such as railway train dispatching. Special low-resistance transmitters intended to operate from 110-volt direct-current lighting circuits are used in connection with loud-speaking telephones for announcing trains, paging guests in hotels, etc.

**17. Solid-back transmitter.** Fig. 1 shows a cross-section of what is commonly known as the White or solid-back transmitter. In this, P is the bridge mounted securely at its ends on the front, F. The diaphragm, D, is of aluminium, with its edges enclosed in a soft rubber ring, *e*, and is held in place by two damping springs, *f*. W is a heavy block of brass, hollowed out to receive the rear electrode, B, which is of carbon secured to the face of a metallic disc, *a*. E is the front electrode, also of carbon, carried on the head of a metal stud, *b*. This electrode is clamped to the diaphragm by means of a

Digitized by Google

threaded stud, *p*, and the thumb nuts, *tt'*. Against the front electrode is clamped a mica washer, *m*, which serves to close the front opening of the electrode chamber, and thus prevents the granular carbon from falling out. The flexibility of the mica washer allows the front electrode to vibrate with respect to the carbon chamber. The interior wall of the chamber is lined with a paper ring, *i*, for insulation.

Another well-known type of solid-back transmitter is shown in Fig. 2. The hard-drawn aluminum diaphragm contains a recessed chamber or cup

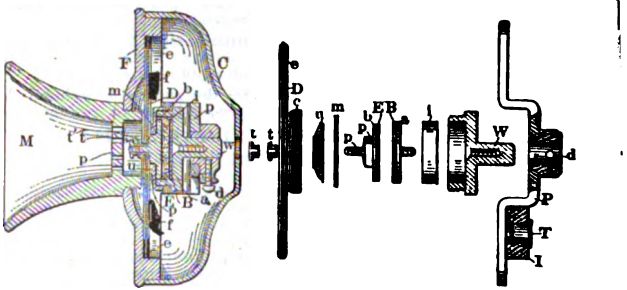

FIG. 1.—Cross-section and exploded view of solid-back transmitter.

which holds the front electrode, the granular carbon and the mica auxiliary diaphragm. The rear electrode is rigidly mounted on the bridge or solid-back support. A hard aluminum sealing ring is riveted over the mica auxiliary diaphragm to render the carbon chamber both dust and moisture proof. The carbon electrodes are each copper plated on one face. A gasket serves to cushion the diaphragm against the casing and also insulates it electrically.

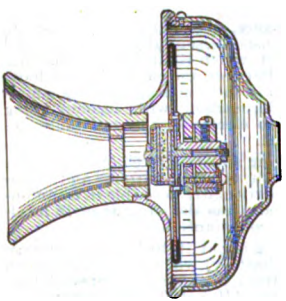

FIG. 2.—Cross-section of solid-back transmitter with recessed diaphragm.

Transmitters are sometimes made with one of the electrodes electrically common or in contact with the metal case of the instrument, but it is preferable to have both electrodes completely insulated, in order that users of the instrument may not come into contact with any part of the electrical circuits.

**18. Transmitter batteries** in local-battery sets are very generally composed of two dry cells (Sec. 20), connected in series. Wet cells were formerly used, but are more expensive, less compact and clean, and more difficult to handle. Two dry cells can be easily placed in the battery box of a wall set, making the set self-contained. Three dry cells will give slightly better transmission, usually, than two cells. Where the use is very severe, Fuller (wet) cells are used (Sec. 20), not less than two nor more than three cells being connected in series, for low-resistance transmitters. The latter type of cell is very well adapted for heavy local-battery service. At magneto switchboards, either Fuller or Edison primary cells are suitable for supplying the operators' transmitters, when storage cells are not available or economical.

The energy supply in common-battery systems is obtained from the central battery at the switchboard, the current flowing from the switchboard over the line circuit to the telephone station and through the transmitter. A

Digitized by Google

storage battery (Sec. 20) of 11 cells is usually employed. When the loudest possible transmission is desired, low-resistance transmitters should be used, supplied from Fuller or Edison cells; storage cells, if they can be conveniently charged, will also be satisfactory.

**19. Induction coils,** when used, form a portion of the transmitting circuit and perform the function of a step-up transformer, in order to transmit to the line impulses or waves of higher potential than those produced in the transmitter circuit. Induction coils are always used with local-battery sets, but not with all makes of common-battery sets (see Fig. 10). It is very important to use the particular type and construction of induction coil which is designed for the transmitter with which it is associated; a different type may operate with fair satisfaction, but not with maximum efficiency.

The general construction of induction coils is shown in Fig. 3. The core consists of a bundle of small iron wires; some manufacturers employ annealed Norway iron. One manufacturer recommends a ratio of primary to secondary turns, for local-battery sets, of one to four. The secondary is usually wound over the primary. Primary resistances vary from a fraction of an ohm up to about 10 ohms; secondary resistances range from about 20 to 150 ohms. Primary windings range in size from No. 18 to 26 A.W.G. and secondary windings from No. 26 to 36. The diameter of the iron core is usually 0.25 in. minimum.

FIG. 3.—Cross-section and end view of induction coil.

**20. Receivers** consist essentially of three elementary parts, a permanent horse-shoe magnet, a sheet-iron diaphragm assembled in front of the magnet poles, and a winding on the polar extremity of each leg of the magnet. The normal tension on the diaphragm varies in synchronism with the current traversing the winding; thus when the winding is energized by voice currents, the diaphragm sets up corresponding voice sounds. Such an instrument is also reversible and may be used as a transmitter of the electromagnetic type; it is not efficient, however, and is used for this purpose only in emergencies, for example when the transmitter battery supply fails, to communicate with the switchboard operator. A modern telephone receiver is shown in Fig. 4. The working parts of this receiver are composed of two bar magnets clamped together by screws passing through an iron tail block, *b*, at one end and through a brass block, *c*, at the end nearest the magnet coils. The magnet unit, in one type, is welded to avoid the presence of joints. The pole pieces are clamped between the magnet ends and the brass block and on their outer ends carry the two coils. The block engages a shoulder in the hard rubber shell and is secured in place by screws, thus holding the working parts securely within the shell. The diaphragm is clamped between the ear piece and the main body of the shell. The terminals of the coils are led to the binding posts, *aa*, to facilitate connecting the receiver in the external circuit. The cord covering is secured to the tail block, *b*, so as to relieve the cord terminals from strain. A type similar in design but differing in that the diaphragm, coils and magnets are all mounted on a separate metallic frame, independently of the enclosing shell, has the advantage that breakage of the shell does not necessarily destroy the adjustment of the instrument.

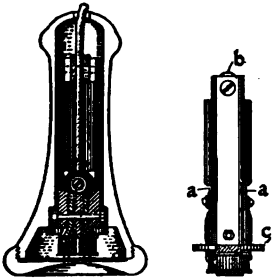

FIG. 4.—Cross-section of receiver and side view of magnets.

Bipolar receivers are also made in the so-called "watch-case" type. This type is attached to a head band and almost universally employed with operators' sets for switchboard service.

Digitized by Google

**21. Receiver terminals.** Receivers are manufactured with both exposed and concealed terminals. The type with concealed and insulated terminals should always be used, in order that the user cannot come into contact with any portion of the electrical circuits.

**22. Continuous-current receiver.** A type of receiver in which the permanent magnet is replaced by a laminated iron core has been brought out recently for common-battery sets. The receiver winding is connected in the line directly in series with the transmitter, and the magnets are energized by the line current. This eliminates the necessity for an induction coil and results in a less expensive set for local or intercommunicating service.

**23. Receiver resistance and impedance.** Receivers are wound for various resistances from 30 to 100 ohms. A resistance of 70 to 80 ohms is very widely used for standard bipolar receivers; the impedance to voice currents (equivalent single frequency, about 800 cycles per sec.) is about 300 ohms. For train-dispatching circuits, where numerous stations may be bridged across the line simultaneously, it is desirable to use receivers of higher impedance in order to avoid excessive transmission losses by reason of low-impedance bridges. For this service, one manufacturer winds receivers for a resistance of 600 ohms, having an impedance to voice currents of about 2,500 ohms.

**24. Polarized bells or ringers** are used to make audible announcement of incoming calls or signals at telephone stations. A typical form of ringer is

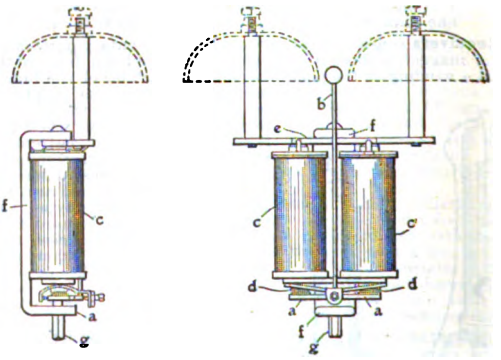

FIG. 5.—Polarized bell or ringer.

shown in Fig. 5. An iron armature *aa* is pivoted at its centre and carries a light rod *b* with a clapper at its outer end arranged to strike the gongs when set in vibration. Electromagnets *cc* are arranged with their pole pieces *dd* in position to attract the ends of the armature *a*; the magnetic circuit is completed by the yoke *e*. A permanent magnet *f* serves to polarise the armature *a*. The air-gap is made adjustable by means of the screw *g*. The magnet windings are connected in series.

A condenser (Par. 30) is frequently connected in series with a polarised bell when alternating current is used for signalling, and almost invariably has no harmful effect on the efficiency of the ringer itself; furthermore, a small condenser connected in series with the ringer increases the bridged impedance and thus improves the efficiency of signalling on heavily loaded party lines.

**25. The resistances of polarised bells** range from 80 ohms, for series ringers, to 3,500 ohms for bridging sets on heavily loaded party lines. Series ringers (80-ohm) are not now used to any great extent. The standard resistances for bridging ringers are 500, 1,000, 1,600, 2,000, 2,500 and 3,500 ohms;

Digitized by Google

1,000-ohm ringers are standard for ordinary lines, while the higher resistances are used for party lines.

**26. Magneto generators** are commonly used for signalling from local-battery (magneto) stations or sets. A typical 3-bar magneto, or hand-generator, is shown in Fig. 6, unmounted. An armature of the Siemens or shuttle type is arranged to revolve in the magnetic field produced by permanent

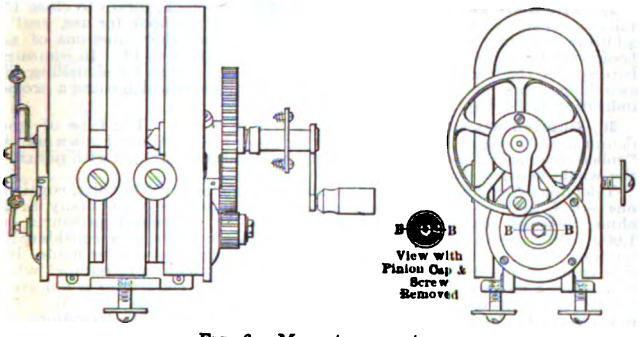

FIG. 6.—Magneto generator.

magnets, being driven through light spur gears increasing the speed in ratio of about 5 to 1. Therefore when the crank is revolved at 200 rev. per min., the frequency will be about 17 cycles per sec.; probably the average frequency is between 10 and 15 cycles.

The **series type**, for series sets (Par. **35**), must be provided with an automatic short-circuiting device to remove it from circuit when not in use. The **shunt** or **bridging type**, for bridging sets (Par. **34**), must be provided with an automatic circuit-opening device to disconnect it from circuit when not in use. These automatic switches are operated by the shaft which carries the generator handle and large spur gear. Fig. 7 shows the circuit of a bridging generator; the shaft *b* is so arranged that it will advance against a coiled spring and engage the spring *c* before rotating the spur gear, thus closing the circuit between the terminals *aa*. In one make of generator, a device is also provided to separately short-circuit the generator armature when out of use, in order to protect it from lightning or excessive foreign potentials.

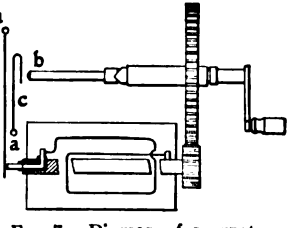

FIG. 7.—Diagram of magneto generator connections.

**27. Magneto generator windings and ratings.** The output of these generators, owing to their small size and high internal impedance, is very limited. The lower the internal impedance and the larger the magnetic flux through the armature, the greater will be the output for a given size and speed. The windings vary in resistance, in different sizes and makes, from about 100 to 500 ohms, with several thousand turns. The best grade of magnet steel (Sec. 4), with maximum retentivity and minimum aging, should be used. Generators for light service are usually equipped with three magnets, and are known as the 3-bar type; four bars are used for medium service and five for heavy service. The generated effective e.m.f. at no load and 1,000 r.p.m. (armature speed, giving 16.7 cycles per sec.)

Digitized by Google

is about 70 to 80 volts. The voltage falls very rapidly as the output increases; the maximum output is of the order of only a few watts, probably rarely exceeding 5 watts.

**28. Receiver hook.** The receiver of a telephone set, when not in use, is hung on a hook which is termed the receiver hook or switch hook, and performs a very important function. The exposed metal portions of the hook should be well insulated from the circuits of the switch.

**29. The hook switch,** which is actuated by the hook, serves to close the talking circuits when the receiver is removed from the hook for use, and in addition performs several auxiliary functions. The other functions of the hook switch will be made clearer by reference to Figs. 8 to 13. In common-battery sets, the hook switch in addition serves as a means for signalling the switchboard through the agency of line relays or signals which cause a proper indication to be displayed before the operator.

**30. Condensers** are described as a whole in Sec. 5. The type of condenser usually employed for telephone purposes is commonly known as the "rolled condenser," made of tin-foil and paper and impregnated with paraffin, the whole being sealed in a moisture-proof case.

Telephone condensers are usually subjected to a test of 500 volts, continuous e.m.f. and required to have an insulation resistance of many megohms. Special condensers are constructed to withstand pressures of 1,000 volts, alternating. Standard condensers are made in a considerable number of sizes, ranging from 0.05 to 2 mf. Larger sizes can be made, but it is common practice to connect a number of condensers in parallel when more than 2 mf. is needed. The capacity of paraffin condensers is not sufficiently constant to permit them to be used as standards (Sec. 5). The impedance of a 1-mf. condenser at 16.7 cycles per sec. (2,000 alternations per min.), which is the standard ringing frequency, is 9,540 ohms; at 800 cycles per sec., the impedance (neglecting the leakage current and internal losses) is 199 ohms, and in both cases this impedance is wholly capacity reactance (Sec. 2). Condensers are used very extensively in telephone apparatus.

**31. There are two general types of local line** for connecting telephone stations with each other, or with a switchboard. The type by far most extensively used is the **bridging line,** to which the stations or sets are connected in the familiar shunt or bridging relation, like incandescent lamps in a constant-potential distribution system. The other type, but little used, is the **series line,** to which the stations are connected in series or looping relation, like arc lamps in a constant-current series distribution system.

**32. Metallic lines** are those composed throughout of insulated wires or conductors, and may be of the bridging or the series type. A bridging metallic line requires two wires, often termed a pair, at every point. The latter type is the preferable one for nearly every kind of private telephone system, except possibly for small interior intercommunicating systems.

**33. Grounded lines** are those composed in part of insulated wires or conductors, with earth or ground return, and may be of the bridging or the series type. Grounded lines are not recommended, because of the insuperable difficulties from cross-talk and inductive disturbances, so frequently present.

**34. Magneto or local-battery bridging sets** (Fig. 8) have been described in Par. **26.**

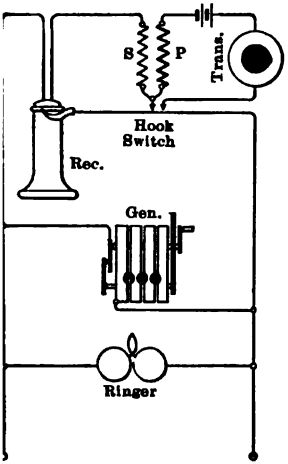
**35. Magneto or local-battery series sets** are typified by the set depicted in Fig. 9 and described in Par. **27.** They are not extensively used.

**36. Bridging sets** (Fig. 8) are those adapted for use on bridging lines (Par. **31**). The receiver and the secondary of the induction coil are in series relation with each other, and bridged across the line through the contacts of the hook switch, the latter being closed only when the receiver is off the hook, as shown in Fig. 8. The ringer is separately bridged across the line, and likewise the generator, although the circuit of the latter is closed only when it is in action. The local battery circuit of the transmitter is closed by the hook switch, only when the receiver is off the hook. The set shown in Fig. 8 is the magneto or local-battery type; common-battery bridging sets are shown in Figs. 10 to 13.

**37. Series sets** (Fig. 9) are those adapted for use on series lines (Par. **31**). The receiver and the secondary of the induction coil are in series relation with

Digitized by Google

ach other, and connected to the instrument terminals through the contacts f the hook switch, the latter being closed only when the receiver is off the ook, as shown in Fig. 9. The ringer and the generator are connected in ries with each other, and stand normally connected to the instrument



IG. 8.—Circuit diagram of typical bridging telephone set.

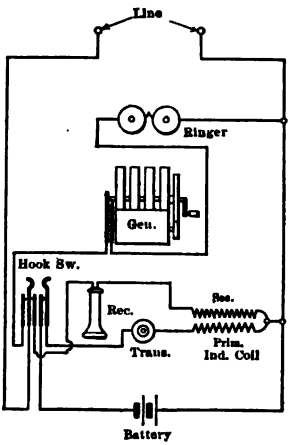


FIG. 9.—Circuit diagram of typical series telephone set (Stromberg-Carlson).

erminals when the receiver is on the hook, but are disconnected when the eceiver is in use. The generator is short-circuited except when in action.

**23. Common-battery bridging sets** are illustrated in Figs. 10 to 13. he simplest type of circuit appears in Fig. 10. The transmitter current is btained over the line circuit from the central battery at the switchboard.

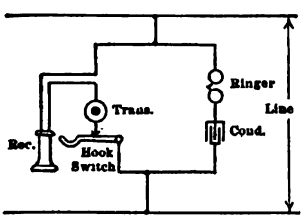

FIG. 10.—Circuit diagram of typical ommon-battery bridging set without nduction coil.

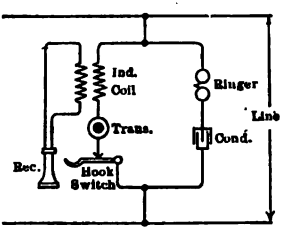

FIG. 11.—Circuit diagram of typical common-battery bridging set with induction coil.

Receivers of the permanent-magnet or polarized type must be properly oled, so that the transmitter current will strengthen their magnets instead of weakening them. Continuous-current receivers (Par. 22) are sometimes used in this type of set.

Digitized by Google

A similar type of set, modified to the extent of employing an induction coil and placing the receiver in a local circuit, is shown in Fig. 11. The Kellogg Switchboard and Supply Company's set is shown in Fig. 12. In the latter type the transmitter circuit is completed through a 25-ohm retardation coil which is shunted by a circuit composed of the receiver and a condenser in series. The Western Electric Company's set is shown in Fig. 13. These types are representative of modern practice; other methods of wiring can be obtained from manufacturers' bulletins.

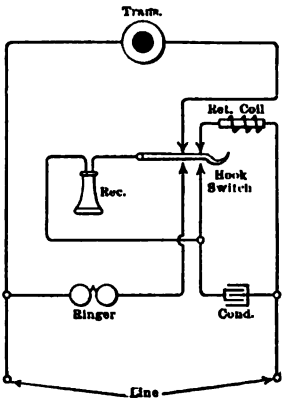

FIG. 12.—Circuit diagram of Kellogg common-battery set.

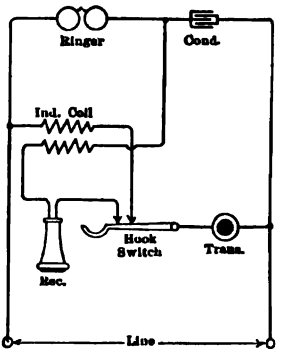

FIG. 13.—Circuit diagram of Western Electric common-battery bridging set.

## LOCAL-BATTERY MANUAL SWITCHBOARDS

**39. The essential elements of a manual switchboard** are the line terminals or jacks, the line signals and the switching mechanisms; the last are comprised of pairs of cords and plugs, with their associated talking and ringing keys, supervisory signals, and the operators, talking sets. In very small manual boards the pairs of cords and plugs are sometimes replaced by keys, so arranged and wired as to perform the desired switching operations at will.

**40. Non-multiple switchboards** are those in which there is but one terminal or jack for each local line. Therefore this type of board is limited in size by the fact that each operator at the board must be able to reach every line terminal, unless local or transfer trunks are provided from one operator's position to another. It is not the practice to handle any considerable amount of traffic by means of transfer trunks, but instead to resort to multiple boards (Par. 41). The limit of size of a non-multiple board is usually about 400 lines, with two operator's positions; 600-line boards with three positions and transfer trunks from the first to the third position, are employed, however.

**41. Multiple switchboards** are those in which there are two or more terminals or jacks connected in multiple to each line, in such a manner as to provide for each line at least one jack within the reach of each operator. By this means transfer trunks are made unnecessary and any operator can connect together any pair of lines in the switchboard. Multiple boards are made in many sizes, from a few hundred lines up to 18,000 lines. Local-battery multiple boards are not now employed for installations of more than a few hundred lines, because of the greater economy of common-battery multiple boards.

**42. Switchboard line signals** in local-battery or magneto systems are usually **drops**, which commonly consist of an iron-clad electromagnet with

Digitized by Google

an armature arranged to disengage a shutter and display the number of the calling line, when the drop winding is energised by an incoming ringing current. The drop shutter is also arranged to close a pair of local contacts for sounding an auxiliary calling signal termed the "night alarm." Drops

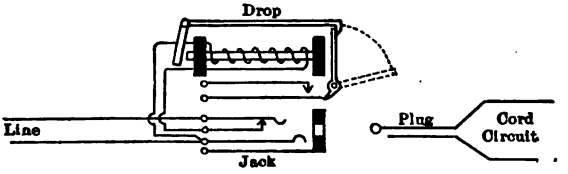

FIG. 14.—Circuit diagram of line jack and drop in non-multiple magneto switchboard.

are made in some cases with a restoring coil which serves to return the shutter to normal position when the operator answers the call by inserting a plug in the answering jack (Par. 43); in other cases the drop and the answering jack

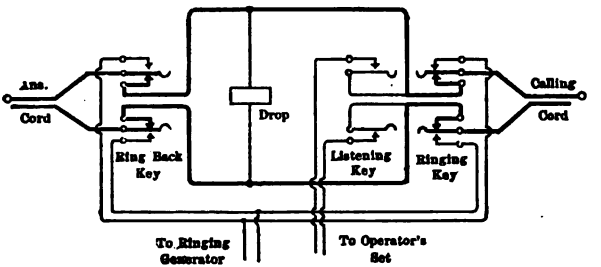

FIG. 15.—Circuit diagram of cord-circuit in non-multiple magneto switchboard; single clearing-out drop.

are mounted together and so arranged that the plug restores the shutter mechanically when the plug enters the jack. The terminus of the line circuit is usually wired as indicated in Fig. 14. Drops are wound of various resistances from 80 ohms to 1,000 or 1,200 ohms; a resistance of 500 to 600 ohms is very commonly used.

**43. Switchboard line jacks** for non-multiple magneto boards are usually of the type illustrated in Fig. 14. The drop is disconnected from one side of the line by the insertion of the plug in the jack. The night-alarm contacts are shown just below the drop winding.

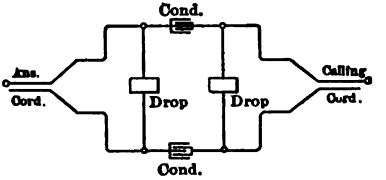

FIG. 16.—Circuit diagram of cord-circuit with double clearing-out drops, for double supervision.

**44. The wiring of a cord circuit** with ringing keys, listening key and single supervisory drop is given in Fig. 15. The wires of the through talking circuit are shown in heavy lines. There is some disadvantage in having but one supervisory drop, since it is not possible for the operator to predetermine which line is signalling for attention. This difficulty is overcome in the cord circuit which appears in Fig. 16 (keys not shown), inasmuch as

Digitized by Google

the condensers tend to shunt the low-frequency ringing current through the nearest drop instead of permitting it to pass readily along the cord circuit to the other drop or any other bridged apparatus.

**45. Repeating-coil cord-circuits** are employed where it is necessary to connect metallic lines with grounded lines, or to reduce the inductive disturbances which sometimes occur when two metallic lines are connected together by a straight cord-circuit (Fig. 15). A cord circuit with a repeating coil is shown in Fig. 17, with ringing and listening keys omitted from the diagram. Sometimes the repeating coil is connected to the cord circuit through the contacts of a special key, so that the coil may be cut into circuit at will. The transmission will be more efficient with a straight cord than with one having a repeating coil in circuit, and therefore such coils should be used only when necessary to reduce inductive disturbances or line noise.

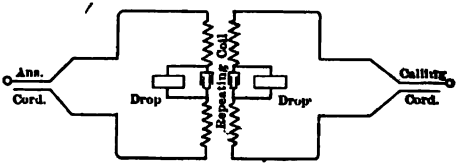

FIG. 17.—Circuit diagram of cord-circuit with repeating coil and double supervisory drops.

**46. Commercial sizes of non-multiple magneto switchboards** are usually limited to not more than 600 lines, arranged and equipped for not more than three operators' positions. The following sizes are standard with the Kellogg Switchboard and Supply Co.

| Lines | Operators' positions | Pairs of cords per position | Lines | Operators' positions | Pairs of cords per position |
|---|---|---|---|---|---|
| 20 | (Wall type) | 5 | 250 | 2 | 12 |
| 50 | 1 | 10 | 300 | 2 | 15 |
| 100 | 1 | 10 | 350 | 2 | 15 |
| 150 | 1 | 15 | 400 | 2 | 15 |
| 200 | 1 | 15 | 450 | 3 | 15 |
| 200 | 2 | 10 to 15 | 600 | 3 | 15 |

**47. Transfer trunks** for the purpose of transferring or trunking connections from one position to another, are not only convenient, but often necessary in these small boards, especially those arranged for three operators' positions.

**48. Multiple jacks** (Par. 41) are sometimes employed in boards of 400-line size and are very common in boards of 600 lines. The purpose of multiple jacks is to avoid the necessity of transfer trunks and the attendant extra labor in operation. The details of multiple magneto boards are beyond the scope of this section and the reader should consult the authorities mentioned in the Bibliography, Par. **263**.

**49. Distributing frames** or cross-connecting racks are installed in connection with switchboards of every type, and are intermediate in position between the incoming lines and the switchboard. This frame takes various forms, but is usually built up of light structural iron shapes, on one side of which are arranged the terminals of the incoming lines and their associated protectors, and on the other side are arranged the terminals of all the lines leading to the switchboard. By means of jumpers any outside or incoming line can be wired to any switchboard line, thus providing the necessary flexibility for distributing or grouping the lines in the switchboard in any manner desired.

There are two styles of distributing frames, known as the **main frame** and the **intermediate frame.** The former is the one described just above; the latter is used only in connection with multiple boards, being intermediate

Digitized by Google

in position between the main frame and the board, for the purpose of enabling any answering jack to be associated with any set of multiple jacks.

**50. Switchboard wiring** is usually in cable, and the style of cable is commonly referred to as **switchboard cable.** This type of cable is made from various sizes of tinned annealed copper wire (Sec. 4), ranging from No. 18 to 24 A.W.G. The insulation, where the cable is for use in dry places, usually consists of two wrappings of silk and one of cotton; the conductors are twisted into pairs or triples, then a wrapping of paper is applied over all, next a wrapping of thin metal tape (lead, antimony and tin), and finally an outside cotton braid saturated with beeswax. The insulation of the individual wires is sometimes varied, using one silk wrapping and one cotton wrapping, or one silk and two cotton, or two silk and two cotton. These cables are laid up in round, oval or flat cross-sections as desired, in twisted pairs or triples, ranging from 6 pairs to 100 pairs; 5, 10, 15, 20, 25, 30, 40, 50 and 100 pairs are approximately standard sizes. A code color scheme is employed in the cotton covering of individual wires, for the purpose of identifying the pairs and facilitating splices and connections; the manufacturers' bulletins give the codes employed.

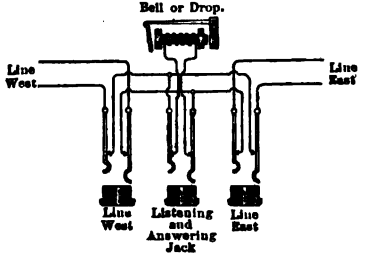

FIG. 18.—Circuit diagram of cut-in station or looping bridge.

**Wool-insulated cable** is now generally employed in place of pot-head wire (rubber insulated) for connecting underground or aerial cable terminals with the main frame, and in places where there might be trouble with ordinary cotton insulation on account of moisture.

**Lead-covered interior cable,** insulated with double silk and single cotton saturated with beeswax, is very useful for interior wiring in moist or damp places. It is standard in sizes of 5 to 40 pairs, by steps of 5, and 50, 60, 75, 100, 120, 150 and 200 pairs, of No. 22 A.W.G. tinned annealed copper.

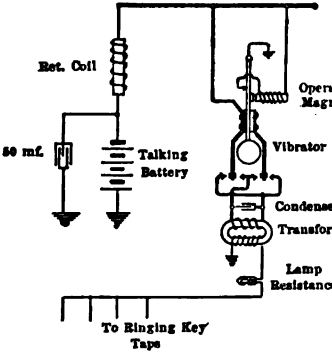

FIG. 19.—Circuits of vibrating pole changer for supplying ringing current from a battery source.

**Twisted pairs** should be used invariably for all **talking circuits** in order to avoid cross-talk. The length of one complete twist should not exceed 4 or 5 in.

**51. Wiring of a through line** is shown in Fig. 18. The middle jack is so wired that the operator can listen to determine whether the line is busy before attempting to use it. Code ringing must be employed on a through line connected in this manner. This style of jack wiring is termed a **cut-in station** or **looping bridge.** It can also be arranged with keys instead of jacks, and mounted in a special cabinet if desired.

**52. Ringing energy** can be obtained in three ways: (a) from a ringing dynamotor (Sec. 9) supplied on the primary side from a lighting or motor circuit, or from a storage battery (in common-battery installations); (b) from a hand generator (Par. **26**) mounted in the switchboard; (c) from a

Digitized by Google

vibrating pole-changer arranged to periodically reverse the impressed e.m.f. of a battery, usually composed of dry cells. In small installations a pole-changer and dry battery are very economical. The arrangement of a typical pole changer is indicated in Fig. 19, with its associated apparatus. When a dry battery is employed for ringing, it is customary to employ about 75 cells; the use of a transformer as shown in Fig. 19 then becomes unnecessary. Another type of vibrator employs but one vibrating contact, and requires two groups of dry cells, about 75 cells per group, connected in series and grounded at the centre; the vibrator makes alternate connections with the free terminal of each group.

## COMMON-BATTERY MANUAL SWITCHBOARDS

**53. The central battery** supplies the energy for both talking and signalling, at the stations as well as the switchboard. The method of signalling from the switchboard to the stations is the same as that described under "Local Battery Manual Switchboards," Par. **39** to **52**. The method of signalling from the stations to the switchboard, however, consists of moving the receiver hook up and down to interrupt the line circuit and thus interrupt the flow of current from the central battery through the line signal, over the line to the station, and return. The central battery is customarily grounded on the positive side, and the "tip" side of the line is the grounded side, while the "ring" or "sleeve" side is the battery side.

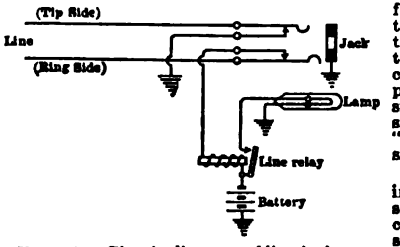

FIG. 20.—Circuit diagram of line jack, relay, and lamp in non-multiple common-battery switchboard.

**54. The line circuit** forming the terminus of a local or station line in a non-multiple common-battery board is shown in Fig. 20. The line signal consists of a lamp associated with the line jack; this lamp becomes energized when the receiver is removed from the hook at the distant station, and is de-energized again when a plug is inserted in the line jack in response to the call. The operation is evident from the figure.

**55. Commercial sizes of non-multiple common-battery boards** are given in the following table, representing two of the leading makes.

| Lines | | Operators' positions | Pairs of cords per position | | Transfer trunks |
|---|---|---|---|---|---|
| Common battery | Local battery | | Common battery | Combination | |
| 75 | 20 | 1 | 7 | 3 | 8 |
| 100 | ..... | 1 | 10 | ..... | 8 |
| 120 | 20 | 1 | 10 | 5 | 14 |
| 160 | ..... | 1 | 15 | ..... | 14 |
| 200 | 20 | 1 | 10 | 5 | 14 |
| 240 | ..... | 1 | 15 | ..... | 14 |
| 200 | 50 | 1 | 10 | 5 | 10 |
| 280 | 20 | 2 | 11 | 4 | 28 |
| 320 | ..... | 2 | 15 | ..... | 28 |
| 400 | ..... | 2 | 15 | ..... | 40 |
| 440 | 20 | 2 | 11 | 4 | 28 |
| 480 | ..... | 2 | 15 | ..... | 28 |
| 600 | ..... | 3 | 15 | ..... | 60 |

**56. Cord circuits** are arranged in several ways, according to the method used for supplying transmitter current to the local lines. Fig. 21 illustrates

Digitized by Google

one type of cord circuit, complete with ringing and listening keys; this type employs a repeating coil, and is used by the Western Electric Co. in non-multiple boards. The lamp signals are termed supervisory signals,

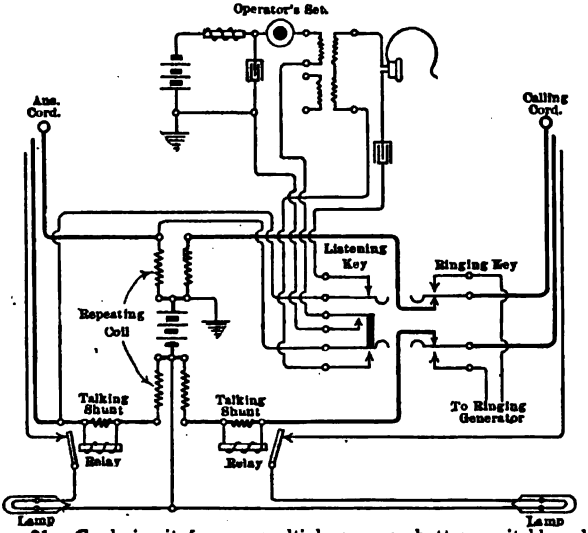

FIG. 21.—Cord circuit for non-multiple common-battery switchboard.

and will be lighted whenever the receiver hook at the line station is depressed. The method of operation is obvious from the figure. Combination cord circuits are those specially wired for the purpose of connecting common-battery lines with local-battery lines.

**87. Retardation and repeating coils** are quite similar in general construction, but differ in their windings. The principal types of simple impedance or retardation coils are shown in Figs. 22 to 24. Soft Norway iron wire is commonly used in core construction; the **toroidal coil** in Fig. 24 is

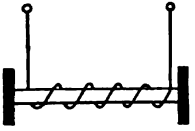

FIG. 22.—Impedance coil with open magnetic circuit.

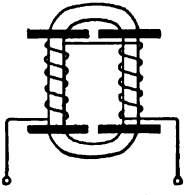

FIG. 23.—Impedance coil with closed magnetic circuit.

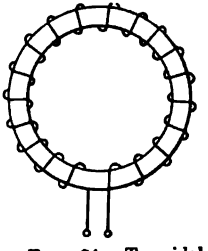

FIG. 24.—Torroidal type of impedance coil.

usually constructed with very fine iron wire covered with a very thin insulation of cellulose or enamel to reduce the eddy-current losses. The desired properties of the iron are high permeability, high resistivity and low hysteresis loss. Enamel insulation for the electrical windings is the most economical

Digitized by Google

of space, although cotton and silk are sometimes employed. The winding should be vacuum baked and impregnated.

Commercial repeating coils are made in various types, corresponding to the retardation coils above described. The torroidal type, properly constructed, is one of the most efficient coils known. A completely balanced torroidal coil is shown in Fig. 25. The terminals *l* are the line terminals and *m* are the middle taps. A torroidal type of coil for common-battery cord circuits has four windings of 21 ohms each, being designed for high efficiency with talking currents, but not especially efficient for ringing (16-cycle, alternating) currents. A larger coil, with two outer windings of 35 ohms each and two inner windings of 30 ohms each, has high efficiency for both ringing and talking, thus suiting it for phantom and simplex circuits. Another type of simplex coil having high ringing efficiency, is wound with two inner windings of 45 ohms each and two outer windings of 36 ohms each.

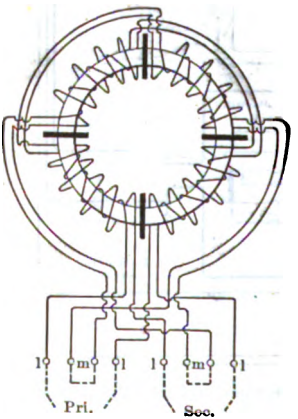

FIG. 25.—Torroidal type of repeating coil; four balanced windings.

When repeating coils are mounted close to each other, base to base, cross-talk from one coil to another will result unless they have closed magnetic circuits and are enclosed in iron cases to reduce stray fields.

**58. Main and intermediate distributing frames** are practically the same as for magneto boards, covered in Par. 49. Also see the bibliography Par. 263.

**59. Relay racks** are also provided in common-battery installations of large size, for mounting the line and cut-off relays. The cord-circuit apparatus should be mounted if possible in the switchboard.

**60. Power plants** for common-battery switchboards comprise a source of energy for the talking circuits, relays and lamps, and a source of energy for signalling or ringing purposes. The former source usually consists of a storage battery (Sec. 20) of 11 cells, giving normally 22 volts; in some cases 22 cells are used to meet especially severe transmission requirements. In very small installations primary batteries (Sec. 20) are sometimes used, if no source of primary energy is accessible.

**61. Battery-charging generators** are different from standard direct-current machines (Sec. 8) in two respects. They have smooth-core armatures and more than the usual number of commutator segments, in order to supply as nearly as possible an absolutely continuous current. Otherwise the minute but very rapid pulsations in the current, caused by armature core teeth and commutation, will give rise to slight pulsations of potential at the battery terminals and make the telephone lines noisy during charging.

**62. Ringing generators** for supplying both alternating and pulsating current at various fixed frequencies from 16 to 66 cycles per sec. are in general covered in Sec. 9, under Dynamotors, or in Sec. 7 and 8 under Generators. Machines of the dynamotor type are wound for operation from 22-volt, 115-volt and 230-volt direct-current sources, and deliver from 75 to 100 volts alternating. Ringing dynamotors are standard in sizes rated from about 25 watts, suitable for small offices, up to about 1 h.p. for large exchanges. Each ringing tap is fused and a lamp resistance is connected in series in order to prevent excessive currents in the event of ringing on a short-circuited line.

**63. Prevention of battery noise** in common-battery installations, caused by the small but very rapid pulsations or ripples (Par. 61) in the current delivered by the charging machine, requires a circuit arrangement which is illustrated in theory in Fig. 26. The function of the condenser is to short-circuit the ripples of e.m.f. from the generator, which are of high

Digitized by Google

frequency, while the impedance coils tend to suppress the corresponding ripples of current in the battery circuit. In large installations, especially with large batteries (of very small internal impedance), the condenser is not required.

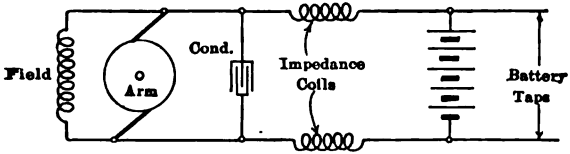

FIG. 26.—Method of suppressing battery noise caused by generator or motor operation.

## AUTOMATIC SWITCHBOARDS

**64. Fundamental features.** There are two general types of automatic systems, the **full automatic** (Par. **65** to **72**) and the **semi-automatic** (Par. **73** to **75**). The former type performs all switching operations by means of automatic mechanisms under the control of the selector dials or calling devices at the telephone stations; the latter type requires switchboard operators, as in the manual system, but the automatic switching mechanism is under their direction, in the place of using dials at the instruments.

**65. Numerous systems** have been invented and reduced to commercial practice, including the Strowger, the Lattig-Goodrum, the Lorimer, the Bullard-Rorty and the Clark systems. These systems are all complicated when viewed in their entirety, and cannot be described in the space here permitted. The following description, Par. **66** to **72**, covers the **Strowger system** (Automatic Electric Co.) as developed for small installations not exceeding 100 lines.

**66. Telephone sets** for automatic service are equipped with **calling devices**, one of which is shown attached to a desk stand in Fig. 27. The circuit diagram of this set is given in Fig. 28. The calling device consists of a dial with eleven holes, ten of which numbered with the ten digits, consecutively from 1 to 0. In order to call line No. 73, for example, the person calling first removes the receiver from the hook and then, placing his finger in the seventh hole, pulls the dial around until his finger engages the stop, which causes seven impulses (which are really interruptions of a steady current) to pass over the line to the switchboard; he then places his finger in the third hole and repeats the operation, whereupon the automatic switching mechanisms connect the calling line with line No. 73 and ring the station. When someone answers at station No. 73, the ringing current is automatically cut off and the talking circuits are clear.

FIG. 27.—Desk stand equipped with calling device or dial for automatic (Strowger) service.

The mechanism of the calling device is shown in Fig. 29. The dial winds a spring which drives an interrupter, consisting of a fibre cam engaging the impulse springs; a tiny ball governor is attached, which insures uniform speed. The line circuit is normally closed (when the receiver is off the hook) and an impulse, so-called, is really a brief interruption of the line current.

Digitized by Google

**67. Line switch.** Each line terminates at the central office in a line switch, whose function is automatically to connect the line to an idle connector as soon as the receiver is removed from the hook. For the sake of simplicity the line switch is omitted from the accompanying illustrations. The lines are also multipled to the connector banks (Par. 68). Each line might, if desired, terminate in a connector, but the provision of line switches is

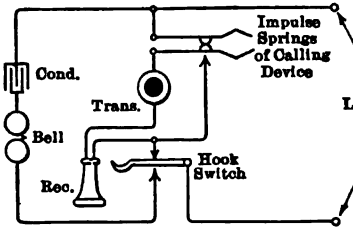

FIG. 28.—Circuit diagram of bridging common-battery set for Strowger automatic system.

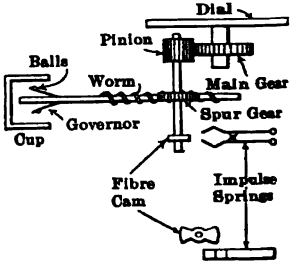

FIG. 29.—Skeleton diagram of mechanism of calling device.

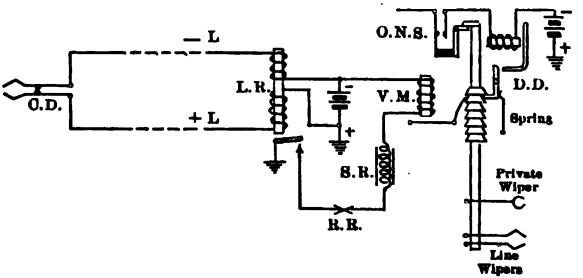
more economical because it makes possible a reduction in the number of connectors.

**68. Connectors.** The circuits of a line connected to a connector (omitting the intermediate line switch) are shown in Fig. 30. The principal features of the connector mechanism are illustrated in Fig. 31. Each switch consists of two principal parts: first, the shaft, carrying brushes or wipers and equipped with two magnetically operated ratchets and pawls, one of which is



C.D.—Calling device.

V.M.—Vertical magnet.

FIG. 30.—Theoretical diagram of a connector.

adapted to impart a vertical step-by-step movement to the shaft, and the other a rotary step-by-step movement; second, the contacts over which the brushes or wipers are made to pass by means of these two movements. The contacts are arranged in banks, 10 rows high and 10 rows wide, or 100 in all.

**69. Operation.** The line relay causes the first set of impulses to actuate the vertical magnet and step the wipers up to the corresponding row, which would be row No. 7 in the case of a call for line No. 73. Meanwhile the

Digitized by Google

series relay is energised by these impulses, and in turn energises the private magnet; the series relay is made slow-acting, so that it will remain constantly closed while energised by a series of rapid impulses. When the first set of impulses has ceased, the series relay is de-energised and this in turn de-energises the private magnet; the latter, on its back stroke, moves the side switch to the second position, and thus opens the circuit of the vertical magnet and closes the circuit of the rotary magnet. These details are made clearer in Fig. 32.

The second set of impulses actuates the rotary magnet and rotates the shaft until the wipers rest on the corresponding set of contacts, which would be the third set in the seventh vertical row, in the case of a call for line No. 73. When the second set of impulses ceases, the private magnet moves the side switch again, and closes the ringing circuit on the called line; ringing continues at short periodic intervals until the receiver at the called station is removed from the hook, upon which the direct current through the back bridge relay operates the same and in turn the ringing cut-off relay. The circuits are then clear for through communication.

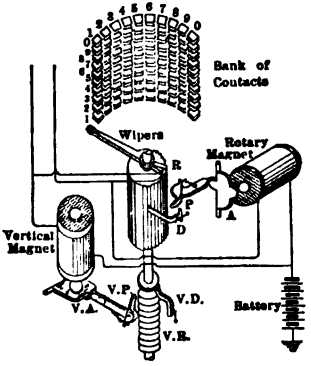

FIG. 31.—Connector switch.

When the receiver at the calling station is returned to the hook, the slow-acting release relay (Fig. 32) is de-energised by the line relay and thus releases the double-dog (Fig. 30) and the wiper shaft returns to normal, clearing the connection. The off-normal switch serves to keep open the circuit of the release magnet unless the wiper shaft is in action or use.

For the sake of simplicity certain details have been omitted, but the essential principles have been emphasized as fully as space will permit. The busy test, which is not shown, is so arranged that a call for a busy line will not be completed, and the usual busy signal will be communicated to the calling line. For further details see the references below* and the Bibliography (Par. 163).

**70. Mounting.** Line switches are usually mounted in groups of 100 each. The necessary connectors for a group of 100 lines are mounted with

Digitized by Google

the line switches, forming a 100-line unit. The number of selectors or connectors required for each 100 lines depends upon the volume of traffic during the busiest period.

**71. Selectors.** When there are more than 100 lines, it becomes necessary to employ selectors. The first selectors are connected to trunks leading to the connectors. The first group of impulses in a number, say line No. 528, controls the vertical movement of the shaft of the first selector; the rotary movement of the shaft, however, is automatic and continues until the wipers rest on the contacts of the first idle trunk to the connectors in the 700 group. The second and third sets of impulses respectively step up the shaft of the connector to the second row of contacts and rotate the shaft to the eighth set of contacts, completing the connection to line No. 528. In order to call a number containing four digits, second selectors are necessary; five digits, third selectors, etc.

**72. Costs.** The cost per line of the central office equipment (Strowger automatic) completely installed and including the station equipment, uninstalled, is approximately $35 per line.

**73. Semi-automatic systems** of several types have been produced, including the Clement (Automanual), Western Electric and Corwin systems. The general features of semi-automatic systems have been described in Par. 64.

**74. Clement or automanual system.** In this system the station equipment is the same as in manual common-battery practice. When the receiver is removed from the hook at the calling station, the line is automatically connected to the first idle **primary selector** (of the 100-line type), which automatically steps in the rotary and vertical motions until its **test brush** connects with the calling line terminal. The test brush, in arresting the switch in connection with this line terminal, also energizes the cut-off relay of the calling line and establishes an electrical "busy" guard against incoming calls. Simultaneously an idle **key-set switch** (100-line type) is automatically placed in operation, and this switch automatically selects the occupied primary selector and conveys the call to the first idle operator. The last operation lights a key-set line lamp and the operator answers by pressing the answering button, which places her in communication with the calling station.

Upon receiving the desired number, the operator sets up that number on the key set (which is similar to the adding machine) and if a party-line designation is given, a button corresponding thereto is also pressed, and the call is then completed (so far as the operator is concerned) by pressing the starting button of the key set. The call is from this point taken up by the key-set switch, which controls the emanation of impulses from the sending machine, as indicated by the depressed buttons of the key set. The first series of impulses being in the thousands, are directed to the **first selector** which is associated with the primary in use. This first selector is propelled rotarily by the impulses, designated in the thousand-row buttons in the key set, or if the call is for another exchange, to the row of contacts on which the trunks between the exchanges are terminated and automatically tests up the row in the vertical position until its brushes are connected with an idle trunk. This trunk connects with an idle **second selector** which receives the impulses as indicated in the hundred row of buttons of the key set rotarily and automatically tests for an idle connector vertically.

The next series of impulses controlled by the key-set ringing buttons sets up the party-line **ringing selector** associated with the first idle **connector** (of the 20-point distributing switch type) and the tens and unit impulses, as indicated on the key set, are directed respectively to the rotary and vertical movement of the connector switch (of the 100-point type); this brings into connection the test relay, which, if the called line is busy, is actuated to connect busy-back tone to the calling subscriber and if not busy, connects the ringing current to the called line and actuates the cut-off relay of the called line, making this line busy to all other connectors. At this point, the key-set switch releases from the trunk and is made immediately available for connection with other calling primaries and the connection is then controlled entirely from the calling and called stations; by manipulating the receiver hook either station may disconnect for immediate recall.

Digitized by Google

**75. Trunking between automatic and manual switchboards** can be readily provided by means of appropriate apparatus, and is extensively employed. For details of such trunking in exchange systems see the Bibliography (Par. 263).

## INTERCOMMUNICATING SYSTEMS

**76. Intercommunicating systems** comprise relatively compact private telephone systems, in most cases without any switchboard or operating attendants, for the purpose of internal communication in factories, industrial plants, stores, offices, hospitals, residences, apartment buildings, etc.

**77. Equipment.** Each station is equipped with a telephone set and a switching device mounted in a small box or cabinet. For each station there is a telephone line or circuit extending to all other stations, and so arranged that by depressing the appropriate switching key or button in the switching cabinet at any other station, connection can be established with this particular line; at the home station there is also a calling signal or bell (or buzzer), and an answering key arranged to connect the home telephone set with the line. Thus for a 10-line system there will be 10 keys or buttons in each switching cabinet and 10 talking circuits in a small cable multipled to all 10 cabinets; in addition to the 10 line-circuits there is another pair for supplying the talking current (common battery) to each station, and still another pair for supplying ringing current to each station. Direct-current is usually employed for ringing, and dry batteries are used for both ringing and talking.

The keys or buttons are usually so arranged that when depressed as far as possible, the ringing current is sent out on the line; when released, the key automatically returns to an intermediate position, where it is held by a lock or detent, and thereupon the ringing connection is broken and the talking circuit completed. The several keys in any individual switching cabinet are usually so arranged or interlocked, that the depression of one key automatically releases or restores all the others.

**78. The operation** is very simple. In order to call station No. 7 from station No. 3, the No. 7 button at station No. 3 is depressed as far as possible and held there a moment before releasing it, and meanwhile the bell connected to line No. 7, which is at station No. 7, responds. At station No. 7, the home button is depressed and the receiver taken from the hook, thus establishing communication. The ringing connection on the home button can be omitted, since it is obviously unnecessary.

**79. Other equipment combinations** can be arranged readily, including master stations for switching, with annunciator; one-way stations for inward calls only; non-selective code-ringing party lines, etc. The manufacturers offer many varieties of equipment for such combinations, which are readily understood from their bulletins.

**80. The line capacity of standard equipments** varies somewhat among the different manufacturers, but not to any great extent. One manufacturer offers complete units equipped for 6, 12, 22 or 32 stations; another offers sets for 11, 21 or 31 stations; another, 6, 12, 16, 20 or 24 stations, etc. These equipments are usually made in several styles, for desk mounting, wall mounting, or the flush wall type.

## PHANTOM CIRCUITS

**81. Two types** of phantom circuits are in use, one derived by means of repeating coils, the other by bridged impedance coils. Both types are illustrated in theory in Fig. 33, all circuits being metallic.

**82. The repeating-coil type** of phantom circuit is shown in theory in Fig. 33, at the left of the diagram, where *RC* are repeating coils tapped at the centres of the line-side windings for the derived or phantom circuit.

**83. The impedance-coil type** of plantom circuit also appears in Fig. 33, at the right, where *IC* are retardation or impedance coils tapped at the centres of their windings for the derived or phantom circuit. This type is especially suitable for station circuits, where it is possible to economise in line wire by connecting the more distant stations to a phantom circuit. In this case grounded signalling cannot be employed. The side circuits should be subtantially alike in all particulars, including length.

Digitized by Google

This type may also be used for switchboard or office installations, instead of repeating coils, and in this case it is generally the practice to install a condenser in series with each side of the line, between the coil and the jack, as in a simplex set (Par. 116).

**84. Identical side circuits** should always be employed in deriving metallic phantom circuits, for the best results. This is necessary, for the proper electrical balance of the phantom. Special transpositions are also required; see Par. 168 and 169.

**85. Grounded phantoms,** or half phantoms, can be obtained by connecting repeating or impedance coils to a metallic circuit and employing an earth return for one side of the phantom. This arrangement is open to the same objections which apply to the use of ground-return circuits in

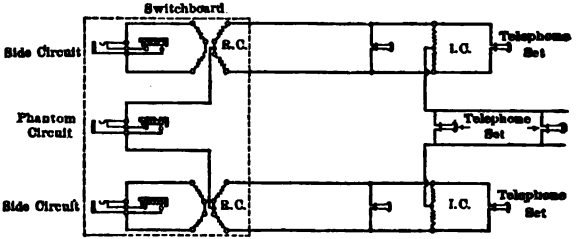

FIG. 33.—Phantom circuit.

general—namely, cross-talk and noise (induction) caused by lack of transposition and by earth potentials.

**86. Phantom circuits in cable** require specially constructed cables of the quadded type, described in Par. 150. This form of construction is essential in order to transpose the phantom and prevent cross-talk.

**87. The repeating and impedance coils** for phantom circuits should be carefully balanced electrically in order to prevent cross-talk between the side circuits and the phantom. The windings should be subdivided, grouped and balanced in such a way that the currents of the phantom circuit will induce (electromagnetically) no e.m.fs. in the side circuits and *vice versa;* see also Par. 57. The torroidal type of coil with two inner and two outer windings, 35 ohms per winding, is extensively used.

## STANDARD MANUAL TELEGRAPH SYSTEMS

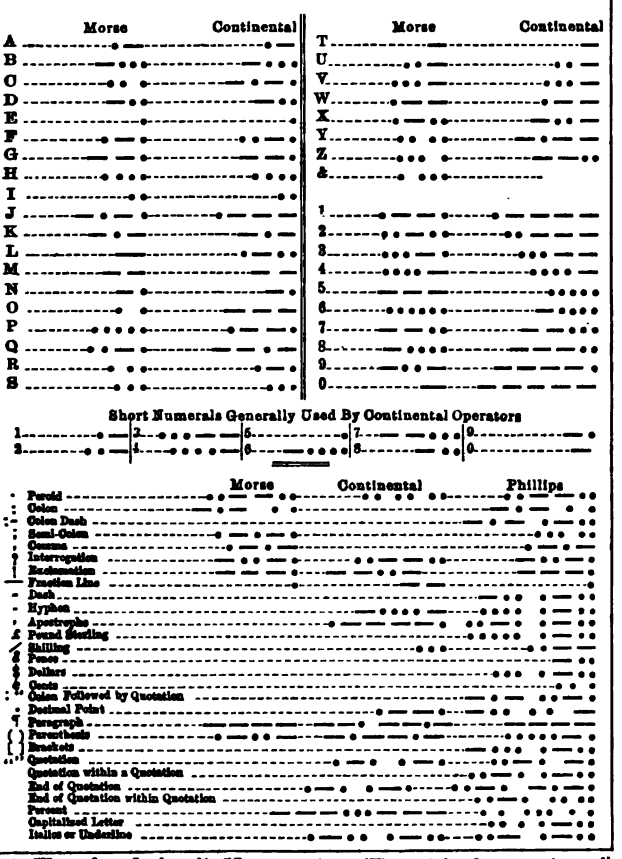
**88. The manual Morse telegraph system** comprises a means of transmitting combinations of short and long impulses or signals over an electrical circuit joining two or more points; the transmitting mechanism consists of a hand-operated key and the receiver consists essentially of an electromagnet with a sound-amplifying device for audibly registering the signals, which are read by ear. The combinations of long and short signals are so arranged as to form a code or alphabet, of which there are two in common use; the **Morse alphabet** is universally employed in American practice (except wireless) and the **Continental alphabet** in Europe.

**89. Morse characters.** The basic element of the Morse alphabet is the **dot**; a **dash** is equal in duration to three dots; the **space** between the elements of a letter equals one dot; between complete letters of a word, three dots; between words, six dots. The 26-letter American Morse alphabet has 77 elements, or an average of 2.96 elements per letter; the Continental alphabet of 26 letters has 82 elements, or 3.15 elements per letter. The average five-letter word has 36.7 elements or dot-equivalents in American Morse. A speed of 25 words per min. in American Morse corresponds to an average of 370 signals per min., or between 6 and 7 per sec.

Digitized by Google

**90. Morse and Continental Alphabets.***

**TELEGRAPH CHARACTERS**



**91. The closed-circuit Morse system** (Fig. 34) is almost universally employed in this country, except for a few installations of automatic printing systems, some of which employ multiplex or high-speed transmission. The ordinary closed-circuit Morse system, worked simplex, duplex, or quadruplex, is the only one here treated in any detail.

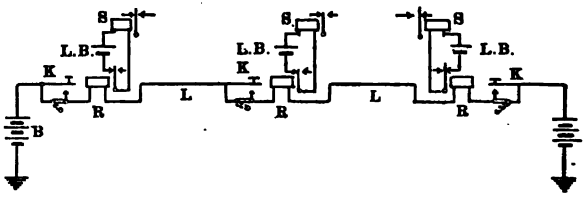
**92. The open-circuit Morse system** is employed extensively in England and on the Continent, but has never found favor in American

* Appendix "*C*" from McNicol's, "American Telegraph Practice," page 492.

Digitized by Google

practice. For the details of this system consult the references on telegraphy given in the Bibliography, Par. 263.

**93. Simplex or single working** is indicated in Fig. 34, which shows the theory of a circuit with two terminals and one intermediate station. In this system but one message can be sent at one time. But one line wire is required, with earth return. The station equipment consists of a main-line relay, a local sounder and battery, and a sending key. There are but two main-line batteries, one at each terminal; these batteries or sources of e.m.f. should be of equal voltage for best results, and the terminals should have substantially equal resistances. The terminal resistances should also be as small as practicable.



B.—Main-line batteries.
K.—Keys.
R.—Main-line relays.
S.—Local sounders.
L.B.—Local batteries
L.—Line.

FIG. 34.—Closed-circuit Morse system.

**94. Sources of energy** for telegraph working are usually one of four types, viz., gravity batteries, dry batteries, storage batteries, or generators. For details on batteries, see Sec. 20; generators, Sec. 8; dynamotors, Sec. 9. Gravity cells are now employed only for small installations, as a rule, working a few wires; dry cells have been employed to a limited extent, for working individual wires; the general objections to such batteries are high internal resistance and high cost of maintenance. Storage batteries have been used in large installations and are considered fairly satisfactory. Generators or dynamotors are coming into quite general use wherever a source of cheap primary energy is available. Any number of lines can be operated from one machine of adequate output.

**95. The main-line relay** consists merely of a double-pole electromagnet with a light armature and retractile spring, provided with suitable adjustments and arranged with local contacts for closing the circuit of a local sounder. The standard main-line relay is wound for 150 ohms of resistance and should be operated with currents of 40 to 50 milliamperes. Relays for intermediate offices on way circuits are generally wound for 35 ohms, in order to reduce the total line-resistance and improve the operating efficiency; the operating current should be from 60 to 70 milliamperes or more. Pony relays for short lines are usually wound for 20 ohms. Special relays are wound as high as 300 ohms.

**96. The proper relay adjustment** depends upon the condition of the line. In clear weather, with high insulation, the air gap may be small and the spring tension high; in wet weather, with low insulation, the air-gap should be lengthened and the spring tension reduced, because the margin of operating current caused by the opening and closing of a distant key, is much reduced. An ordinary 150-ohm relay, operating on 0.050 amp., will not release at commercial speed on much more than 75 per cent. of the normal current, or at about 0.0375 amp. The armature play should be as confined as possible, in order to shorten the stroke.

**97. Sounders** are necessary because the ordinary line relay has insufficient power to make audible signals for easy reading of Morse characters. Sounders are usually wound for 4 ohms or 20 ohms resistance; in the latter case the sounder may practically serve in place of a pony relay for short lines.

Digitized by Google

**98. The operating currents required** in closed-circuit Morse working vary according to the system of working and the sensitiveness of the relays. The usual current with 150-ohm relays, line-circuit closed, is about 0.040 to 0.050 amp.; with 35-ohm relays, 0.060 to 0.075 amp.; for 20-ohm pony relays, about 0.100 amp.; for local sounders, 0.100 to 0.250 amp.

**99. The polar duplex** is illustrated in theory in Fig. 35, which shows but one terminal of the line, since the other is identical. The polar relay, as its name indicates, is polarised, and responds to currents in one direction but not the other. In order that the armature may be under a slight normal attraction when no signals are passing, it is given a slight bias, or so adjusted that it is nearer one pole-piece, than the other. The polar relay, being differentially wound, is neutral to outgoing currents from the home key, if the artificial and the real line-circuits are electrically balanced. When the distant key is closed the line current in the upper limb of the polar relay becomes (theoretically, with a perfectly insulated line) double that in the lower limb and actuates the local sounder; if the home key is next closed, the relay is not affected. If the home key is closed, while the distant key is normal, the home relay will also be unaffected, as can be seen from consideration of the relative strengths and directions of the currents in the two limbs.

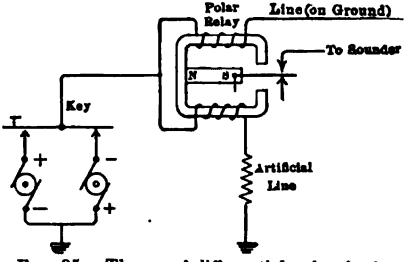


FIG. 35.—Theory of differential polar duplex.

**100. The bridge duplex** is shown theoretically in Fig. 36, where $R_1R_2$ are two equal resistances, or equal windings of an impedance coil. The relay is a plain non-polarised type. The compensating resistance should be equal to the internal resistance of the battery, in order not to upset the adjustment of the artificial line.

**101. The bridge polar duplex*** is similar to Fig. 36, except that the battery and key are displaced by the generators and key in Fig. 35, and a polar relay is required.

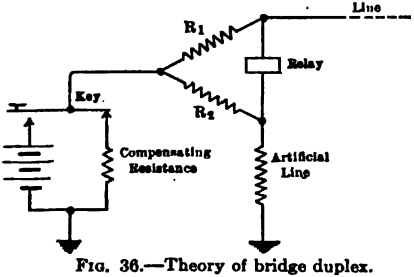

FIG. 36.—Theory of bridge duplex.

**102. The bridge quadruplex of the Western Union type** developed by Athearn† is shown in theory in Fig. 37. The function of the holding coil *H* on the neutral relay is to hold down the armature of the relay during reversals on the polar side. The extra current condenser *E.C.* has a capacitance of about 0.25 mf. and is in series with a 20-ohm resistor. The impedance coils *U* have a total resistance of 1,000 ohms, or 500 ohms per side. The operating currents are about 0.020 amp. for the polar side and 0.060 for the neutral or common side. This type of quad is very efficient and less subject to interference from inductive disturbances on the line than the differential quad.

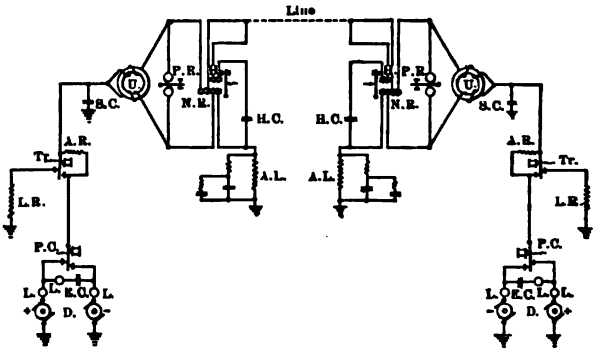
Digitized by Google

The polar side is virtually a bridge polar duplex, working on current reversals, and the neutral side is a Stearns duplex, working on a current margin of about one to three. The Field key system used with the transmitter for the neutral or common side is next described. The pole-changer and the transmitter for the common side are both worked from separate keys in local circuits.



D.—Dynamos.
P.C.—Polechanger.
Tr.—Transmitter
A.R.—Added Resistance.
L.R.—Leak resistance
S.C.—Spark condenser.
L.—Resistance lamps.
U.—Retardation coil.
P.R.—Polar Relay.

H.C.—Holding condenser.
H.—Holding coil on N.R.
A.L.—Artificial line.
E.C.—"Extra current" condenser.

FIG. 37.—Theoretical circuits of Athearn (Western Union) improved quadruplex.

**103. The Field key system** is very useful in quadruplex working where generators or dynamotors are employed as sources of e.m.f. This system requires but one source of e.m.f. at each terminal, giving the full voltage required for the neutral side. The circuits of the system are given in Fig. 38, which shows the transmitter for the neutral side, with the pole-changing transmitter omitted; $L$ is the protective resistor, and $A$ and $B$ are respectively the "added" resistance and the "leak resistance." If the ratio of long to short voltage, for neutral working, is $n$, the values of $A$ and $B$ are:

$$A = L(n-1) \text{ and } B = L\left(\frac{n}{n-1}\right) \text{ (ohms)} \quad (1)$$

where all resistances are expressed in ohms.

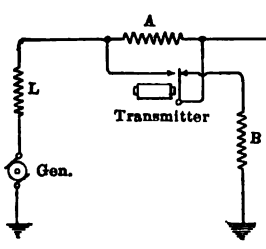

FIG. 38.—Circuits of the Field key system.

**104. The Postal improved quadruplex** is of the differential type, but is equipped with a special system of condensive shunts. For a description of the system, see Skirrow, J. F. "Postal-Telegraph Cable Company's Improved Multiplex Apparatus," *Telegraph and Telephone Age*, Dec. 1, 1912, p. 761.

Digitized by Google

**105. The artificial line** must be adjustable, both in resistance and capacitance, in order to establish readily a balance with the real line. When adjusting for a balance the distant battery or generator should be cut out, and a connection made to ground in its place, through an equivalent resistance.

**106. Single-line repeaters** designed to repeat signals from one Morse circuit to another, with single working, are of various types, including the Milliken, Toye, Weiny-Phillips, Ghegan, Atkinson, Neilson, Horton, d'Humy and others. Only one of these types will be shown; for descriptions of others see the references in Par. 263. Every repeater embraces, for each line, a receiving relay, a transmitter and a holding device; these elements, in duplicate, are common to every type. The principal differences among the various types relate to the form of holding device.

**107. The Milliken single-line repeater** is shown in Fig. 39, where *RR'* are the main-line relays, *TT'* are the transmitters, and *EM*, *EM'* are the extra magnets or holding devices. When the circuit opens on the west, relay *R* is released, opening the local circuit of transmitter *T* and in turn disconnecting the battery of the line east; simultaneously the magnet *EM'* is released and its armature falls back on the armature of relay *R'*, holding it closed and thus protecting the transmitter *T'*. The other operations will be evident from this description and the circuits in Fig. 39.

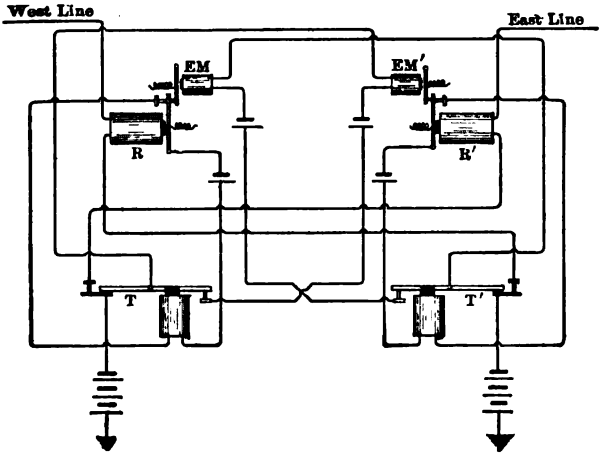

FIG. 39.—Circuits of the Milliken single-line repeater.

**108. Duplex and quadruplex repeaters*** are very simple, it being necessary only to place the pole-changer of the east line under control of the polar relay on the west line, and the transmitter (common side) of the east line under control of the neutral relay on the west line, with corresponding connections for working from east to west.

**109. Half-set repeaters** consist of one relay and one transmitter for connecting a duplexed line with a single line, or one side of a quad with a single line.

**110. The phantoplex** is a system for superimposing an alternating-current telegraph on an ordinary single, duplex or quadruplex circuit.† It

* "Western Union Bridge Duplex." *Telegraph and Telephone Age;* Jan. 16, 1913, p. 54; Feb. 1, 1913, p. 84.

† McNicol, D. "American Telegraph Practice;" McGraw-Hill Book Co., Inc., New York, 1913; Chap. XIX.

Digitized by Google

operates at from 60 to 120 cycles, being linked to the line through series transformers. The phantoplex can be duplexed, and, when superimposed on a polar duplex, provides a quad. It has been used to some extent by the Postal Telegraph-Cable Co. The phantoplex should not be used on composited telephone circuits, and may give rise to inductive disturbances in parallel telephone circuits.

111. **The phonoplex** is a system for superimposing a high-frequency alternating-current telegraph on a morse circuit of the usual type.*

112. **Telegraphing to moving trains** has been successfully accomplished by means of inductively related circuits situated on the trains and parallel to the track. The Edison system of inductive telegraphy from a stationary wire along the road, to moving trains, operated by electrostatic induction; the Phelps system operated by electromagnetic induction. The most successful method of communication for such service, however, is wireless or radiotelegraphy (Sec. 21), which has been given extensive trials on the Delaware, Lackawanna and Western Railroad.

113. **Telegraph switchboards** are of three principal types, the early peg switchboard, the spring-jack and wedge type, and the telephone-jack and plug type. The first type is still used in small offices; the second and third are both in extensive use. The connections of looping and test jacks, in the third type, are shown in Fig 40, where *L L* are looping jacks for cutting into the line with morse sets and *T T* are test jacks for line patching and testing, using cords and plugs. When the last type is equipped only with test jacks, it is termed a **test panel**. Composite and simplex sets are often mounted near the switchboard and their terminals brought to cords and plugs, or to jacks, in the board.

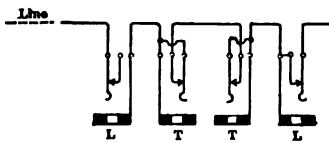

FIG. 40.—Circuits of looping and test jacks.

114. **The telautograph**, an invention of the late Elisha Gray, is a system of telegraphy which reproduces long-hand writing or any other figures or characters desired. Fig 41 shows the principle of the writing part of the apparatus. A is the sending station and B the receiving station; the operator writes on a tablet (not shown in sketch), with pencil 1, which is so linked to arms 2 of rheostats 3, that the motions are split into two components and the resistances varied in proportion to these components. Each of the rheostats is situated in a separate line-circuit, at the receiving end of which is connected a magnet coil, 4, the coil being located in magnetic field of constant value. Variations in the current value in coils 4 cause corresponding variations in the pull acting between the coil and the constant field; coils 4 are connected mechanically to arms 5, the pull being opposed by springs 6. It is easy to see that pen-point 7 will follow the movements of pencil 1 and reproduce any motions which the latter may make. This system requires two line wires, in order to transmit two independent currents of varying strength.

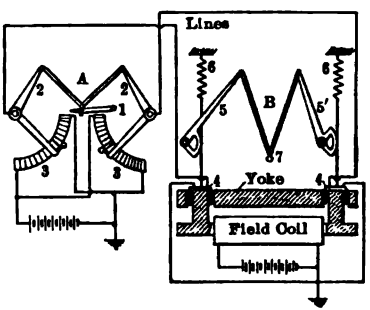

FIG. 41.—Theory of the telautograph.

* Maver, Wm. Jr., "American Telegraphy and the Encyclopedia of the Telegraph," New York, 1909.

Digitized by Google

The telautograph is extensively used in railway terminals, hotels, clubs, factories, etc., where the distances covered are not large. It is not applicable, as yet, to long-distance transmission. See Dixon, J. "The Telautograph;" *Trans.* A. I. E. E., 1904, Vol. XXIII, p. 645.

## SIMPLEX AND COMPOSITE SETS

**115. Simultaneous telephony and telegraphy** over the same wires is obtained commercially by means of two different systems, known as the simplex and the composite.

**116. Simplex sets** operate on precisely the theory of a grounded or half phantom, employing either an impedance coil or a repeating coil. The telephone circuit corresponds to the side circuit of the half-phantom (Par. 85) and the telegraph circuit corresponds to the phantom circuit. An impedance-coil simplex set is illustrated in theory in Fig. 42. Battery, relay and key are connected to the morse leg in the familiar manner. This system permits only one telegraph circuit (with earth return) to be derived from a metallic pair or physical circuit.

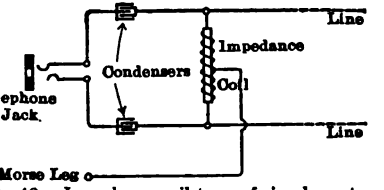

FIG. 42.—Impedance-coil type of simplex set.

**117. Composite sets** permit the use of both sides of a metallic pair for telegraphy, thus deriving two telegraph circuits, or one circuit per wire, with earth return. A composite set for a single-wire grounded telephone circuit is indicated in theory in Fig. 43. The combination of 6-mf. condenser and 50-ohm impedance coil is for the purpose of retarding the rise of current and e.m.f. in the line when the key is closed. Without such retardation the very sharp rise of current and e.m.f. would produce a marked sound or click in the telephone receiver and make communication impossible during the

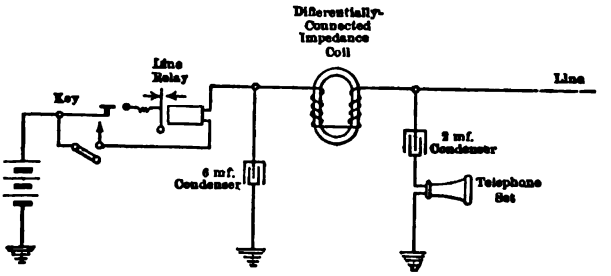

FIG. 43.—Composite set for grounded lines.

sending of telegraph signals. The effect of the coil and condenser, is so to round off the morse impulses that they are almost entirely inaudible in the telephone receiver, and when heard are usually so soft as to constitute practically no impediment to speech transmission. The size of the condenser is usually regulated to some extent by the battery voltage; 6 mf. is usually adequate for any voltage up to 125 volts at each terminal. The 2-mf. condenser is obviously for the purpose of preventing the morse currents from shunting or leaking to ground through the telephone set; a condenser of 1 mf. is sometimes used. When the impedance coil is connected serially for maximum impedance, instead of differentially as shown, the 6-mf. condenser can be replaced by a considerably smaller capacitance, or about 1 mf. The coil and condenser combination always retards the speed of morse signalling

Digitized by Google

to some extent, although the drag is not usually serious unless the coil impedance and the capacitance are too large.

A full composite set for metallic circuits is indicated in Fig. 44. This set is comprised of two sets of the type in Fig. 43, with the addition of the coils *ee* and condensers *dd*. The 50-ohm differential coils *aa*, the 6-mf. condensers *bb* and the 2-mf. condensers *cc* perform the same functions as in the half-set in Fig. 43. The 2-mf. condensers *dd* and the serially connected 30-ohm coils *ee* are for the purpose of shunting to ground the Morse impulses passing through the condensers *cc*, which otherwise would flow through the telephone circuit and result in cross-writing between the two morse legs.

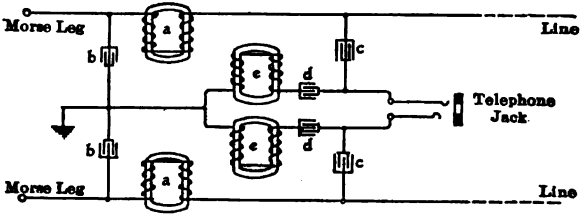

FIG. 44.—Full composite set for metallic circuits.

**118. Duplex working through composite sets** requires the connection of a dummy composite set in the artificial line at each terminal, in order to establish a balance with the sets in the main line. It is also feasible to connect a grounded shunt condenser and serial impedance coil between the pole-changing transmitter and the polar relay, in order to further subdue the sharpness of the impulses when transmitting morse.

**119. Composite ringers.** It is not permissible to signal over composited telephone circuits with the usual 16-cycle ringing current, since it will chatter the morse relays. A high-frequency ringing system is in use which operates with relatively weak currents and does not interfere with simultaneous morse transmission.*

## DISPATCHING AND PATROL SYSTEMS

**120. Train dispatching systems** on steam railroads were formerly operated by Morse telegraph exclusively, but the telephone has extensively superseded the telegraph during the last 6 or 8 years. Dispatching systems on electric interurban railways have been operated by telephone almost without exception since the earliest days of such systems. A train-dispatching system comprises in brief a master sending or transmitting station, with means for selectively signalling all other stations, a line circuit, and a plurality of way stations equipped primarily for receiving. Dispatching systems vary in detail, but nearly all embrace the same fundamental features.† Dispatching equipment is manufactured by nearly all of the leading makers of telephone equipment, and the details of each system are too extensive to reproduce here. Only the leading features will be described.

**121. The Kellogg selective signalling system for train dispatching** is shown in theory in Fig. 45. Normally the battery circuits are open. The automatic calling-key s operated by clockwork, there being a separate key for calling each station. The particular key shown will send a combination of impulses to line represented by 3–1–2–1. The object of the retardation coils and condensers at the dispatcher's station is to make the signals inaudible in

* Kissel, N. C. "The Composite Ringer;" *Telegraph and Telephone Age*, May 1, 1910, p. 318.

Clapp, M. H. "A Comparison of the Telephone with the Telegraph as a Means of Communication in Steam Railroad Operation;" *Proc.* A. I. E. E., Mar., 1914.

Digitized by Google

the telephone receivers which may be connected to line (Par. 117). Each way station is equipped with retardation coils to minimize the shunting

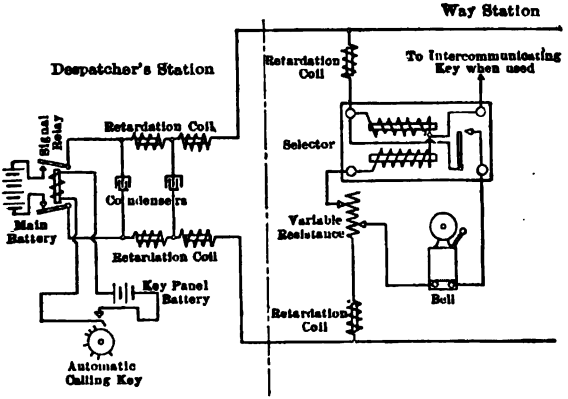

FIG. 45.—Theoretical circuit of Kellogg selective signalling system using Gill selector, for train dispatching.

effect on voice currents, and also has an adjustable resistance designed to equalize the line currents in all the selectors to about 0.008 amp. each. A **Gill selector** is employed at each station, which is so arranged that a combination of impulses, with intermediate intervals, will rotate a wheel and at a certain point in its travel close a local bell circuit. The bell may be operated by local battery or from the main line, and the dispatcher receives a signal in his own receiver which gives a positive indication that the bell is ringing. The dispatcher can also prolong the ringing as long as he desires, by means of a special key.

**122. Way-station dispatching sets** are usually wired in a special manner suited to the peculiar needs of such service. The circuit of the Kellogg "booster" set is shown in Fig. 46. This is a bridging set arranged with a push-button for closing the transmitter battery circuit and shunting the receiver when talking. The adjustable 150-ohm retardation coil is for the purpose of grading the shunt talking impedance so that all stations on the line will hear equally well when several are listening simultaneously; the highest impedance should be at the station nearest the dispatcher, and the lowest impedance at the last station. Obviously the operator can listen without closing the transmitter circuit, which is a great advantage. When the push-button or self-restoring key is depressed, the local battery circuit is closed and the 3.5-ohm adjustable impedance is shunted around the receiver and the 150-ohm coil, so that the outgoing transmission is materially

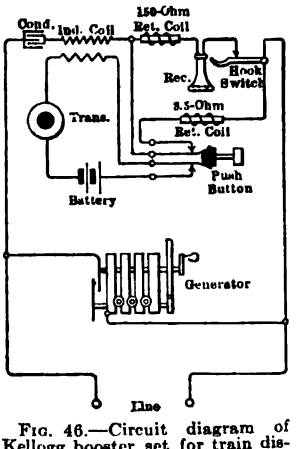

FIG. 46.—Circuit diagram of Kellogg booster set for train dispatching.

Digitized by Google

strengthened and the side-tone greatly diminished. The generator is for emergency use.

**122. Intercommunicating features** can be provided in dispatching systems if desired. One method is to install the complete master station equipment at every station from which it is desired to call other stations. Another method is to simplex the line at the dispatcher's office, with a grounded battery and a relay, and install special grounding keys at each station; the relay can be used to control the selective transmitter and thus call any station desired.

**124. Message telephone circuits** can also be equipped with selective signalling equipment like that described above for telephone dispatching circuits.

**125. Train order semaphore signals** can be controlled by means of selective signalling systems like those employed in train dispatching circuits, so that the dispatcher may set semaphore signals (Sec. 16) against oncoming trains at any one or more of numerous locations along the permanent way. There are several such systems on the market, including the Blake, the Stromberg-Carlson and the Hall Switch and Signal Co.'s systems.

**126. The railway composite system** is designed for operation on ordinary morse telegraph circuits and comprises a grounded composite system for simultaneous telephony and telegraphy (Par. 117). The telephone sets are usually of the bridging type. High-frequency alternating current is used for signalling, with a howler for announcing incoming calls. These grounded circuits are so noisy that it is necessary to connect a low-resistance inductive shunt across the receiver terminals.

**127. Iron-box sets** of the weather-proof type are often employed for mounting on poles or other out-door structures. The line circuit is often arranged to be under control of switches automatically closed by the operation of opening the door; the set is totally disconnected when the door is closed. In some instances these sets are protected with insulating transformers or repeating coils mounted inside of the case.

**128. Sets installed in booths** are quite common practice on interurban electric roads. The booths are usually constructed of wood and pad-locked, so as to be accessible to trainmen or employees only. These booths are generally located at turnouts or sidings. The equipment consists of a wall set, line switch, protector, and train register. The line switch is often arranged so that it is automatically operated by the door of the booth.

**129. Portable sets** are made for numerous purposes, and are frequently very useful in emergencies. Semi-portable sets are carried extensively on trains for emergency use, connection with the telephone line being secured by the use of a fish pole or a jack box and plug. Such sets weigh from 15 to 30 lb. The transmitter and the receiver are often mounted on a combination handle, so that both can be held in position for use by one hand.

**130. Jack boxes** for connection with portable train sets are usually installed at intervals of ½ mile along the right-of-way, mounted on the poles and connected (bridged) to the line circuit through protectors. The portable sets are equipped with suitable extension cords and plugs.

**131. Line poles** or fish poles for connecting portable sets with the wires on a pole line are made of hickory or maple, in sections about 6 ft. long, with telescoping or socket joints. Flexible cords are also provided, and suitable connectors for making contact with the wires.

**132. Linemens' test sets** formerly consisted merely of a hand generator, a polarised buzzer and a telephone receiver, with a switch for signalling and talking. The modern sets are somewhat more elaborately equipped; one manufacturer produces a set weighing 8 lb., equipped with 2-bar generator, buzzer, transmitter, receiver and cord, induction coil, flashlight dry-battery and switch, the whole set being capable of ringing through a 2,500-ohm non-inductive resistance. In another type of set a 1,000-ohm bell is used in place of the buzzer, and a condenser in series with the talking circuit if needed.

**133. Load dispatching** is a comparatively recent development and implies the use of similar means of communication between a main generating station and the substations in a comprehensive electrical distribution system

Digitized by Google

or network, for directing the distribution of electrical energy, that have become familiar in railroad practice for directing train movements. The load dispatcher is situated at the main generating centre and directs the switching operations on the whole system, including all the substations and any auxiliary generating stations; he also directs the starting and stopping of generating units, in response to changes in the system demand. The telephone equipment for such service is not as a whole distinguished by any unusual or radical features, and needs no further elaboration. It is quite essential, in electric trunk line operation, to provide ready communication between the train dispatchers and the load dispatcher.

**134. Patrol systems** may be defined as embracing telephone lines extending along routes covered by patrolmen or inspectors, provided with means at intervals of ½ mile or so for connecting portable sets and establishing temporary communication with headquarters. In the place of portable sets, there may be booths or boxes at fixed locations, with telephones therein. Patrol systems are in use along railroad rights of way and along the routes of transmission and distribution lines. In the case of high-tension lines, it is desirable where possible to have the telephone line on separate poles or supports at some distance away; this not only reduces the induction on the telephone line, but also renders it safer and tends to make it more dependable in emergencies, when it is most needed.

## FIRE AND POLICE ALARM SYSTEMS

**135. Fire alarm systems** consist essentially of signal boxes distributed over the area to be protected, a series line circuit looping through the boxes,

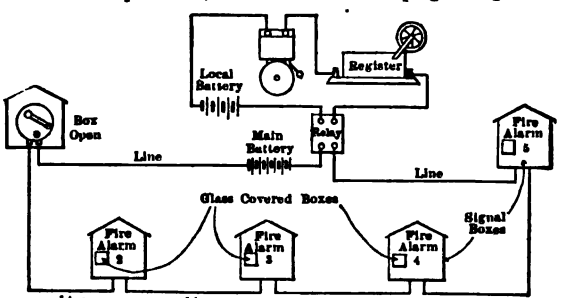

FIG. 47.—Elements of a small fire-alarm system.

and a central station at the engine house or fire headquarters where signals from the boxes will be registered as received and the alarm given. The simple elements of such a system are shown in Fig. 47. Lack of space prevents more than brief description of the characteristic details; further information should be sought in the references given in the bibliography, Par. **263**.

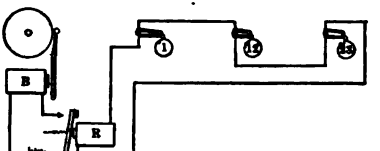

FIG. 48.—Elementary line circuit.

**136. The line circuit** is normally closed, as shown in Fig. 48. If an alarm is turned in at signal box 12, the circuit will be interrupted once, then after a pause, twice, this signal being repeated each time the wheel revolves; and each time the line relay R becomes de-energised, the bell relay B causes the bell to be struck once.

**137. Non-interfering box.** If two or more alarms should be turned in simultaneously on the same line, they would interfere with each other and

Digitized by Google

the bell signals would be confused. In order to avoid such occurrences, the fire-alarm boxes are each provided with non-interfering equipment, so that two simultaneous alarms would be transmitted in sequence, without interference.

**138. The central station equipment** comprises the receiving mechanism for indicating the particular box from which an alarm is sent; the register for keeping record of the alarms received, as to date, time and location; the visual and audible alarms; and in some cases there are included means for repeating the alarms to other points. Small systems having but one or two circuits are frequently automatic in their operation; but large systems having many lines, as in cities, are usually non-automatic and require attendance in order that alarms received at headquarters may be transmitted to the engine houses. Large systems are usually provided, however, with numerous automatic or semi-automatic features, which may be switched in or out of service at will. Many details are described in Maver's "American Telegraphy."

**139. Thermostat systems.** Factory buildings are very often equipped with automatic fire alarms, which can either be used to give an alarm in the central office of the works or to communicate it to the public fire department. Such alarms are actuated by some form of thermostat, which closes a circuit when a given temperature is reached.

**140. Police alarm systems** are similar in a general way to fire-alarm systems, but usually employ the telephone as an auxiliary, for direct communication. Patrolmen on beat turn in signals from the boxes, in rotation, as they reach them. These signals are recorded by the register, at police headquarters or the local police station, showing the date, time and box number. For details see Maver's "American Telegraphy."

**141. Flash-lamp police systems** are now employed to a considerable extent for sending out calls from headquarters to patrolmen on beat. This system employs a lamp signal, usually red, at each patrol box; the signals are under control from headquarters and code signals can be arranged in various ways to convey different orders. Sometimes audible signals or bells are employed in addition to the visual signals.

## TELEPHONE CABLES

**142. Conductors** for telephone cables are almost without exception made of annealed copper wire; this is always tinned if it is to be insulated with rubber or any material containing ingredients tending to corrode copper.

**143. Insulation** is usually composed of dry paper tape wrapped spirally about each conductor. In the case of single wrapping, the paper is overlapped so as to provide double thickness; when double wrapping is employed, the second layer is applied in reverse direction with respect to the first.

Other insulations are employed, such as cotton, silk and wool for interior cables, and impregnated paper, rubber compounds and gutta percha for submarine cables.

**144. Twisted pairs** are formed by twisting together two paper-insulated conductors, the length of one complete twist ranging as follows: 3 in. for No. 22 A.W.G., 3 in. to 5 in. for No. 19 and No. 16, 4 in. to 6 in. for No. 13 and 6 in. to 8 in. for No. 10 A.W.G. The purpose of twisting the pairs is to prevent cross-talk and secure electrical balance of the two conductors composing a metallic circuit.

**145. Laying up the core.** The twisted pairs are laid up in consecutive spiral layers, with adjacent layers spiralled in reverse directions (concentric lay). The numbers of pairs composing the layers are as follows, in progressive order: 1, 6, 12, 18, 24, 30, 36, 42, etc. This rule of course applies only where the pairs are all of the same size.

**146. Cable sheaths** have been made almost universally of a lead-tin alloy, with 97 per cent. of lead and 3 per cent. of tin. The purpose of the tin is to give increased strength and hardness to the lead. A recent development is the use of a lead-antimony alloy containing about 1 per cent. of antimony, which is said to be less susceptible to injury or cracking from vibration, and effects a saving of from 8 per cent. to 10 per cent. in cable cost.

| 480 | 1/16 | 6.920 | 700 | | | |
| 500 | 1/16 | 7.360 | 500 | | | |

These cables have the following constants per mile;

| | No. 22 | No. 19 |
|---|---|---|
| Average mutual capacity (mf.) | 0.070 | 0.074 |
| Average grounded capacity (mf.) | 0.105 | 0.111 |
| Insulation resistance (megohm-miles) | 500 | 500 |

Lead-antimony alloy (Par. **146**) is employed for the sheaths. There is but one application of paper insulation; this is so laid on, however, as to provide two thicknesses of paper over each conductor.

**148. Aerial lead-covered paper-insulated cable,** is made in sizes from 5 to 400 pairs of No. 22 A.W.G. with either double or single wrapping of paper, and pure lead sheaths. Such cable has a mutual capacitance of 0.08 mf. and a grounded capacitance of 0.12 mf. per mile, with a minimum insulation resistance of 500 megohm-miles. On account of the higher capacitance it is somewhat more compact and lighter than No. 22 cable of 0.070 mf. per mile.

**149. Composite cable** is the term applied to cable which is made up of pairs of more than one gage or diameter, as for example, No. 22, No. 19 and No. 14 A.W.G. Such an arrangement is often economical for trunk cables where several different transmission requirements must be met.

**150. Phantom circuits in cable** are made possible by twisting together two similar metallic pairs, constituting a "**quad,**" and laying up such quads in reversed helical layers, after the manner of an ordinary cable. This method is not economical in the use of space within the sheath, however, and it is customary to add as many single pairs as space will permit.

**151. Electrolysis** of lead cable sheaths from stray or foreign currents is covered as a whole by the article in Sec. 16 by Prof. Gans.

## PROTECTORS

**152. Protection** of telephone and telegraph equipment against foreign currents of a hazardous character is necessary for two purposes: first, the protection of the lives and persons of the users of the apparatus; second, the protection of the apparatus itself.

**153. The general practice** in protection is based on the assumption that under ordinary conditions of construction and operation it is not practicable to use protective devices which are adequate to cope with potentials or energies larger than those met in ordinary central station distribution, or say not above 2,300 volts approximately. Such devices are also counted upon to divert ordinary discharges of induced lightning, or distant strokes directly striking the line. Where the conditions of construction and operation unavoidably involve hazardous exposure to high-potential circuits of high energy, it becomes necessary to adopt special types of construction designed to prevent accidental contact of the two systems, or to employ special forms of protectors designed to handle such potentials and energies, or both. It is considered safe by some authorities, however, to depend upon the standard forms of protectors for exposures to circuits operating at not more than 5,000 volts, constant potential, alternating; 5,000 volts, series, alternating current; 7,500 volts, series, direct current; and 1,000 volts, railway trolleys or feeders, direct current.*

**154. Standard telephone protectors,** so-called, consist of fuses in series with the line, and high-potential cut-outs or lightning arresters bridged

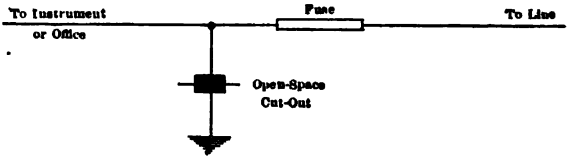

FIG. 49.—Standard telephone protector.

from line to ground. The customary arrangement is shown in Fig. 49, which illustrates the protection for a single wire. In the case of metallic circuits this equipment is provided for each wire.

**155. Fuses** are depended upon for protection from excessive currents and are employed in various ratings from 1 amp. to about 15 amp. A rating very extensively used is 7 amp.; ratings of 10 and 12 amp. are also used. Fuses of the enclosed type are almost invariably used, vertically mounted; if the enclosing tubes are slotted to permit escape of hot gases, the slots should be turned toward the wall, and the latter protected with an asbestos mat.

**156. Arresters or open-space cut-outs** are manufactured in various types. Two carbon blocks separated by a perforated or slotted sheet of thin mica form one of the very common types; in some cases one of the carbon blocks is recessed and filled with fusible metal, to melt and permanently ground the line under heavy discharge. Such an arrester is usually adjusted to break down at about 350 volts continuous current.

A type of open-space cut-out arranged with copper or non-arcing metal blocks separated by a thin mica, is also used where there is no attendant near to keep the arresters clean, and overcomes the objectionable tendency of the carbon type to clog with carbon dust as the result of discharges in action.

**157. Vacuum arresters.** A comparatively recent development is the vacuum arrester, consisting of a spark-gap situated in a rarefied atmosphere. This type is claimed to have a number of advantages, among which are relatively wide gap, larger electrodes, absence of fusing and grounding of electrodes and sensitiveness to high-frequency discharges. It can be set to discharge at 400 to 425 volts.

* Clapp, M. H. "Protection against Lightning and High Currents for Telegraph and Telephone Equipment;" Annual *Proceedings*, Association of Railway Telegraph Supts., 1913.

Digitized by Google

**158. Ground wires** from arresters to earth form a most important link in the system of protection. The conductor should be not smaller than No. 14 A.W.G. and should pass by the nearest accessible route to a substantial ground plate, rod, or coil, or to a water pipe; **gas pipes should never be used** for this purpose. Too much care cannot be given to securing good electrical connection with the earth, with means of a substantial and reliable character.

When a wrought-iron or steel water pipe (service connection) is not available, a fairly efficient earth connection can be made by driving an iron or steel pipe or rod into the ground, in a moist location, to a depth of 5 or 6 ft. See Hayden, J. L. R. "Notes on the Resistance of Gas-pipe Grounds;" *Trans.* A. I. E. E., 1907, Vol. XXVI, p. 1209.

**159. Heat coils or sneak-current arresters** are, in reality, fuses of special construction, designed to overcome the unreliability of ordinary fuses for very small currents. For example, a heat coil can be constructed to operate on a current of 0.2 amp. in 30 sec., or a variety of other ratings. This device comprises a small winding of fine wire, which develops sufficient heat to melt a small piece of fusible metal and release a spring which grounds the line circuit; the resistance of the winding usually amounts to several ohms, at least. The function of heat coils is to protect telephone apparatus wound with fine wire (relays, drops, etc.), such that injury might result from foreign currents insufficient to blow the fuses. The proper location for the heat coils is between the protectors and the apparatus.

**160. Protective or insulating transformers** are employed to protect telephone sets, switchboards or terminals connected to lines which are exposed in a hazardous manner to high-tension high-energy transmission lines, such as those erected on the same poles or structures with a transmission circuit. An insulating transformer of this character* made by one of the leading manufacturers is built to withstand a 25,000-volt test between windings for 1 min., and requires a magnetising current equal to about half the current taken by a 1,000-ohm polarised bell. The transformer is mounted in a weatherproof case for out-door mounting; the casing should always be thoroughly grounded. It should be observed that such transformers introduce additional losses in both transmission and ringing, which should be taken into account in arranging circuit layouts.

**161. Special protectors** are usually employed with these insulating transformers, located between the line and the transformer. The protector consists of extra long fuses in the line circuit, with spark-gaps bridged to ground; sometimes the fuses are so mounted as to be integral with an air-break disconnecting switch. See Sec. 11.

**162. Insulating stools** are often used in conjunction with telephones connected to hazardously exposed lines, as in the case of patrol circuits on transmission lines, so that the attendants may be thoroughly insulated from earth while telephoning. An ordinary four-legged hardwood stool, with the legs inserted in inverted porcelain line insulators, will serve very well. **Insulating mats** are sometimes used, in dry interior locations, in place of stools, but in general are not as efficacious.

**163. Extra insulation of telephone sets** used in connection with hazardously exposed lines is very desirable. Exposed terminals or connections and uninsulated exposed parts should be particularly avoided in selecting equipment for such service. The hook switch should also be very thoroughly insulated.

## CROSS-TALK AND INDUCTIVE DISTURBANCES

**164. Induction between parallel aerial wires** is due to a combination of electrostatic and electromagnetic induction. Such induction is the cause not only of cross-talk between parallel aerial telephone circuits, but also the inductive disturbances in aerial telephone lines situated in parallel exposure to aerial distribution circuits (Sec. 12) or high-tension transmission circuits (Sec. 11). The general means of eliminating such induction is by interchanging or transposing the wires of each circuit at suitable locations, in accordance with a predetermined system. In severe cases it is necessary to resort to further measures of protection. The subject has been treated at

*"Insulating Transformer for Telephone Lines;" *Telephony*, June 5, 1909, Vol. XVII, p. 666.

Digitized by Google

considerable length in different papers, a short bibliography of which is given below.*

**165. Cross-talk between parallel grounded circuits** cannot be eliminated by transposition because it is physically impossible to transpose a circuit consisting of only one wire, except by inserting repeating coils and this method has never developed into a practical system.

**166. Cross-talk between parallel metallic circuits** can be eliminated by a system of **transpositions,** as shown in Fig. 50.

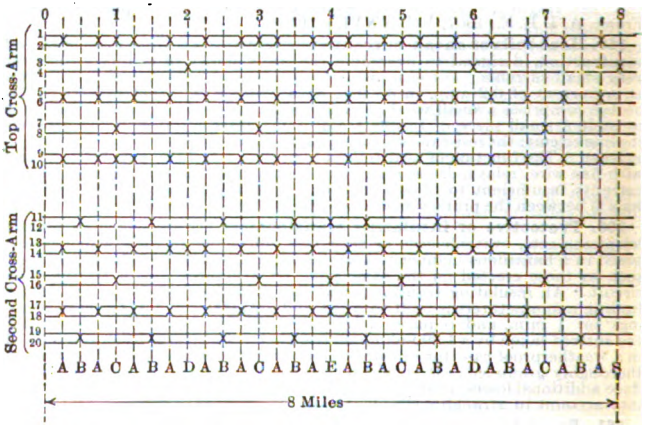

FIG. 50.—Eight mile transposition section for twenty wires.

**167. A modern transposition system** is shown in Fig. 50, which illustrates an 8-mile section for 20 wires or 10 circuits. This section comprises a unit which is applied successively, and the last section, if not exactly 8 miles, is taken care of by stretching or shortening the unit section to suit the case.

**168. Phantom circuits** impose additional transposition requirements. Each side circuit must be transposed, or the phantom will be entirely inoperative. The phantom itself must be transposed, with respect both to its side circuits and to other physical and phantom circuits.

**169. Phantom transpositions** make it necessary to modify the details in Fig. 50 quite materially; changes are necessary at one-half the total number of transposition poles and only the "A" poles remain as they were. An 8-mile section, arranged for phantom circuits, is given in Fig. 51. It is also feasible to transpose pairs 5–6 and 15–16 to make a fifth phantom circuit.

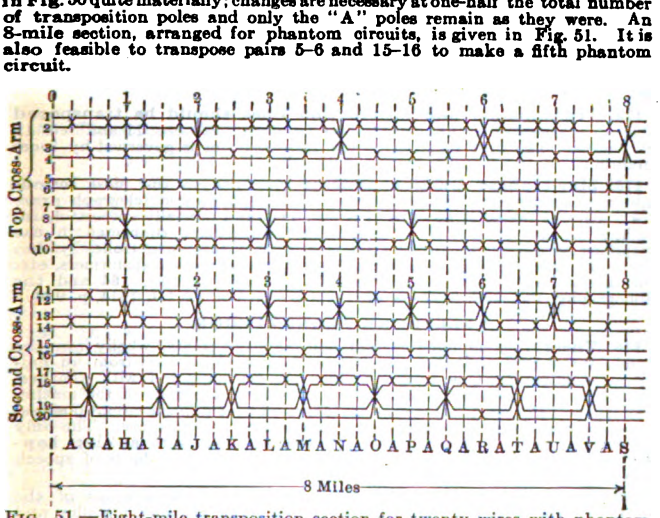

FIG. 51.—Eight-mile transposition section for twenty wires with phantom circuits.

**170. Balancing coils,** Fig. 52, are sometimes employed to improve the balance of metallic circuits and diminish the intensity of inductive interferences from high-energy circuits. Such coils interfere, however, with phantom, composite or simplex operation, unless installed in the drop side or leg.

**171. Drainage coils,** Fig. 53, are useful in preventing excessive rise of potential on telephone lines from heavy inductive disturbances caused by parallel high-tension high-energy circuits. The installation of these coils at intervals along the circuit establishes local circuits through

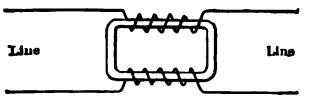

FIG. 52.—Balancing coil for metallic circuit.

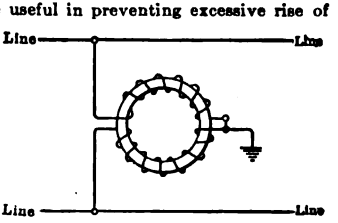

FIG. 53.—Drainage coil for metallic circuit.

earth for the flow of induced currents and thus prevents the cumulative rise of potential which otherwise might occur.

**172. Inductive disturbances may be minimized by proper arrangement of phase wires,** as indicated in the specifications forming part of the report of the Committee on Overhead Line Construction, N. E. L. A., 1911. The phase wires constituting any individual circuit should be grouped as close to each other as feasible. Series circuits should be laid out on the closed-loop system (Sec. 12) and the lamps should be inserted alternately in each side of the loop, to maintain electrostatic balance.

Digitized by Google

**173. Special transpositions for the elimination of foreign induction** are sometimes effective, but require as a rule a rearrangement of the whole transposition system within the section of exposure, if the latter is complicated by the presence of numerous transformers, street lamps, feeder intersections, changes in series loops, etc. The general principles governing the location of such transpositions have been covered in the author's paper, "Transposition of Electrical Conductors," *Trans.* A. I. E. E., Vol. XXIII, 1904, p. 659.

**174. Transmission and distribution lines should be transposed** when they give rise to serious inductive troubles. See Sec. 11 and Sec. 12 for details. The best location of the transpositions is governed by local conditions.

**175. Single-phase traction systems** give rise to the most serious inductive disturbances ever encountered in telephone and telegraph practice. Various remedies have been tried and found partially successful, including the use of special compensating transformers, connected in the telephone system, sectionalizing the trolley system, three-wire trolley system where two or four trolley wires are employed, special track transformers, etc. For discussion of these devices see the references in Par. **164** and the bibliography, Par. **263**; also see *Electrical World*, Vol. LXIII, 1914, p. 984.

## TELEPHONE TRANSMISSION

**176. Theory.** Telephone transmission cannot be treated wholly from the standpoint of analytical theory, but must be handled in part from an empirical standpoint. One telephone line can be compared with another, when the high-frequency constants are known, on the basis of the mathematical theory of electrical energy transmission over a linear circuit possessing distributed resistance, reactance, capacitance and leakance. The only satisfactory method of comparing one telephone set with another, however, is by means of comparative tests and empirical standards of speech transmission.

**177. Transmission equivalents** are usually stated in terms of the lengths of No. 19 A.W.G. standard cable (88 ohms per mile, metallic; and 0.054 mf. per mile, mutual, at 800 cycles per sec.) which give the same total transmission losses as the lines or equipment in question.

**178. Empirical standards of transmission** are usually stated in terms of the transmission over a certain mileage of standard No. 19 A.W.G. cable, with certain types of telephones connected to each terminal and equipped in a certain specific manner. Such a definition serves to fix the standard volume of transmission, but not the quality. A standard equal to 30 miles of cable has been used for long-haul transmission, whereas standards equal to 20 miles or better have been considered in local service.

**179. The range of frequencies** which needs to be considered in telephone transmission is from about 80 to 2,000 cycles per sec. For many purposes the use of a **single equivalent frequency** of 750 or 800 cycles is sufficient.

**180. The properties of conductors** are treated as a whole in Sec. 4. In telephone transmission calculations the constants of the circuit should be those determined by actual test with sine-wave currents and e.m.fs. at 750 to 800 cycles per sec. The skin effect is important to consider; in small copper wires it is negligible, while in copper-clad steel wires it increases the effective resistance a few per cent. over the ohmic or real resistance, say 3 to 6 per cent., and in iron or steel wires it increases the effective resistance from 25 to 75 per cent. The skin effect also diminishes the effective inductance. The permeability of iron wire at high frequencies and low current-densities is about 70, and at power frequencies it is about 100 to 125. The energy loss in the dielectric of insulated conductors is also appreciable, as a rule, and shows itself as an increase in the effective leakage conductance.

**181. The analytical theory of transmission** is given in Sec. 2. It can be shown from the fundamental equations there given, and their solution, that the rate of attenuation on a very long uniform circuit is

$$\text{Propagation Constant} = \epsilon^{-\beta - j\alpha} \qquad (2)$$

Digitized by Google

where $\epsilon$ is the base of Naperian logarithms, $\beta$ is the attenuation constant and $\alpha$ is the wave-length constant. In a line of length $l$, the total attenuation is

$$\epsilon^{-\beta l - j\alpha l} = \epsilon^{-\beta l}(\cos \alpha l - j \sin \alpha l) \quad (3)$$

The quantity $\epsilon^{-\beta l}$ is the numerical magnitude of the attenuation and the quantity within the bracket is the directive or vector portion; the latter has always a numerical magnitude of unity, and is merely a unit vector expressed in terms of complex imaginary quantities. It follows that when two dissimilar lines give equal transmission,

$$\beta_1 l_1 = \beta_2 l_2 \quad (4)$$

**182. The attentuation constant** is given by the expression

$$\beta = \sqrt{\tfrac{1}{2}[\sqrt{(R^2+\omega^2L^2)(G^2+\omega^2C^2)} + (RG-\omega^2LC)]} \quad (5)$$

where $R$ is the effective resistance in ohms per mile, $L$ is the effective inductance in henries per mile, $G$ is the effective leakage conductance in mhos per mile, $C$ is the effective capacitance in farads per mile, and $\omega = 2\pi f$, where $f$ is the frequency in cycles per sec.

**183. The wave-length constant** is given by a similar expression, which is

$$\alpha = \sqrt{\tfrac{1}{2}[\sqrt{(R^2+\omega^2L^2)(G^2+\omega^2C^2)} - (RG-\omega^2LC)]} \quad (6)$$

where the symbols have the same meaning as in the preceding paragraph.

**184. The wave length** is $\lambda = 2\pi/\alpha$, where $\lambda$ is the length of one complete wave, $\alpha$ is the wave-length constant and $\pi = 3.1416$. If the line constants are taken per mile, as customary, $\lambda$ will be in miles.

**185. The velocity of propagation** is $V = f\lambda$, where $V$ = the velocity, $\lambda$ is the wave length and $f$ is the frequency. If $\lambda$ is in mile units, $V$ will be in miles per sec.

**186. The KR law**, which is strictly applicable only to cables, can be obtained by substituting $L = 0$ and $G = 0$ in Eq. 5. This will give $\beta = \sqrt{RC\omega/2}$. Therefore two dissimilar cables, neglecting the dielectric losses, will give equal transmission when

$$\frac{l_1}{l_2} = \sqrt{\frac{R_2C_2}{R_1C_1}} \quad (7)$$

where $l_1$ and $l_2$ are the respective lengths, $R_1$ and $R_2$ the respective resistances per mile and $C_1$ and $C_2$ the respective capacitances per mile. The term $KR$ law comes from the use of the symbol $K$ for capacitance; it might also be called the $CR$ law.

**187. The line impedance** at the sending end is given by the formula

$$Z = \sqrt{\frac{R+j\omega L}{G+j\omega C}} \quad (8)$$

**The surge impedance** is equal to $\sqrt{R/G}$. For example the line impedance of 9 A.W.G. open copper metallic circuit at 800 cycles is about 690 ohms; for No. 9 copper clad, of 47 per cent. conductivity, it is about 830 ohms; and for a sample of No. 9 A.W.G. iron it was 1,640 ohms.

**188. Wave reflection**, or reflection loss, occurs at the junction of dissimilar impedances, such as the junction of open-wire line and cable, or more particularly at the junction of a loaded circuit with a non-loaded circuit.

**189. Transmission tests** are usually made under talking conditions by comparing one instrument with another, or one line circuit with another, and introducing extra cable in the more efficient circuit until the two are alike in talking volume as nearly as can be determined. The amount of extra cable measures the loss, which is expressed in so-called **cable equivalent.** For this work it is very convenient to have a portable artificial cable.

**190. Artificial cable for transmission tests** can be made in very compact portable form. A 32-mile artificial cable, equivalent to 32 miles of No. 19 A.W.G. metallic copper cable, 88 ohms loop resistance and 0.054 mf. (at 800 cycles per sec.) mutual electrostatic capacity, is a convenient size; the whole cable is subdivided into two 1-mile, one 2-mile, one 4-mile, one 8-mile and one 16-mile sections.

**193. Inductance loading or Pupin coils*** are now used extensively to improve transmission, although in America the art of loading is still a monopoly under the fundamental patents which are held by the Bell system. Loading coils are made in torroidal form and inserted in the line as shown in Fig. 54, at intervals of about 8 miles in open wire and from 1 to 2.5 miles in cable. Such coils are also applicable, when properly wound, to phantom circuits. The transmission gains cannot be secured with very short lines, say 4 or 5 miles of No. 19 A.W.G. cable, or roughly 75 miles of No. 12 N.B.S.G. open copper wire. For further details see the literature in the bibliography, Par. **263**.

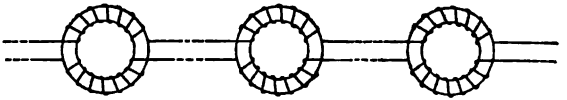

FIG. 54.—Method of connecting loading coils into a telephone line.

**194. Experimental values of transmission equivalents** for various types of telephone circuits have been determined by different investigators and are fairly well established. Tables of such values are given in Par. **191** and **192**.

**195. Transmission equivalents of equipment and apparatus** vary greatly according to the type and construction. The loss due to a bridged relay or drop, wound to 500 ohms, varies from 0.2 to 0.5 mile of standard No. 19 cable; if an efficient impedance coil be connected in series with the drop, the loss can be reduced to practically zero. A 1,000-ohm bridging bell has a loss of less than 0.1 mile. The loss due to series 2-mf. condensers is about 0.2 mile each. When an operator's set is bridged across a cord circuit the loss will vary from 0.5 to 4 or 5 miles.

The loss due to a repeating coil ranges from 0.5 to about 4 or 5 miles; efficient phantom coils have a loss as low as 0.05 to 0.15 mile each on the phantom leg and 0.25 to 2 miles on the side circuits. Telegraph composite sets have a loss of about 0.75 mile per set.

**196. Reflection losses** between non-loaded open wires of different sizes, or side circuits and phantoms, or open wires and cables, are usually but a fraction of a mile of cable. In the case of a loaded open-wire circuit connected to an open-wire non-loaded circuit the reflection loss may become equal to 3 or 4 miles of standard cable.

**197. Cost balance between open-wire line and cable.** When a through line between two given points is comprised of a section of open wire connected to a section of cable, there is a certain size of open wire and a certain size of cable conductor which will provide the required standard of transmission (expressed as a certain fixed number of miles of standard cable) for the lowest annual cost, and any other combination of wire or conductor sizes, giving the same total transmission, will cost more.

**198. Telephone repeaters** of the Shreeve type† have been in successful use on certain long toll lines for several years. This type of repeater operates most successfully at or near the centre of a line section of considerable length; if placed too near either end of the line it will be unbalanced and will give forth a continuous note or "howl." The gain in transmission with one repeater at the centre of the line is the equivalent of about 12 miles of standard No. 19 A.W.G. cable (Par. **177**). Two or even three of these repeaters have been successfully employed on very long trunk lines.

## TELEGRAPH TRANSMISSION

**199. The theory of telegraph transmission** has been developed from a number of standpoints. Herbert* has treated it empirically for English (open-circuit) practice, while Kennelly† has handled it from the purely analytical standpoint, regarding morse impulses as nearly the equivalent of a low uniform frequency (Par. 89). The author has applied the leakage theory to uniform open-wire lines, for American practice, with results given in Par. 202. None of these theories is perhaps satisfactory from the standpoint of every type or condition of line met in practice, but collectively they form a fairly reliable guide.

**200. The leakage theory** as applied to uniform aerial (low-capacitance) lines, derived from the theory of the distribution of continuous currents in the steady state, has been extensively studied by the author,‡ and appears to be applicable to open-wire lines of the closed-circuit type, if there are no considerable lengths of cable in circuit.

**201. Commercial operative limits of transmission,** with given line resistances and an assumed leakage conductance of 4 micromhos per mile, have been tabulated in Par. 202, under the further assumptions next stated: single working, 150-ohm main-line relays, 300 ohms total resistance at each terminal, and a ratio of releasing to operating current equal to 0.75; differential polar duplex, 800-ohm polar relays, and a 300 ohm protective resistor at each terminal; differential quadruplex, 400-ohm polar relays, 800-ohm neutral relays, an e.m.f. of 90 volts on the short (polar) side, ratio of long to short voltages equal to 3.5 and a 600-ohm protective resistor at each terminal.

**202. Table of commercial operative limits, with closed-circuit single, duplex and quadruplex Morse working**

(Based on a leakage conductance of 4 micromhos per mile)

| Resistance per mile (ohms) | Maximum permissible length of line§ (miles) | | |
|---|---|---|---|
| | Duplex (two sides) | Simplex or single | Quadruplex (four sides) |
| 2 | 783 | 597 | 531 |
| 3 | 658 | 510 | 442 |
| 4 | 580 | 450 | 386 |
| 6 | 485 | 376 | 313 |
| 8 | 425 | 331 | 268 |
| 10 | 384 | 299 | 236 |
| 15 | 318 | 248 | 186 |
| 20 | 278 | 217 | 156 |
| 25 | 250 | 195 | 135 |
| 30 | 229 | 179 | 120 |
| 40 | 200 | 156 | 98.7 |
| 50 | 180 | 140 | 84.3 |

**203. The KR law of transmission** as developed by Herbert (see footnote of Par. 199) can be stated as follows:

$$W = \frac{A}{KR} \qquad (9)$$

where $W$ is the maximum commercial speed in words per min., $K$ is the total capacitance and $R$ is the total resistance of the line; $A$ is a constant having a value of 10,000,000 for open-wire lines of iron, 12,000,000 for open-

* Herbert, T. E. "Telegraphy;" Whittaker and Co., London, 1906, Chap. XVII.

§ No intermediate stations.

Digitized by Google

wire lines of copper, and 18,000,000 for cables of the submarine type with gutta-percha insulation. The assumed working conditions are 8 milliamperes of line current, not less than 100 volts impressed e.m.f. from a source whose internal resistance does not exceed 3 ohms per volt, and a shunted condenser at the receiving end. For a speed of 400 words per min. Herbert gives the following limits of distance:

| | Miles | Km. |
|---|---|---|
| 150-lb. aerial copper line | 590 | 950 |
| 100-lb. aerial copper line | 490 | 785 |
| 450-lb. aerial iron line | 360 | 580 |
| 400-lb. aerial iron line | 290 | 465 |
| Gutta-percha underground cable | 83 | 134 |
| Screened paper cable, 40-lb | 128 | 210 |

**204. Intermediate stations** on the line (in single working) increase the total resistance of the line and decrease the transmission efficiency. If the stations are about uniformly spaced, every few miles, the effect can be equated by adding the resistances of the intermediate stations to the resistance of the line wire. It is good practice to employ 35-ohm main-line relays for way circuits, with a line current of at least 60 milliamperes.

**205. Effect of varying leakage on single (simplex) working, with a line measuring 10 ohms per mile**

(No intermediate stations)

| Insulation resistance (megohm-miles) | Leakage conductance (micromhos per mile) | Operative limit (miles) |
|---|---|---|
| 1.000 | 1.0 | 624 |
| 0.500 | 2.0 | 433 |
| 0.250 | 4.0 | 299 |
| 0.125 | 8.0 | 204 |

**206. The use of automatic repeaters** becomes necessary when the total distance between the line terminals exceeds the operative mileage limit of the line wire under the most adverse weather conditions (maximum leakage). In providing for through telegraph transmission over long distances it is uneconomical to employ line wires having more than the necessary tensile strength,* because one or more sets of repeaters can readily be installed in such a manner as to subdivide the line electrically into sections suitable for the electrical characteristics of the line wire. Repeaters are installed about once in every 450 to 500 miles with No. 9 A.W.G. copper wire, and at shorter intervals with wires of lower efficiency.

## CONSTRUCTION

**207. The types of outside construction** are open wire, aerial cable, and underground cable. These types are briefly described in the following paragraphs.

**208. Pole lines** comprise poles, cross-arms, guy stubs, braces, guys, anchors, and the right of way. The aerial wire or cable construction is not usually included under the definition of pole lines, but classed by itself.

**209. Poles.** The timber used most extensively is cedar, and next in order come chestnut, oak, pine, and cypress.† Poles as they come from the stump require peeling, roofing and gaining before they are ready for use; in addition the poles for certain classes of construction require shaving, stepping and painting. The sizes of poles used in line construction are regulated by the loads they will ultimately be required to carry. A number of the larger telephone companies classify their cedar poles as follows:

* Fowle, F. F. "Economical Spacing of Telegraph Repeaters;" *Telephone Engineer*, Vol. VI, Sept., 1911, p. 147.

† See reports of the U. S. Forest Service, Dept. of Agriculture.

| 50 | 24 | 53 | 22 | 50 | 18.8 | 46 | 22.0 | 22.0 | 18.8 | ..... |

Class A poles are used in lines carrying 50 to 80 wires; Class B poles for 40-wire lines; Class C poles for 20-wire lines; Class E for 10-wire lines; Classes F and G for light farmer lines and bracket lines. For properties of timber, see Sec. 4.

**210. Pole setting. The depth of poles in the ground** should be as follows, for ordinary soil or for solid rock.

| Length of pole (ft.) | Depth in the ground | | Length of pole (ft.) | Depth in the ground | |
|---|---|---|---|---|---|
| | Earth (ft.) | Rock (ft.) | | Earth (ft.) | Rock (ft.) |
| 20 | 4.0 | 3.0 | 50 | 7.0 | 4.5 |
| 25 | 5.0 | 3.0 | 55 | 7.5 | 5.0 |
| 30 | 5.5 | 3.5 | 60 | 8.0 | 5.0 |
| 35 | 6.0 | 4.0 | 65 | 8.5 | 6.0 |
| 40 | 6.0 | 4.0 | 70 | 9.0 | 6.0 |
| 45 | 6.5 | 4.5 | 75 | 9.5 | 6.0 |

**211. Reinforced concrete poles** have been used to a very limited extent, largely on an experimental basis. They are not in sufficient use to warrant any considerable description here; see Still, A. "Over-head Electric Power Transmission," New York, 1913. Coombs, R. D and Slocum, C. L. "Reinforced Concrete Poles;" Universal Portland Cement Co., 1910.

**212. Preservative treatment of poles** to prevent decay, especially below the ground line, is constantly becoming more common. Among the preservatives employed are creosote, carbolineum avenarius, creolin, spirittine, coal

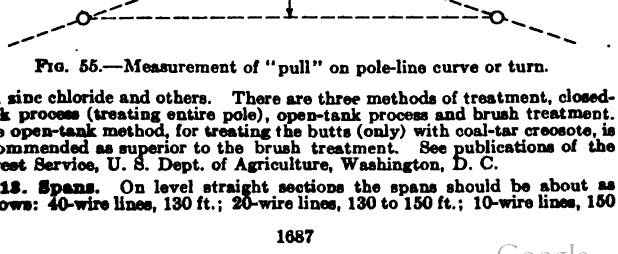

FIG. 55.—Measurement of "pull" on pole-line curve or turn.

tar, zinc chloride and others. There are three methods of treatment, closed-tank process (treating entire pole), open-tank process and brush treatment. The open-tank method, for treating the butts (only) with coal-tar creosote, is recommended as superior to the brush treatment. See publications of the Forest Service, U. S. Dept. of Agriculture, Washington, D. C.

**213. Spans.** On level straight sections the spans should be about as follows: 40-wire lines, 130 ft.; 20-wire lines, 130 to 150 ft.; 10-wire lines, 150

Digitized by Google

to 200 ft. A span of 132 ft. corresponds to 40 poles per mile; the number of poles per mile is seldom less than 30 and in some cases, for heavy lines or in exposed locations, may be as high as 50 or 60 per mile. On curves or turns the spans are regulated by the "pull," which is defined in Fig. 55. The following table shows the lengths of span for different pulls.

| Pull (ft.) | 10-wire line (span in ft.) | 20-wire line (span in ft.) | 40-wire line (span in ft.) |
|---|---|---|---|
| 1–5 | 150–175 | 130–150 | 130 |
| 6–10 | 140–160 | 120–140 | 120 |
| 11–15 | 130–145 | 115–130 | 110 |
| 16–20 | 120–135 | 110–120 | 100 |
| 21–25 | 115–125 | 105–115 | 90 |
| 26–30 | 110–120 | 100–110 | 75 |

**214. Pole gains** are usually 24 in. between centres, with the uppermost gain 12 in. from the pole top. The gains for the ultimate number of cross arms are usually cut before the pole is erected.

**215. Approximate weights and dimensions of standard Washington fir cross-arms**

Size 3½ in. by 4¼ in., bored for 1½-in. pins, ¾-in. through bolt and two ¾-in. brace bolts; unpainted

| Length ft. | Pins | Spacings | | | Weight (lb.) |
|---|---|---|---|---|---|
| | | Between side pins (in.) | Between pole pins (in.) | End (in.) | |
| 3 | 2 | ..... | 28 | 4 | 10 |
| 4 | 4 | 12 | 16 | 4 | 13 |
| 5 | 4 | 17 | 18 | 4 | 17 |
| 6 | 4 | 21 | 22 | 4 | 20 |
| 6 | 6 | 12 | 16 | 4 | 20 |
| 8 | 6 | 17½ | 18 | 4 | 27 |
| 8 | 8 | 12 | 16 | 4 | 27 |
| 10 | 10 | 12 | 16 | 4 | 34 |

Lighter cross-arms, 2¾ in. by 3¾ in., are sometimes used.

**216. Approximate weights and dimensions of yellow pine cross-arms.** The dimensions of yellow pine cross-arms are the same as fir cross-arms given in Par. **215**, and the respective weights are approximately 6, 7, 10, 16, 21 and 25 lb. each. These arms are usually painted (red) to increase their life.

**217. Cross-arms** on adjacent poles face in opposite directions, except on steep hills or grades, when they face up-grade; on curves they should face toward the centre of the curve. In general they should be so faced that the stresses pull them against the pole. Double arms are often used at long spans and railroad crossings.

**218. Pole and cross-arm construction** is shown in Fig. 56. **Cross-arm braces** (24 in. or 26 in. long) should be attached as shown in the figure. For further details on construction see McMeen, S. G. ad Miller, K. B. "Telephony;" Amer. School of Correspondence, Chicago, 1912; also Thiess, J. B. and Joy, G. A. "Toll Telephone Practice;" D. Van Nostrand Co., New York, 1912.

**219. Pins** are made of locust, hedge, oak, maple and elm; the preferable wood is locust. The standard size is 1½ in. by 9 in. For light cross-arms the pins are 1½ in. by 8 in.

**220. Guying** or reinforcement of a pole-line is necessary on curves and at corners or abrupt turns. This is usually done by means of steel guy strand attached near the top of the pole or at the load centre, and anchored to a buried log or plank, or some form of patent anchor. Methods of guying are

Digitized by Google

shown in Figs. 57 and 58; in some cases it is desirable also to guy from the top of pole 1 to the butt of pole 2, and from the top of pole 4 to the butt of pole 3. Back-braces are required on cross-arms on corner poles.

**221. Guy strand** consists of a galvanized seven-wire strand (or concentric-lay cable) and is usually obtainable in four standard sizes having an ultimate tensile strength of 4,000 lb., 6,000 lb., 10,000 lb. and 16,000 lb., respectively.

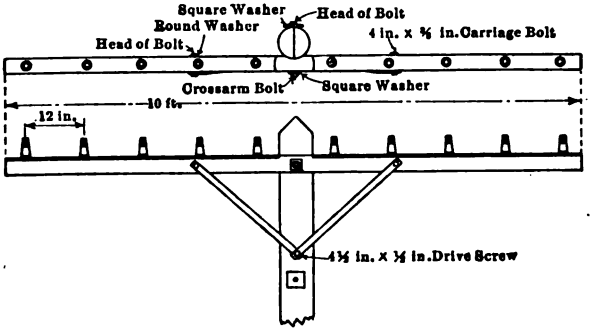

FIG. 56.—Standard pole top and cross arm.

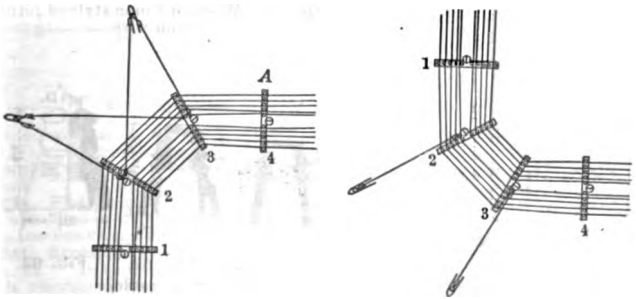
**222. Wire** used in aerial construction ranges in size from No. 8 B.W.G. (435 lb. per mile) to No. 14 S.W.G. (102 lb. per mile) in hard-drawn copper and from No. 6 B.W.G. (573 lb. per mile) to No. 14 B.W.G. (96 lb. per mile) in galvanized annealed iron and steel. The independent telephone companies employ No. 6 to No. 12 A.W.G. copper, while the Bell companies have



FIGS. 57 and 58.—Methods of guying at a corner.

standardized No. 8 B.W.G. and No. 12 and No. 14 S.W.G. copper. For the properties of wire see Sec. 4.

Insulated open wire is usually covered with two cotton braids saturated with weather-proof compound; this is known as ordinary weather-proof wire. Twisted pairs are insulated with a covering of rubber compound and a braid over each conductor. For weights of insulated wire see Sec. 12 and Sec. 13.

| 11 B.W.G. | 120 | 230 | 14 S.W.G. | 80 | 102 |
| 11 S.W.G. | 116 | 215 | ..... | ..... | ..... |

A.W.G. = American (Brown & Sharpe) wire gage.
B.W.G. = Birmingham wire gage.
S.W.G. = Standard (British) wire gage.

**222. Line-wire joints** in the case of hard-drawn copper should be made with connecting sleeves, also known as McIntire sleeves. Lineman's connectors should always be used in twisting the sleeves to make a joint. Joints in iron line wires are usually made with a **Western Union joint**, as illustrated in Fig. 59; it is very essential to solder every joint of this type in order to prevent premature corrosion and preserve satisfactory electrical connection. Also see Rashman, C. T. "Some Tests on Splices in Galvanized Iron Wire;" *Electrical World*, Nov. 17, 1910, p. 1187.

**224. Tie wires** should be of the same size and material as the line wire, except that they should be annealed or soft.

FIG. 59.—Western Union style of joint for iron wire.

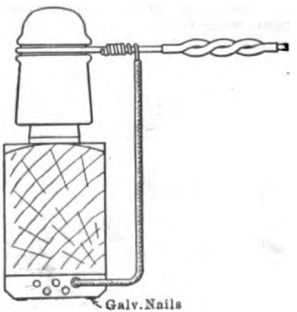

FIG. 60.

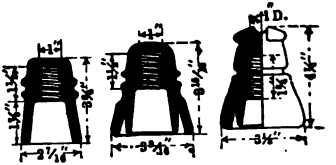

FIG. 61. FIG. 62. FIG. 63.

FIG. 60.—Method of attaching wire terminal to bridle cable.
FIG. 61.—Long-distance type glass insulator.
FIG. 62.—Western Union standard glass insulator.
FIG. 63.—Postal telegraph standard glass insulator.

**225. Bridle cables** are rubber insulated, and the individual conductors are carried from the main cable (up and down the pole) to their respective line wires by means of cleats beneath the cross-arms. Attachment to the line wires may be made by means of a soldered wrap on one leg of the dead-end turn around the insulator, or by means of a screw clamp on the line wire just outside of the dead-end. See Fig. 60.

Digitized by Google

**226. Test connectors** are usually installed at intervals along a pole line, in order to provide facilities for opening the lines for test without cutting the wires. A pole thus equipped with test connectors is termed a **test pole.** The location of test poles is varied in different installations to suit convenience.

**227. Line insulators** are ordinarily made of glass, in one of the patterns shown in Figs. 61 to 63. Porcelain is used to a limited extent in place of glass, especially to secure the high insulation necessary on loaded circuits, but is more expensive. Porcelain is used to a much greater extent in Europe than in this country.

**228. Sag table for hard-drawn bare copper line wire** consisting of No. 12 S.W.G. (0.104 in. diam.) is as follows. The sags are given in inches.

| Temp. (deg. fahr.) | Length of span (ft.) | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | 75 | 100 | 115 | 130 | 150 | 175 | 200 | 250 | 300 |
| −30 | 1.0 | 2.0 | 2.5 | 3.5 | 4.5 | 6.0 | 8.0 | 14.0 | 22.0 |
| −10 | 1.5 | 2.5 | 3.0 | 4.0 | 5.0 | 7.0 | 9.0 | 16.0 | 26.0 |
| +10 | 1.5 | 3.0 | 3.5 | 4.5 | 6.0 | 8.0 | 11.0 | 19.0 | 30.0 |
| 30 | 2.0 | 3.5 | 4.0 | 5.5 | 7.0 | 10.0 | 12.0 | 21.0 | 33.0 |
| 60 | 2.5 | 4.5 | 5.5 | 7.0 | 9.0 | 12.0 | 16.0 | 27.0 | 43.0 |
| 80 | 3.0 | 5.5 | 7.0 | 8.5 | 11.5 | 15.0 | 19.0 | 31.0 | 49.0 |
| 100 | 4.5 | 7.0 | 9.0 | 11.0 | 14.0 | 18.0 | 23.0 | 36.0 | 55.0 |

The sags for No. 14 S.W.G. (0.080 in. diam.) hard-drawn bare copper under like conditions, should be at least 2 in. greater than the above values for No. 12.

**229. Transpositions** are made by means of special line insulators known as transposition insulators. These insulators are made sometimes in one piece with double grooves, and sometimes in two pieces, with one groove in each.

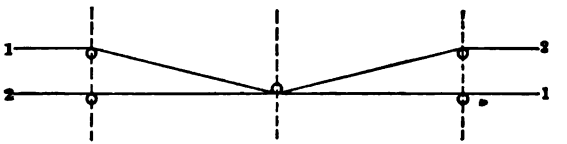

FIG. 64.—Plan view of single-pin transposition.

In modern practice the single-pin transposition is used very extensively (Fig. 64); an alternative method is the use of a two-pin upright iron bracket mounted on the cross-arm so that one wire passes over the arm and one beneath.

**230. Phantom transpositions** are made by means of upright iron brackets attached to the cross-arms; these brackets may support either transposition insulators or standard insulators, as designed.

**231. Stresses in pole lines and wire spans** are covered in Sec. 11 and Sec. 12.* In territories subject to sleet storms, the maximum stresses occur with combined sleet and wind loads. The maximum load sometimes assumed in calculating pole and wire stresses is that due to an ice coating ¾ in. thick combined with a wind velocity of 50 miles per hr. Sleet frequently accumulates to a greater thickness, however; assumptions of 0.5 in. to 0.75 in. have been made in some cases.

* Also see Report of Committee on Overhead Line Construction; N. E. L. A., 1911, 1912, 1913 and 1914.

Still, A. "Overhead Electric Power Transmission;" McGraw-Hill Book Company, Inc., New York, 1913.

Digitized by Google

**232. Overhead wire clearances** vary according to local conditions and the statute requirements. At **railroad crossings** the minimum clearance is usually prescribed by law, but this varies somewhat, being in the vicinity of 24 ft.; the local statute should always be looked up and followed.

**233. High-tension crossings,** or crossings between telephone and telegraph lines and high-tension (over 5,000 volts) high-energy lines should be specially constructed to minimise the hazard of accidental contact or electrical conduction between the two systems. The high-tension line is usually the stronger and should, for that reason, cross over the low-energy line. Where physically practicable, the crossing span of the high-tension line should be shortened until the free end of any broken phase wire in that span will swing clear of the wires or structure of the lower line. If the span cannot be shortened, the construction of the high-tension line should be well reinforced. Cradles or baskets suspended beneath the high-tension wires are not recommended. For further details see the references given in Par. **231** and in the Bibliography, Par. **263**.

**234. Joint line construction with electrical distribution (central station) systems** is now quite common in congested districts. Certain restrictions should be strictly observed in this class of construction; see reference to N. E. L. A. Proceedings in Par. **231**. The proper arrangement is with the distribution lines on the upper cross-arms and the telephone wires below.

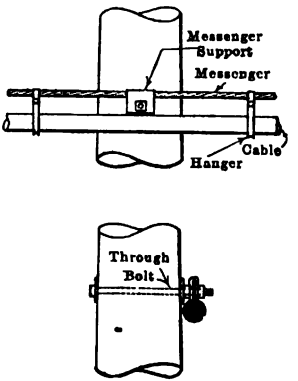

FIG. 65.—Aerial cable suspension.

**235. Aerial cable construction** is indicated in a general way in Fig. 65, which shows a single cable and messenger supported from a pole. Another cable can be supported on the opposite side of the pole in the same manner. When several cables are to be supported, an angle-iron cross-arm is attached to the pole and the messengers are suspended therefrom.

**236. Messengers** are usually made of seven-wire concentric-lay cable, each wire being of galvanised steel; such a cable is also known as a seven-strand cable. Messenger cables have been standardized to a considerable extent, employing three different sizes having ultimate tensile strengths of 6,000 lb., 10,000 lb. and 16,000 lb., respectively. For further details of galvanised strand see Sec. 4. For spans not exceeding 200 ft. the following rules are used to a considerable extent in determining the standard size of messenger to employ.

| | |
|---|---|
| 0–100 pr. No. 22, or 0–50 pr. No. 19 cable | 6,000 lb. |
| 100–200 pr. No. 22, or 50–100 pr. No. 19 cable, | 10,000 lb. |
| Over 200 pr. No. 22, or over 100 pr. No. 19 cable, | 16,000 lb. |

**237. Stresses in messenger spans** are computed from the known or assumed loads as in the case of wire spans (Par. **231**; also see Sec. 11 and Sec. 12).

**238. Table of Messenger Sags**

(Bell Telephone Companies)

| Span (ft.) | Sag (in). | Span (ft.) | Sag (in.) | Span (ft.) | Sag (in.) |
|---|---|---|---|---|---|
| 80 | 16 | 110 | 26 | 150 | 44 |
| 90 | 20 | 120 | 30 | 175 | 62 |
| 100 | 22 | 130 | 34 | 200 | 82 |

For small cables, not larger approximately than 25-pair No. 19, the sags can be reduced about one-third.

Digitized by Google

**239. Cable rings** (galvanized) attached to the messenger are now extensively employed for supporting the cable. Rings should be spaced from 15 to 20 in. apart.

**240. Continuous cable lengths** in aerial construction are limited by the amount of cable which can be pulled into place in one operation without injury. Except with very small cables, the continuous lengths do not ordinarily exceed 1,000 to 1,200 ft.

**241. Cable splices.** A straight splice is shown in Fig. 66. The conductors are twisted together in pig-tail fashion and folded back so that a

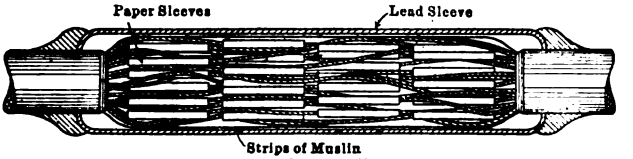

FIG. 66.—Cable splice.

paper tube or sleeve may be slipped over the joint to insulate it. These individual joints are staggered as shown in Fig. 66 and the whole is covered with a lead sleeve made water-tight by means of wiped joints. A number of forms of patented construction for such joints are also on the market.

**242. Twisted pairs in rings,** the latter supported from a messenger (perhaps carrying a cable also), constitute a form of construction now extensively used in reaching drops from a cable terminal or box.

**243. The messenger should be bonded to the cable and grounded** as a means of protection against foreign currents and lightning.

**244. Grounds** may be made by means of a coil of messenger or guy strand buried in coke, at a depth of 5 to 6 ft. in the ground, or by means of an iron pipe (about 6 to 8 ft. long and 1.5 in. diam.) driven into the ground. The first method is preferable. See Par. **188.**

**245. Underground conduit construction** consists of a system of ducts laid from 2 to 4 ft. below ground, with intercepting manholes at intervals of 300 to 700 ft. (Fig. 68).

FIG. 67.—Section of four-duct underground conduit, showing cover.

**246. Ducts** are made of vitrified clay tile, creosoted wood, concrete, impregnated fibre, or iron pipe. The material most used is vitrified tile; this is made in both single duct and multiple duct, the latter including two-duct, three-duct, four-duct, six-duct, and nine-duct combinations in one piece The length of a single piece of duct is from 1.5 ft. to 3 ft., and the duct opening about 2½, 3½ or 3¾ in. in diameter.

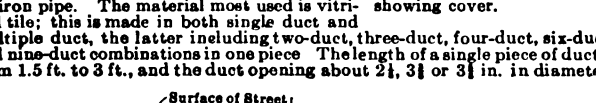

FIG. 68.—Section of underground conduit showing method of grading for drainage of ducts.

**247. Standard conduit construction** consists of some one of the above mentioned materials laid in a properly graded trench on a bed of Portland cement concrete and covered with an envelope on the top and sides, of the

Digitized by Google

same material. (See Figs. 67 and 68.) There are many modifications of this type of construction.

**248. Manholes** (Fig. 69) may be constructed of sewer brick, rejected paving brick (vitrified), or reinforced concrete. There is not very much difference in the cost of manholes constructed by these three methods. The top of the manhole should have sufficient strength to support any traffic passing overhead. The cast-iron cover and supporting framework should be set in concrete to prevent corrosion. The sewer connection, if one is provided, should have a trap to prevent the rise of sewer gas. Ventilation, by perforations in the cover, is desirable to release foul or explosive gases.

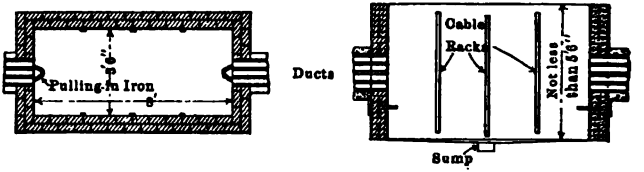

FIG. 69.—Brick manhole.

**249. Cable lengths** are ordered from the manufacturer to fit the distances from manhole to manhole.

**250. Pulling in** the cable is effected by means of short jointed **conduit rods** which are used to pull in rope and the latter in turn is used to pull in the cable with a hand or power capstan, or winch. About 600 to 700 ft. of cable is as much as can be drawn in safely or conveniently in one length.

**251. Cable splices** are made in each manhole and the cables are trained along the sides of the manholes on the racks provided for the purpose.

## TESTING

**252. Two general classes of testing** are necessary in telephone and telegraph practice; the first comprises those tests made to determine whether lines or equipment are in normal operative condition and, if not, to ascertain the character and location of the trouble; the second comprises those tests made to determine the properties of circuits, including resistance, inductance, capacitance and insulation.

**253. Trouble location** in ordinary maintenance work can be said to include tests for the following conditions: (a) electrical continuity; (b) open circuits; (c) crossed circuits; (d) grounded circuits; (e) noise or induction; (f) apparatus adjustment.

**254. Continuity tests** can be made with direct or alternating (ringing) current. Where available, an ordinary morse relay, sounder, key and necessary battery are extremely useful; this method of testing continuity is almost universal in telegraph practice. In telephone work great use is made of a magneto test, next described.

**255. The magneto test set,** used very extensively in continuity tests, is a very simple apparatus consisting merely of a hand-driven magneto generator and a buzzer or polarized bell, connected in series with each other and with the free terminals brought out to a pair of binding posts. See Par. **26** and **27**.

**256. The location of an "open"** is not usually difficult in the case of cable conductors, and the capacity test is a common method. A number of patented devices are also on the market for finding the location of a break in a cable conductor. In the case of aerial open wire it is not always easy to find the location by means of a test; experienced wire chiefs are able to use the listening test to good advantage, judging the location by the noise on the circuit.

**257. The location of a cross** is usually a rather simple operation if a Wheatstone bridge (Sec. 3) is at hand, with which to measure resistances. A magneto or a morse set can be used to determine, first, which conductors are crossed. The Varley and Murray loop tests can also be used to locate crosses.

Digitized by Google

**258. The location of a ground** usually requires the use of the Varley loop test or the Murray loop test, next described.

**259. The Varley loop test,** Fig. 70, is frequently employed. When the bridge is balanced,

$$R_x = \frac{R_1R_0 - R_2R}{R_1 + R_2} \quad \text{(ohms)} \quad (10)$$

$$R_0 = R_x + R_y + R_z \quad \text{(ohms)} \quad (11)$$

Equation (10) expresses the resistance of the grounded conductor from the bridge to the fault and (11) expresses the loop resistance of both conductors Assuming the conductors to be uniform, it is a simple matter to calculate the distance to the fault. If desired, the resistance $R$ can be connected in series with the other conductor, and in that case the formula given above (Eq.

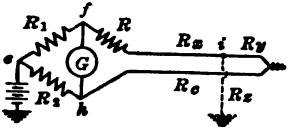

FIG. 70.—Varley loop test.

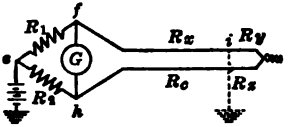

FIG. 71.—Murray loop test.

10) no longer holds true, and instead becomes, $R_x = R_1(R + R_0)/(R_1 + R_2)$. This test is especially useful because it is not affected by the resistance of the fault.

**260. The Murray loop test,** Fig. 71, is quite similar to the Varley test. The resistance of the defective conductor from the bridge to the fault is given by this formula, assuming the bridge to be balanced.

$$R_x = \frac{R_1R_0}{R_1 + R_2} \quad \text{(ohms)} \quad (12)$$

**261. Insulation resistance** comes under the class of high-resistance measurements (Sec. 3). A simple method in extensive use for measuring insulation resistance is the so-called **voltmeter method,** Fig. 72. The insulation resistance in megohm-miles is

$$R = lr_v\left(\frac{E}{V} - 1\right)10^{-6} \quad (13)$$

where $E$ = potential in volts of the battery; $V$ = voltmeter reading when connected to line: $r_v$ = voltmeter resistance in ohms; $l$ = length of line in miles. See discussion of this method, and a modification of it, by the author in the *Electrical World*, Feb. 6, 1904 and Mar. 9, 1912. The reciprocal of insulation resistance is termed leakance, and is a conductance expressible in mhos or micromhos.

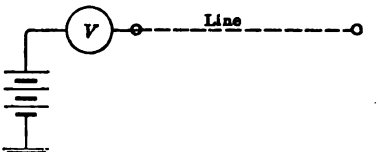

FIG. 72.—Voltmeter test for insulation resistance.

**262. Quantitative measurements** of telephone or telegraph circuits to determine resistance, inductance, reactance, capacitance and leakance, either to continuous or alternating currents, are covered as a whole in Sec. 3.

# RADIOTELEGRAPHY

BY

**LOUIS W. AUSTIN, Ph.D.**

*Head of U. S. Naval Radiotelegraphic Laboratory, Member American Institute of Radio Engineers*

## HIGH-FREQUENCY OSCILLATIONS

**264. High-frequency circuits.** All high-frequency circuits consist of inductance and capacity. Fig. 73 shows a closed circuit consisting of a spark gap, inductance and condenser. Fig. 74 shows a **Hertzian oscillator** in which the capacity is concentrated in the two spheres and the inductance is distributed throughout the straight wires. The power in watts taken up by such oscillatory systems is equal to

$$W = \tfrac{1}{2}\frac{CV^2N}{10^6} \qquad (14)$$

where $C$ is the capacity in microfarads, $V$ the maximum voltage in volts to which the condenser is charged, and $N$ the number of times the spark passes per sec. At each spark the charge in the condenser oscillates back and

Digitized by Google

forth until the energy is consumed either in the form of heat in the circuit itself, or through radiation of electrical waves. The number of times the charge surges back and forth before it is dissipated and the discharge across the spark gap ceases depends on the equivalent resistance of the various sources of energy loss in the circuit.

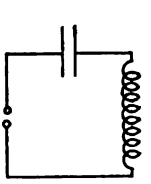

FIG. 73.—Closed oscillatory circuit.

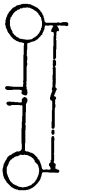

FIG. 74.—Hertzian oscillator.

**265. Damped oscillations.** Gradually decreasing oscillations of this kind are called damped oscillations and obey the law that each succeeding amplitude is a given fraction of the one before it. The constant difference between the natural logarithms of the successive amplitudes is known as the **logarithmic decrement.**

**266. Spark.** In the simplest form of sending set, the spark is placed directly in the antenna (see Figs. 74 and 78), but in order to use any except the smallest power (since the antenna capacity is in all ordinary cases small), a high voltage must be applied to the antenna. This necessitates the use of a long spark, which in turn introduces a high resistance into the antenna circuit, thus limiting the antenna current obtainable.

**267. Coupled circuits.** In order to get rid of this objectionable spark resistance, it is customary to excite the antenna circuit by means of a step-up transformer either inductively connected (Fig. 75) or directly connected (Fig. 76), the antenna circuit and the closed circuit containing the spark-gap

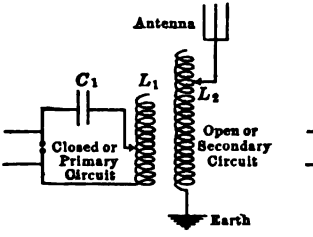

FIG. 75.—Inductive coupling.

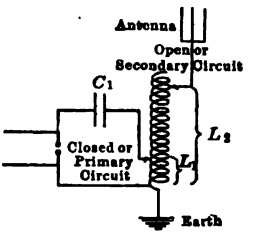

FIG. 76.—Direct coupling.

being tuned to resonance. Two circuits are in resonance, or the electric charges oscillate with the same frequency, when the product of the inductance and capacity in one circuit is equal to the product of the inductance and capacity in the other. A certain portion of the energy oscillating in the antenna is returned and is lost in the spark circuit; that is, the presence of the spark circuit is equivalent to a definite resistance introduced in the antenna. The amount of this equivalent resistance can be regulated by varying the mutual inductance between the antenna and spark circuit.

The fact that the spark length and the capacity in the spark circuit can be varied, provided the conditions of resonance are maintained, makes the double-circuit sending system far more flexible and capable of producing much higher currents in the antenna than the simple system shown in Fig. 78. The only disadvantage of the double-circuit system is that in general

Digitized by Google

the two circuits must be adjusted separately, thus adding to the complication of making rapid changes in wave length.

## THE ANTENNA

**268. The antenna** in radiotelegraphy may be considered to be a special case of the Hertzian oscillator (Fig. 74) in which the lower half is replaced by a conducting plane, the earth, to which it is connected (Fig. 77). Such an oscillator, if the earth be a perfect conductor, will have the same electric field distribution as a complete oscillator in free space, the lower half being indicated in the figure by the dotted lines.

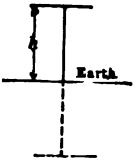

FIG. 77.—Antenna and image (earthed oscillator).

FIG. 78.—Simple antenna (Marconi).

**269. The intensity of the electric field** due to the radiation of such an oscillator (Par. **268**) in its equatorial plane and at a distance of several wave lengths from the oscillator may be expressed by the equation.*

$$E = 2\pi \left(\frac{lI_s}{\lambda d}\right) 3\times 10^{10} \qquad \text{(abvolts)} \qquad (15)$$

where $l$ equals the length of the oscillator, $I_s$ the current in the wire connecting the oscillator capacity spheres, and $d$ the distance from the oscillator to the point in question. In transforming this equation to apply to the earthed antenna, the length of the equivalent oscillator must be taken as twice the height of the antenna. Bearing this in mind and changing to practical units,

$$E = 377\,\frac{hI_s}{\lambda d} \qquad \text{(volts per meter)} \qquad (16)$$

where $I_s$ is in amperes and $h$, $\lambda$ and $d$ are in meters.

**270. Antenna types.** In practice the capacity sphere of the Hertzian

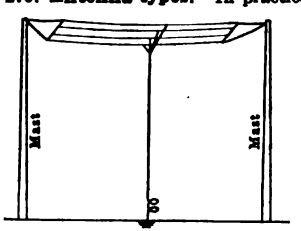

FIG. 79.—Flat-top antenna.

FIG. 80.—Umbrella antenna.

oscillator is replaced by the various systems of wires of the antennas shown in Figs. 78, 79 and 80. Fig. 78 shows the original single wire antenna of Marconi. Fig. 79 is the flat-top or ship's antenna consisting of a number of

* J. Zenneck. "Lehrbuch d. drahtl. Telegr.," 1913, p. 46.

Digitized by Google

parallel wires separated by spreaders and supported by two masts. Fig. 80 s an umbrella antenna. This consists of a system of wires supported on a ingle tower and held in position by insulated guys. Another type is the platform antenna which is the one used in the high-power Naval station at Arlington, Va. In this, the antenna is supported by three towers and may consist either of a system of wires supported on spreaders, or simply of a triangular network of wires between the towers. All of these forms of antenna n practical use are subject to various modifications which cannot be entered nto here. The effective height of the antenna is measured to the geometric centre of capacity of the wire system, if the ground is perfect (salt water) and there are no elevated masses of metal (steel supporting towers) close to the antenna. In land stations the actual effective height is from 50 to 90 per cent. of the measured height. That the height may be made as great as possible, it is desirable to increase the capacity of the upper portion, and to diminish the capacity of the leading-down wires, keeping them bunched together and using only enough to supply proper conductivity.

**271. The amount of energy which can be introduced into an antenna** (Eq. 14) is proportional to its capacity, the square of its maximum voltage, and the number of times it is charged per sec.; *i.e.*, the spark frequency. The voltage is limited by the insulation and on shipboard should not exceed 70,000 volts maximum. The fact that the energy for a given voltage is proportional to the spark frequency shows the great advantage of making the latter large, and explains why 60-cycle apparatus will not deliver a large amount of energy.

**272. Antenna capacity required per kilowatt of antenna energy**

| Maximum antenna potential | 1,000 sparks per sec. | 120 sparks per sec. |
|---|---|---|
| 50,000 (volts) | 0.0008 (mf. per kw.) | 0.0067 (mf. per kw.) |
| 71,000 | 0.0004 | 0.0033 |
| 100,000 | 0.0002 | 0.0017 |

**273. Energy in antenna of 0.001 microfarad capacity at 50,000 volts maximum potential***

| Sparks per second | Kilowatts | Antenna current† |
|---|---|---|
| 120 | 0.15 | 5.0 amp. |
| 240 | 0.30 | 7.1 amp. |
| 500 | 0.625 | 10.2 amp. |
| 1,000 | 1.25 | 14.3 amp. |

**274. Capacity required per kw. at 1,000 sparks per sec. and various voltages**

| Volts, (max.) | Mf. per kw. | Volts, (max.) | Mf. per kw. |
|---|---|---|---|
| 14,500 | 0.010 | 25,000 | 0.003 |
| 17,700 | 0.006 | 31,400 | 0.002 |
| 22,400 | 0.004 | | |

**275. Wave length.** If no inductance coil is introduced into the antenna, it oscillates with a period corresponding to the distributed inductance and capacity of the antenna wires, and the wave length produced is called the fundamental wave length of the antenna. If it is desired to increase this wave length, inductance coils are placed in series between the antenna and the earth, and if it is desired to decrease it, a condenser is placed between the antenna and the earth. In the case of the excitation of the antenna by the closed circuit, it is of course necessary to have a certain amount of inductance in the antenna for the purpose of coupling.

**276. Radiation resistance.** The process of radiation withdraws energy from the antenna and it is customary to speak of radiation resistance,

* *Journal* of the Washington Academy; 1911, Vol. I, p. 5.

† Antenna resistance assumed to be 6 ohms.

Digitized by Google

meaning the equivalent resistance which would consume the same energy as that withdrawn from the antenna by radiation. If the height from the earth to the centre of capacity of the antenna system is $h$, and if $\lambda$ is the wave length, the radiation resistance* is approximately

$$R = 1{,}600\,\frac{h^2}{\lambda^2} \qquad \text{(ohms)} \qquad (17)$$

**277. Table of antenna radiation resistances† (ohms)**

($h$ = height to centre of capacity of conducting system)

| Wave length ($\lambda$) (meters) | $h$ = 40 ft. | $h$ = 60 ft. | $h$ = 80 ft. | $h$ = 100 ft. | $h$ = 120 ft. | $h$ = 160 ft. |
|---|---|---|---|---|---|---|

| 7,000 | 0.121 | 0.19 | 0.27 | 0.61 | 1.09 | 4.4 |

The above table is calculated on the assumption that the antenna represents a Hertzian oscillator (Fig. 77). On account of the shapes of the antennas actually used, and the fact that the earth in most cases is not an ideal conductor, the radiation resistances actually observed are in general from 25 to 90 per cent. of the values given in the table.

**278. Approximate capacity of flat-top antennas with 2-ft. separation of wires**

| Antenna width | Capacity per 100 ft. | Antenna width | Capacity per 100 ft. |
|---|---|---|---|
| 10 ft. | 0.0005 mf. | 40 ft. | 0.0010 mf. |
| 20 ft. | 0.0007 mf. | 80 ft. | 0.0014 mf. |

## METHOD OF EXCITING THE ANTENNA

**279.** The antenna is usually excited by a closed circuit composed of a spark gap, inductance, and capacity to which it is coupled either inductively or directly (Figs. 75 and 76). If the mutual inductance between the two

* Ruedenberg, R. Ann. d. Phys.; Vol. XXV, p. 460; 1908.

† *Journal* of the Washington Academy; Vol. I, p. 290; 1911.

Digitized by Google

circuits is large, they are said to be closely coupled; if small, they are loosely coupled. The coupling is defined as $K = M/\sqrt{L_1 L_2}$. In the case of close coupling, owing to the mutual reactions between the circuits, oscillations of two wave lengths are produced in each circuit, even though the two circuits singly are tuned to resonance with each other. As the coupling is loosened, the two wave lengths approach each other and eventually merge. It was formerly customary to employ close coupling, but modern practice finds that the greatest range is attained with a coupling loose enough to cause the antenna to radiate waves of a single frequency.

**280. Types of spark gap.** For small sets the simple **sphere gap** such as commonly seen on induction coils is sometimes used, but for larger powers either a **rotary gap** or the so-called **quenched gap** is commonly employed.

**281. The rotary gap** (Fig. 81) usually consists of two stationary electrodes with a rotating disc provided with projecting metal spokes or knobs which form the movable electrodes. The disc is usually attached to the shaft of the alternator and insulated from it, and is so adjusted that the maximum potential in the circuit is reached just before the movable electrodes come opposite the stationary electrodes. This ensures the regular passage of the spark, and the rapid motion produces sufficient cooling to prevent the formation of an arc. When used with a 500-cycle alternator, a pure musical note of 1,000 vibrations per sec. is produced in the receiving telephones. This high-pitched musical note is particularly advantageous in telephonic reception, being easily read through the atmospheric disturbances.

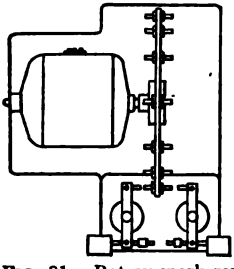

FIG. 81.—Rotary spark gap.

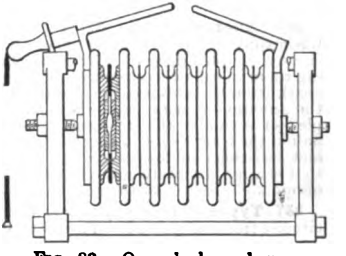

FIG. 82.—Quenched spark gap.

**282. The quenched gap** (Fig. 82) consists of a number of plates insulated from each other and separated by spaces of a fraction of a millimeter. It is in reality a number of gaps in series. On account of the spark being divided up into many parts in close proximity to large surfaces of metal, the cooling is very rapid. This, in addition to the rapid flow of energy from the closed circuit into the antenna, causes the spark to go out after four or five complete oscillations, and before a sufficient time has elapsed for any of the energy transferred to the antenna to return to the closed circuit. By adjusting the mutual inductance between the two circuits it is possible to make this quenching take place at the exact moment when practically all the energy is in the antenna. The fact that no energy can flow back into the closed circuit does away with the complicated reactions of ordinary double-circuit sending, and ensures that the radiated oscillations shall be of only one wave length. This gap is slightly more efficient in transferring energy to the antenna than the rotary gap.

**283. Antenna ground connections.** The outward and inward movement of the lines of electric force during the oscillations in the antenna give rise to earth currents. These earth currents are most intense in the immediate neighborhood of the antenna, and if the earth is a poor conductor a large waste of energy ensues. To guard against this loss, a radiating network of wire is placed beneath and around the antenna. In the case of a flat-top antenna, the radius of this wire net should not be less than the length of the horizontal portion of the antenna. In addition, if ground water is

Digitized by Google

easily reached, copper plates connected to the wire net are buried so as to reach the water. Actual contact with the water is of less importance however than the proper arrangement of the wire net. On shipboard, the good conductivity of salt water and the conducting hull of the ship ensure a good ground if proper connection to the hull is made.

## RECEIVING CIRCUITS

**284. Receiving antenna.** It is customary to use the same antenna for receiving as for sending. When an electric field of intensity $E$ (Par. **269**) is produced on the antenna, there is an electromotive force in the antenna equal to $Eh_2$, where $h_2$ is the height of the receiving antenna from the earth to its centre of capacity.

**285. Received antenna current.** When tuned to resonance with the incoming waves, the received antenna current is from Eq. 16 (Par. **269**),

$$I_R = \frac{Eh_2}{R} \quad \text{(amp.)} \qquad (18)$$

where $R$ is the high-frequency resistance of the antenna system. This is strictly true only for incoming undamped oscillations. If the oscillations are damped, the expression becomes

$$I_R = \frac{Eh_2}{R\sqrt{1+\frac{\delta_1}{\delta_2}}} \quad \text{(amp.)} \qquad (19)$$

where $\delta_1$ and $\delta_2$ are the logarithmic decrements of the sending and receiving systems.

**286. Energy in the detector.** Since most detectors used in radiotelegraphy are of high resistance, they are nearly always placed in separate circuits coupled directly or inductively to the antenna. The reason for placing them in separate circuits is practically the same as that for removing the spark from the antenna in the case of sending, since by varying the coupling the amount of energy consumed by the detector can be varied. When coupled so as to give the strongest response in the detector, approximately one-half of the total received energy is in the detector circuit; that is, the equivalent resistance added to the antenna circuit by coupling the detector circuit to it is approximately equal to the total original resistance (sum of radiation, ohmic and ground) of the antenna, with the detector circuit removed.

**287. Types of receiving circuits.** Figs. 83 to 86 show types of receiving circuits frequently used. The placing of a variable condenser in series, as in

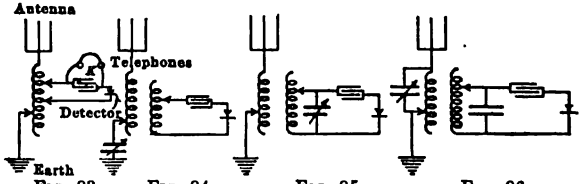

FIG. 83. FIG. 84. FIG. 85. FIG. 86.

FIGS. 83 TO 86.—Receiving circuits.

Fig. 84, shortens the wave length to which the antenna is tuned and enables it to be used for wave lengths shorter than its own natural period. Placing a condenser in parallel with the antenna inductance, as in Fig. 86, increases the period of the antenna without adding additional inductance. In Figs. 83 and 84 the detectors are placed in aperiodic circuits, all of the tuning being done in the antenna. In Figs. 85 and 86 the secondary circuit is tuned to the antenna and to the incoming signals, the detectors being placed in shunt around the tuning condensers.

## DETECTORS

**288. Types of detectors.** A very large variety of detectors, coherer, magnetic, vacuum valve, and others, have been used in wireless telegraphy,

Digitized by Google

ut at present, for damped-wave telegraphy at least, the only detectors enerally employed in the better types of apparatus are various kinds of ectifying contacts and vacuum detectors.

**289. Contact rectifiers.** The rectifiers most frequently consist of a ontact between a fine wire and some variety of mineral. Among the minrals frequently used are iron pyrites, galena, silicon, and molybdenite. In ther forms, two crystals are used in contact, such as zinkite with chalcoyrite or bornite, or silicon with metallic arsenic.

The exact nature of the action of the contact rectifiers is not known. hey behave in general like high resistance thermoelements (though it is ertain that they are not thermoelements in the ordinary sense), the rectified urrent pulses produced by each wave-train being very approximately roportional to the square of the oscillatory current passing through the letector.

For detecting the direct-current pulses, **head telephones** of from 1,000 o 3,000 ohms resistance are ordinarily used. These are placed in shunt across he stopping condenser $K$ (Fig. 83) of from 0.01 to 0.02 mf., which permits the scillatory currents to pass freely through it but stores up the direct-current ulses and discharges them through the telephone. If the spark at the sendng station is regular, the sound produced in the telephone is a pure musical ote. As a rough method of measuring the strength of signal, a resistance ox is frequently placed across the telephones and the resistance reduced ntil the signals just remain audible. The relative strength of the telephone urrent at various times can thus be determined from the law of shunts. For laboratory purposes a galvanometer is frequently used in place of the elephones.

## TRANSMISSION OF WAVES FROM THE SENDING TO THE RECEIVING ANTENNAS

**290. Day transmission.**—The radiation from a radiotelegraphic antenna nay be conceived to consist of lines of electrostatic force with their ends erminating in positive and negative electric charges at the earth's surface omewhat as shown in Fig. 87. At moderate distances the strength of the lectric field is represented by Eq. 16. For distances of more than 100 miles, over sea water, and for stillshorter distances over land, an absorption of nergy appears which modifies the results of Eq. 16. This absorption is due n part, at least, to the resistance of the earth to the passage of the positive nd negative electric charges at the base of the electrical wave. At great listances the bottom of the wave is o much retarded that the wave front ecomes bent forward. When rought into this position the electric ield can be divided into two components, one at right angles to the arth's surface and the other parallel o it. The latter produces oscillatory earth currents which, while they withdraw energy rapidly from the wave, make possible the reception of ignals by means of long horizontal ntennas, only a few feet above the round. Experiments by the U. S. Navy Department extending up to a listance of 2,000 miles have given results for flat-top antennas which may be epresented by the following empirical formula*

FIG. 87.—Earthed electric waves.

$$I_R = 377 \frac{h_1 h_2 I_s}{\lambda d R \sqrt{1+\frac{\delta_1}{\delta_2}}} e^{-\frac{0.0015d}{\sqrt{\lambda}}} \quad \text{(amp.)} \qquad (20)$$

where $I_R$ represents the current in the receiving antenna, $I_s$ the current in the ending antenna, $R$ the receiving resistance, $d$ the distance, $\lambda$ the wave ength, and $h_1 h_2$ the height to the centre of capacity of the sending and

Digitized by Google

receiving antennas, respectively, the currents being given in amp. and all lengths in km. The formula applies to day signals with transmission entirely over salt water. A similar formula will probably apply to land transmission except that the absorption coefficient (0.0015) is much larger and depends on the character of the ground over which the waves pass and also on the season of the year. It is found for example, that the absorption between New York and Washington at a wave length of 1,000 meters, is approximately three times as great in summer as in winter. The formula indicates that for short distances stronger signals may be obtained by the use of short wave lengths, while for great distances longer wave lengths, from 3,000 to 10,000 meters, are used. Over land for distances greater than 150 miles, wave lengths of more than 2,000 meters are generally desirable.

| 0.6 | 5.0 | 0.2 | 12.5 | 0.06 | 39.0 | 0.02 | 116.0 |

Good tuning is not possible with less than fifteen waves in the train.

**294. Night transmission.** While day transmission of radiotelegraphic signals is comparatively regular, night transmission is subject to very great

Digitized by Google

fluctuations. At times night signals between two stations will be no stronger than those observed in the day time, while at other times sending sets of very moderate power and efficiency have been known to transmit signals several thousand miles. During the colder months of the year, night transmission can be depended upon to be considerably superior to day, with a fair degree of regularity. The cause of the increased night range is not definitely known. It has been thought by some authorities that it is due to a clearing up of the absorption supposed to exist in the upper atmosphere caused by the shorter light waves, and possibly cathode rays from the sun. Another explanation is that the absorption is fairly constant and that the increased received energy is due to reflection from the upper conducting layers of the atmosphere. This last view is supported by certain interference phenomena which cannot be entered into here, and by the fact that the abnormally strong night signals appear to pass over land almost as freely as over salt water, although the absorption in the day time is many times greater over land. That the normal energy is at times augmented in long-range night communication is shown by the fact that in many cases the received signals are stronger than would be expected from the geometric diminution of intensity with the distance, leaving absorption entirely out of account. It must also not be forgotten in this particular that observations show that the day condition is the stable one while the longer ranges covered at night show the irregularities which might be expected to come from irregular conditions of reflection.

## UNDAMPED OSCILLATIONS

**295. Advantages of undamped oscillations.** It has already been said (Par. 264) that the oscillations produced from the electric spark form damped wave trains with intervals between in which no energy is given off. If, instead of supplying energy merely at the beginning of the wave train, a constant source of supply can be obtained, the oscillations will continue indefinitely and with equal amplitude. The use of such undamped oscillations in radio communication has a number of advantages; first, if the energy is divided among a great number of waves of equal amplitude, instead of being concentrated in a few wave trains, the maximum voltages required for a given amount of power are very much less than in the case of damped waves, and consequently the insulation of the apparatus is much less difficult, and much larger amounts of energy can be sent out from moderate sized antennas. Second, undamped oscillations allow a greater sharpness of tuning and enable a looseness of coupling to be used at the receiving station between the antenna and secondary which greatly reduces the danger of interference and disturbance from atmospheric discharges. Third, and most important of all, observations indicate that undamped oscillations in passing over the surface of the earth fall off in intensity less rapidly at great distances than the damped oscillations from the spark.

**296. Production of undamped oscillations.** The most obvious way of producing undamped oscillations is by means of high frequency generators. Three types of such machines have been built; the Fessenden-Alexanderson, the Goldschmidt, and the Arco. The first has been used successfully with small powers, and the last two have been constructed with a capacity of more than 100 kw. and are in successful use in communication between Germany and America. For descriptions of these machines the reader is referred to Zenneck's "Lehrbuch der drahtlosen Telegraphie."

## THE ELECTRIC ARC WAVE GENERATOR

**297. The arc method of producing oscillations** was discovered by Elihu Thomson in 1892 and has been developed by V. Poulsen, R. A. Fessenden and others. In this method a circuit containing suitable inductance and capacity is placed around the arc as shown in Fig. 88. Choke coils and resistance are placed in the main dynamo circuit to control the voltage and to prevent the oscillations from running back into the dynamo. When the shunt condenser circuit is closed around the arc a part of the current flows into the condenser thus robbing the arc of a portion of its current. But since the arc has the characteristic that the potential across the arc increases as the current decreases, this decrease in current increases the potential difference and the condenser continues to charge. At the next instant, however, the condenser commences to discharge, increasing the direct arc current until it is entirely discharged. Then the process repeats itself. For the

Digitized by Google

best results it is necessary that the direct-current voltage be 500 volts or more, and that the positive electrode be capable of conducting heat rapidly away.

**298. Poulsen arc.** In the Poulsen arc, the positive electrode is copper and the negative carbon, and the arc is formed in a chamber filled with hydrogen or a hydrocarbon gas or vapor. Hydrogen being an excellent conductor of heat assists materially in the rapid cooling. A common method of producing a hydrocarbon vapor is to allow alcohol to fall drop by drop into the heated arc chamber. To still further increase the energy of the oscillations in the Poulsen apparatus the arc is formed in a strong magnetic field at right angles to its length.

**299. The arc circuit.** When the arc is used for producing oscillations in a radiotelegraphic antenna, it is customary, when the antenna is of sufficient capacity, to place the arc directly in it (Fig. 89), thus doing away with the necessity of

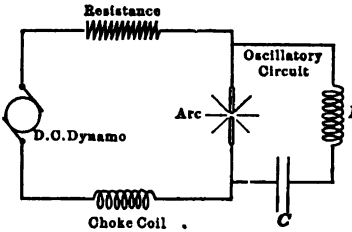

FIG. 88.—Arc circuit.

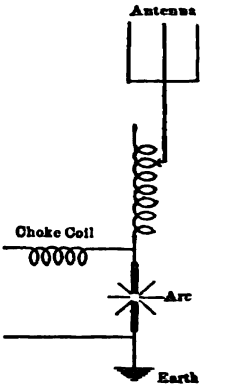

FIG. 89.—Arc in antenna

tuning two separate circuits, the inductance and capacity of the antenna taking the place of the closed-circuit inductance and capacity of Fig. 88.

## THE RECEIVING OF CONTINUOUS OSCILLATIONS

**300. Ticker.** Since undamped oscillations pass through the detector continuously, they produce little effect upon the telephones. In small sets a circuit breaker is sometimes placed in the antenna for the purpose of breaking up the oscilliations into separate wave trains and thus making them audible. The better practice, however, and the only one applicable to large powers, is to have the oscillations broken up at the receiving station. For this purpose the Poulsen Company originally used an instrument called the ticker which consisted essentially of a minute circuit breaker actuated by a magnetic vibrator kept in action by a dry cell. At first a detector was used in connection with the ticker but it was soon found that the ticker itself formed an efficient detector, being connected as shown in Fig. 90. During the time of contact, the condenser $K$ becomes charged and when the contact is broken it discharges through the telephone.

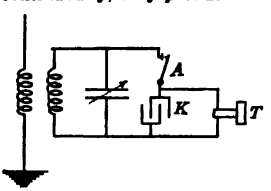

FIG. 90.—Ticker circuit.

A more sensitive detector of this type is the **slipping contact detector** or rotary ticker.* In this a wire presses lightly on a rotating disc driven either by a motor or clock work. The slipping contact detector while many times more sensitive than the best crystal detectors both for continuous oscillations and high-frequency spark oscillations, cannot in general produce a musical note, the sound being more of the nature of a rustling or hissing.

*Austin, L. W. *Journal* of the Washington Academy; Vol. I, p. 8; 1911.

Digitized by Google

This places it at a disadvantage in receiving through atmospheric disturbances.

**301. The Fessenden heterodyne.** In the heterodyne method of receiving, an ordinary receiving set is used, as shown in Fig. 91. The heterodyne proper is a piece of auxiliary apparatus consisting of a small arc circuit coupled to the antenna and so tuned to the incoming waves as to produce beat tones in the detector and its telephone. By slightly shifting the frequency of the heterodyne any desired tone can be produced in the receiver proper which makes it particularly efficient in working through interference and atmospheric disturbances. It has also the property of increasing somewhat the sensitiveness of the detector. The heterodyne is also used with spark oscillations but in this case a musical note is not generally obtained.

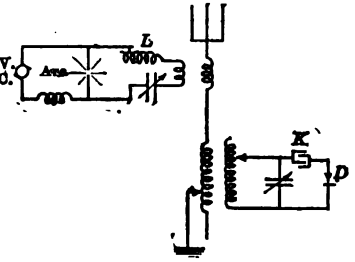

FIG. 91.—Heterodyne circuit.

**302. Vacuum detectors.** Hot-filament vacuum detectors were first invented by Prof. Fleming. The modern oscillating types, of which the DeForest ultra audion, the von Lieben and the Marconi tubes are examples, all operate on the same principle, differing only in arrangement of electrodes, voltage employed, etc. The DeForest ultra-audion is shown diagrammatically in Fig. 92. It consists of a highly evacuated glass bulb containing a filament F heated to incandescence by a storage battery of 6 volts, A, an intermediate grid electrode G, and a plate electrode P. The secondary receiving circuit LC is connected through a small variable stopping condenser C′ of a few ten-thousandths microfarad to P and G. The incoming oscillations produce disturbances in the electron flow in the tube which are heard as audible sounds in the telephone T. When the condenser C is small and the inductance L large, instability is automatically set up in the electron flow and continuous oscillations take place in the secondary circuit. The strength of these oscillations is increased by a variable bridging condenser C″. Then, as in the case of the heterodyne, if the local oscillations are slightly detuned from the incoming continuous oscillations, musical beat tones are produced which are heard in the telephone and by means of which the incoming signals may be read. The presence of the oscillations in the local circuit may be ascertained by touching with the finger any metallic portion of the circuit between the inductance of the secondary circuit and the stopping condenser. If oscillations are present a sound is heard in the telephones. For receiving spark signals the ultra-audion may be used either oscillating or non-oscillating. In both cases it is far more sensitive than the crystal detectors, especially when oscillating. In this case however the muscial tone of the spark is not clear.

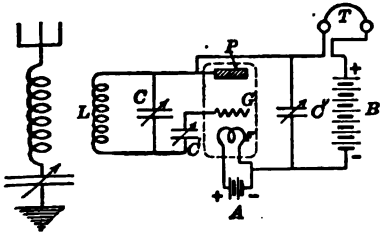

FIG. 92.—Deforrest ultra audion vacuum detectors.

**The Audion Ampliphone.** The audion ampliphone consists of two or three audions connected in cascade through small transformers by which the strength of signal in any detector may be increased from 20 to 150 times.

## THE WIRELESS TELEPHONE

**303. General principles.** As long as continuous oscillations either from the high frequency machine or from the electric arc are of the same intensity,

Digitized by Google

they produce no sound in the telephones attached to an ordinary radio receiver. If, however, a microphone transmitter be placed in the antenna at the sending station, any words spoken into the transmitter are faithfully reproduced in the telephones of the receiver.

**304. The range of radiotelephonic transmission** is limited by the amount of current which can be carried by the microphone. Very successful communication can easily be carried on up to 40 or 50 miles, and with large antennas conversation can be faintly heard up to perhaps 200 or 300 miles.

**305. Applications.** In its present form there seems to be little demand for the wireless telephone. It obviously cannot take the place of the ordinary local telephone service and its limitations regarding power unfit it for long-distance service. It would undoubtedly find a use in the Navy if the apparatus could be simplified and an arc produced capable of giving oscillations at a direct-current voltage of 110 volts, but since it is incapable of taking the place of the ordinary radiotelegraphic set, and since it occupies quite as much space, there is a general disinclination to duplicate apparatus sufficiently to permit of its use.

## DIRECTIVE ANTENNAS

**306. The advantages** of the ability to concentrate the radiated energy from an antenna in one definite direction, and at the receiving station to confine the received signals to those from one direction are obvious, since such directive systems can evidently work with greater economy of power and with less disturbance from other stations.

**307. Marconi directive antenna.** It has long been known that an inclined receiving antenna receives most effectively when the waves come

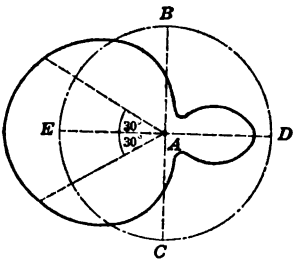

FIG. 94.—Polar curve of intensity about a bent antenna.

FIG. 93.—Marconi bent sending antenna.

FIG. 95.—Earth antenna.

from a direction opposite to that toward which the antenna is inclined. This fact has been made use of by Marconi in his high-power transatlantic stations, Clifden and Glace Bay. In these stations the inclined antenna is replaced by a bent antenna consisting of a comparatively short vertical section and a long horizontal section pointing away from the direction in which the signals are to be received. The principle of the directive action depends at least partly on the fact that at great distances the wave front is tilted forward so that there is a powerful horizontal component of electric force which is made use of by the horizontal portion of the antenna.

Mr. Marconi also employs a directive sending antenna similar to the receiving antenna except that the horizontal portion is usually relatively shorter. This antenna, shown in Fig. 93, radiates most powerfully in the direction of the arrow and measurements have shown that the intensity of the field about the antenna may be represented by the diagram of Fig. 94. In this figure the relative intensities are the distances from the origin to the curve.

Digitized by Google

**308. The theories* of the directive radiation of the bent antenna** have been much discussed and the different authorities are not yet in entire agreement on the subject. Low horizontal antennas several hundred feet long and only a few feet above the earth have been tried by a number of experimenters and have recently been brought into prominence by the work of F. Kiebits.† These antennas usually have the receiving apparatus in the middle while the ends are either free or connected to earth through condensers (Fig. 95). They receive remarkably well in the direction of their length, while at right angles to this direction the energy received is very feeble. Dr. Kiebits has also had some success in using these antennas for sending, but at the present writing it seems doubtful whether they will in practice be made to take the place of the elevated forms already described.

**309. The directive antennas of Bellini and Tosi** differ from those already mentioned. They are based on the fact that a nearly closed oscillating system (Fig. 96) radiates and receives more powerfully in its plane than at right angles. These inventors have very ingeniously made use of two such antennas at right angles to each other (Fig. 97). Each of the antennas contains a primary of a double transformer, the coils lying at right angles to each other. Inside the primaries a single secondary can be rotated so as to receive different amounts of energy from the two primaries. By noting the position of the secondary at which the signals are strongest, the direction of the sending station can be determined within two or three degrees. The same system of antennas can be used for sending if the rotating coil be connected to a suitable spark

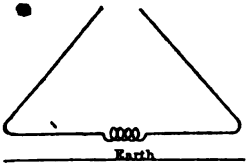

FIG. 96.—Directive antenna (nearly closed type).

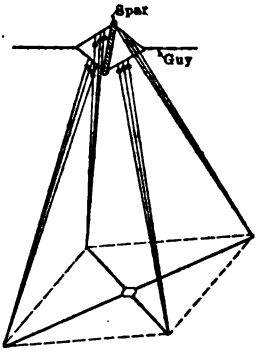

FIG. 97.—Bellini Tosi directive antenna.

gap and condenser. By placing the moving coil in the proper position signals can be sent out in any plane desired.

The Bellini-Tosi system has proved itself valuable in permitting ships to determine the direction of sending stations erected along the coast for the purpose of aiding navigation in time of fog. According to the international regulations, stations used for this purpose must operate with small power and very short wave lengths so as not to interfere with other radiotelegraphic work.

**310. Telefunken compass.** Another system intended to assist in navigation has been developed by the Telefunken Company of Berlin and is called the Telefunken Compass. In this, the directive stations are fixed shore stations and the receiving is done on an ordinary ship's antenna. The sending station has a set of thirty-two bent antennas (Fig. 98) extending radially from it. The sending circuit is connected to each of these in turn by means of a rotating contact. When contact is made with the antenna sending in a certain definite direction, say due North, a special signal differing from the others is produced and sent out also from a non-directive antenna. The mariner desiring to know his direction from the sending station starts a

special stop watch at this signal and stops it at the point where the signals fall to a minimum. The time between the contacts being known, he is able at once to determine the direction of the sending station.

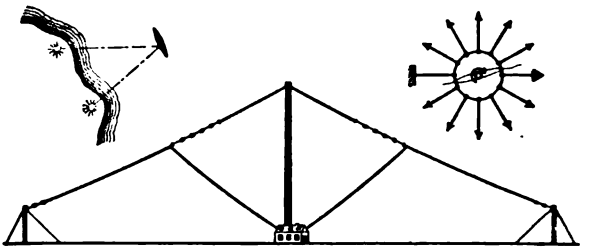

FIG. 98.—Telefunken compass.

## MEASURING INSTRUMENTS FOR RADIOTELEGRAPHY

**311. Measurement of current.** When it is desired to measure high-frequency currents quantitatively, shunted instruments in general are not satisfactory, since the value of the shunt ordinarily changes with the frequency. A form of hot-wire ammeter has been devised by Hartmann & Braun in which the current is carried by a system of wires or bands symmetrically placed in squirrel-cage arrangement so as to ensure a uniform distribution of current among the bands. Each of the bands is of such dimensions that its high-frequency resistance does not differ from that for direct current. The indicating mechanism is attached to one of the bands. These instruments have been made with current-carrying capacities up to 300 amperes. They are especially useful in the sending antenna when it is desired to know with accuracy the amount of energy radiated. For the measurement of very small currents thermoelements are generally used.*

**312. Wave meters.** For determining the wave length of high-frequency circuits wave meters are employed (Fig. 99). These consist essentially of a circuit containing known inductance and capacity, one or both of which are variable, and an indicating device such as a sensitive hot-wire

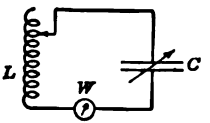

FIG. 99.—Wave meter circuit.

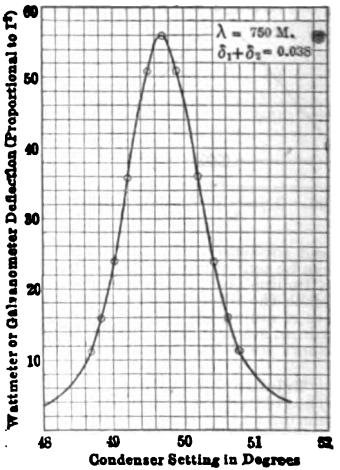

FIG. 100.—Resonance curve taken with wave meter.

Digitized by Google

milliwattmeter which indicates by a maximum deflection when the wave meter is brought into resonance with the high-frequency circuit under examination. The variable capacity in the wave meter usually consists of a semicircular plate air condenser which is varied until the point of resonance is obtained. Fig. 100 shows a so-called **resonance curve** giving the relation between the hot-wire milliwattmeter deflection and the degrees on the condenser. As was mentioned in Par. **267**, when the wave meter is in resonance with the circuit under examination the product of the inductance and capacity in the wave meter circuit is equal to the product of the inductance and capacity in the other. The wave lengths corresponding to various wave meter readings are either engraved on the condenser scale or given in a table.

**313. Formula for wave length.** Since the time of oscillation of the charge is

$$T = 2\pi\sqrt{LC} \qquad \text{(sec.)} \qquad (21)$$

and $v = n\lambda$ and $T = 1/n$, then the wave length is

$$\lambda = v2\pi\sqrt{LC} \quad \text{or}$$

$$\lambda = 1.885\sqrt{LC}.\times 10^8 \qquad \text{(meters)} \qquad (22)$$

where $v$ is the velocity of light, $L$ the inductance and $C$ the capacity, all expressed in electromagnetic units. In place of the milliammeter a thermo-element and galvanometer or some other indicating device is sometimes used to indicate the current strength in the wave meter.

In order that the wave meter may be used for exciting receiving and other circuits at definite wave lengths, it is often connected to a buzzer circuit shown in Fig. 101. When the current from the cell $s$ flowing through the inductance of the wave meter is broken at the vibrator of the buzzer $B$, the induced electromotive force charges the condenser of the wave meter. This charge oscillates back and forth through the inductance and condenser until the energy is dissipated in heat or radiation. As there is little resistance in the wave meter circuit the oscillations produced in this way are very feebly damped. If greater damping is desired, fine-wire resistance is introduced into the circuit at $r$. In order to eliminate the disturbing effects of the buzzer spark, a condenser $K$, of a few tenths of a microfarad, is placed around the coil of the buzzer. As the intensity of the oscillatory current in the wave meter depends on the magnitude of the direct current through the buzzer, this last should be of low resistance, about two or three ohms. Where great steadiness of high frequency current is desired for measurement purposes, the small high-pitch buzzers manufactured by the Eriksson Telephone Co., have proved especially satisfactory.

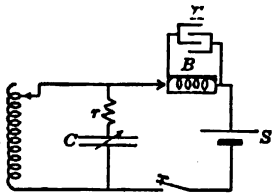

FIG. 101.—Buzzer-driven wave meter.

**314. Measurement of logarithmic decrement.** This measurement is of great importance since it makes possible the determination of the equivalent resistance of the circuits under consideration, and also gives information concerning the lengths of the wave trains. The value of the sum of the decrements of two circuits may be obtained from their resonance curve (Fig. 100).

According to the theory of coupled circuits,*

$$\delta_1 + \delta_2 = \pi\frac{C_m - C}{C_m}\sqrt{\frac{I^2}{I_m^2 - I^2}} \qquad (23$$

where $\delta_1$ is the decrement of the unknown circuit, $\delta_2$ that of the wave meter, $C_m$ the reading of the wave meter condenser for resonance, and $C$ any other condenser setting. $I_m$ is the corresponding current in the wave meter for resonance and $I$ for the setting $C$. If great accuracy in the determination is not desired, the formula becomes much simplified if instead of plotting a com-

* Fleming, J. "Principles of Electric Wave Telegraphy," p. 212.

Digitized by Google

plete resonance curve, the setting $C$ of the condenser is so chosen that $I^2 = 0.5I^2_m$. The quantity under the radical becomes equal to unity and

$$\delta_1 + \delta_2 = \pi \frac{C_m - C}{C_m}. \tag{24}$$

If the decrement of the wave-meter circuit is known or can be calculated from the formula $\delta = R/2nL$, the decrement of the other circuit is at once obtained.

Experiments show that sharp tuning is impracticable when a sending station emits wave trains containing less than thirteen complete oscillations before the amplitude falls to one-tenth. This corresponds approximately to a decrement of 0.2. See Par. **293**. This is the highest sending decrement that is permitted by the United States wireless regulations.

**315. For the determination of small equivalent resistances** in high-frequency circuits, a method of substitution is generally more accurate than the decrement method just mentioned. For instance, the equivalent resistance of a Leyden jar* is best obtained by substituting for the Leyden jar an air condenser theoretically free from resistance and of the same capacity as the jar, with sufficient known fine-wire resistance in series with it so that the current in the circuit is the same as when the Leyden jar was used. The limiting sizes of resistance wire for which the high-frequency resistance is the same as the direct-current resistance are given in Par. **316**. If the high-frequency resistance of an inductance is desired, the only simple method is to substitute for the unknown inductance† an inductance of known resistance and introduce enough non-inductive fine-wire resistance to produce the same high-frequency current in the circuit.

**316. Table of wire sizes**
**For which the high-frequency resistance will be less than 1 per cent. greater than direct-current resistance**

| Wave length (m.) | Constantan or advance wire | | Manganin diameter (mm.) | Platinum diameter (mm.) | Copper diameter (mm.) |
|---|---|---|---|---|---|
| | Diameter (mm.) | Maximum current (amp.) | | | |
| 100 | 0.30 | 3.5 | 0.29 | 0.13 | 0.006 |
| 200 | 0.46 | 4.5 | 0.40 | 0.20 | 0.045 |
| 300 | 0.57 | 5.5 | 0.50 | 0.27 | 0.09 |

| 1,000 | 1.10 | 11.5 | 0.99 | 0.50 | 0.21 |
| 1,200 | 1.20 | 12.5 | 1.10 | 0.57 | 0.22 |
| 1,500 | 1.30 | 14.0 | 1.21 | 0.63 | 0.26 |
| 2,000 | 1.52 | 17.0 | 1.38 | 0.73 | 0.30 |
| 3,000 | 1.80 | 24.0 | 1.62 | 0.80 | 0.33 |

*Journ.* Wash. Acad., Vol. II, p. 112; 1912.

**317. High-frequency voltage.** If the root-mean-square voltage is desired a static voltmeter is employed. The voltage which is ordinarily required is however the maximum voltage, since it is on this that the necessary insulation depends. This is best obtained by measuring the sparking distance between needle points or spheres placed in parallel with the part of the apparatus over which the voltage is desired. The table in Par. **318** shows the relation between sparking distance and maximum volts for brass spheres 2 cm. in diameter.

## MISCELLANEOUS APPLICATIONS OF ELECTRICITY

### ELECTRIC SHOCK AND RESUSCITATION

**1. Report of Commission on Resuscitation from Electric Shock.** The rules for resuscitation of victims of electric shock, as set forth in Par. **2**, **3** and **4**, were recommended in 1912 by the Commission on Resuscitation from Electric Shock, in the report tendered to the National Electric Light Association. This commission, under the chairmanship of Dr. W. B. Cannon of Harvard University, represented the American Medical Association, the American Institute of Electrical Engineers and the National Electric Light Association. The rules are here reproduced verbatim in Par. **2**, **3** and **4** by permission of the latter organization; copies of the rules can be had at a very nominal cost by application to the Secretary, 29 West 39 St., New York. Also see "Report of Committee on Accident Prevention;" Trans. N. E. L. A., June, 1914, Thirty-seventh Convention; pp. 630–654.

*An important note accompanying the rules states that the prone-pressure method of artificial respiration described (Sec. III below) is equally applicable after clearing the mouth of froth, to resuscitation of the drowned, and also to cases of suspended respiration due to inhalation of gases or to other causes.*

**2. Treatment for electric shock.*** An accidental electric shock usually does not kill at once, but may only stun the victim and for a while stop his breathing.

The shock is not likely to be immediately fatal, because:

(a) The conductors may make only a brief and imperfect contact with the body.

(b) The skin, unless it is wet, offers high resistance to the current.

Hope of restoring the victim lies in prompt and continued use of artificial respiration. The reasons for this statement are:

(a) The body continuously depends on an exchange of air, as shown by the fact that we must breathe in and out about fifteen times a minute.

(b) If the body is not thus repeatedly supplied with air, suffocation occurs.

(c) Persons whose breathing has been stopped by electric shock have been reported restored after artificial respiration has been continued for approximately 2 hr.

**The Schaefer or "prone pressure" method** of artificial respiration, slightly modified, is illustrated and described in the following resuscitation rules. The advantages of this method are:

(a) Easy performance; little muscular exertion is required.

(b) Larger ventilation of the lungs than by the supine method.

(c) Simplicity; the operator makes no complex motions and readily learns the method on first trial.

(d) No trouble from the tongue falling back into the air passage.

(e) No risk of injury to the liver or ribs if the method is executed with proper care.

*Aid can be rendered best by one who has studied the rules and has learned them by practice on a volunteer subject.*

**3. Instructions for resuscitation. Follow these instructions even if victim appears dead.**

#### I.—BREAK THE CIRCUIT IMMEDIATELY

(a) With a single quick motion separate the victim from the live conductor. In so doing avoid receiving a shock yourself. Many have, by their carelessness, received injury in trying to disconnect victims of shock from live conductors.

---

Digitized by Google

### OBSERVE THE FOLLOWING PRECAUTIONS

(a) Use a dry coat, a dry rope, a dry stick or board, or any other *dry non-conductor* to move either the victim or the wire, so as to break the electrical contact. Beware of using metal or any moist material. The victim's loose clothing, if dry, may be used to pull him away; do not touch the soles or heels of his shoes while he remains in contact—the nails are dangerous.

(b) If the body must be touched by your hands, be sure to cover them with rubber gloves, mackintosh, rubber sheeting or dry cloth; or stand on a dry board or on some other dry insulating surface. If possible, use only *one* hand.

If the victim is conducting the current to ground, and is convulsively clutching the live conductor, it may be easier to shut off the current by lifting him than by laying him on the ground and trying to break his grasp.

(c) Open the nearest switch, if that is the quickest way to break the circuit.

(d) If necessary to cut a live wire, use an ax or a hatchet with a dry wooden handle, or properly insulated pliers.

### II.—SEND FOR THE NEAREST DOCTOR

This should be done without a moment's delay, as soon as the accident occurs, and while the victim is being removed from the conductor.

### III.—ATTEND INSTANTLY TO VICTIM'S BREATHING

(a) As soon as the victim is clear of the live conductor, quickly feel with your finger in his mouth and throat and remove any foreign body (tobacco, false teeth, etc.). Then begin artificial respiration at once. Do not stop to loosen the patient's clothing; *every moment of delay is serious.*

(b) Lay the subject on his belly, with arms extended as straight forward as possible, and with face to one side, so that the nose and mouth are free for breathing (see Fig. 1). Let an assistant draw forward the subject's tongue.

FIG. 1.—Inspiration; pressure off.

If possible, avoid so laying the subject that any burned places are pressed upon.

Do not permit bystanders to crowd about and shut off fresh air.

(c) Kneel straddling the subject's thighs and facing his head; put the palms of your hands on the loins (on the muscles of the small of the back), with thumbs nearly touching each other, and with fingers spread over the lowest ribs (see Fig. 1).

FIG. 2.—Expiration; pressure on.

(d) With arms held straight, swing forward slowly so that the weight of your body is gradually brought to bear upon the subject (see Fig. 2). This operation, which should take from two to three seconds, *must not be violent*—internal organs may be injured. The lower part of the chest and also the abdomen are thus compressed, and air is forced out of the lungs.

(e) Now *immediately* swing backward so as to remove the pressure, but leave your hands in place, thus returning to the position shown in Fig. 1

Digitized by Google

Through their elasticity, the chest walls expand and the lungs are thus supplied with fresh air.

(f) After 2 sec. swing forward again. Thus repeat deliberately twelve to fifteen times a minute the double movement of compression and release—a complete respiration in 4 or 5 sec. If a watch or a clock is not visible, follow the natural rate of your own deep breathing—swinging forward with each expiration, and backward with each inspiration.

While this is being done, an assistant should loosen any tight clothing about the subject's neck, chest, or waist.

(g) Continue artificial respiration (if necessary, 2 hr. or longer), *without interruption*, until natural breathing is restored, or until a physician arrives. Even after natural breathing begins, carefully watch that it continues. If it stops, start artificial respiration again.

During the period of operation, keep the subject warm by applying a proper covering and by laying beside his body bottles or rubber bags filled with *warm* (not hot) water. The attention to keeping the subject warm should be given by an assistant or assistants.

(h) *Do not give any liquids whatever by mouth until the subject is fully conscious.*

**4. First care of burns.** When natural respiration has been restored, burns, if serious, should be attended to until a doctor comes.

A raw or blistered surface should be protected from the air. If clothing sticks, do not peel it off—cut around it. The adherent cloth, or a dressing of cotton or other soft material applied to the burned surface, should be saturated with picric acid (0.5 per cent.). If this is not at hand, use a solution of baking soda (one teaspoonful to a pint of water), or the wound may be coated with a paste of flour and water. Or it may be protected with a heavy oil, such as machine oil, transformer oil, vaseline, linseed, carron or olive oil. Cover the dressing with cotton, gauze, lint, clean waste, clean handkerchiefs, or other soft cloth, held lightly in place by a bandage.

The same coverings should be lightly bandaged over a dry, charred burn, but without wetting the burned region or applying oil to it.

Do not open blisters.

**5. Physiology.** Victims of severe electric shock may suffer from a cessation of natural breathing or from an impairment of their heart action. In cases where the latter condition amounts to a complete stoppage of the regular expansion and contraction of the heart, and where the organ merely fibrillates or quivers there appears at present to be no adequate relief, and death follows speedily. It is, however, extremely difficult to discriminate accurately between the fibrillating heart and one in which the action has been greatly diminished; in the latter case some method of artificial respiration may prove successful, hence the correct assumption in all cases should be the safe one, and alleviatory measures should be undertaken.

Artificial respiration may be successful in cases of suspended respiration, and also in cases of impaired heart action. The weakened heart detracts from an already impaired respiration and may completely annul it. In turn, the absence of breathing reacts upon the heart and completely quells its feeble beating. If, through any combination of these two factors, the brain cells are deprived of oxygen for longer than 10 min., recovery is impossible in almost all cases, hence the necessity for speedy action.

**6. Choice of Schaefer method of artificial respiration.** The Schaefer method was chosen as a result of experiments which were performed upon living subjects and upon completely curarised animals. To approximate the toneless condition of unconscious persons, the test subjects were put in a state of apnœa following a period of enforced breathing which lasted several minutes. Experiments to determine the elasticity of the toneless body were made upon cadavers. It was also found that the Schaefer method is greatly improved by the extension of the subjects' arms forward.

**7. Mechanical respiratory devices** now upon the market, operate by oxygen pressure, the inspiration being made under pressure and the expiration being accomplished by suction. The inspiratory gas may be either pure oxygen or a mixture of oxygen and air.

**8. The pulmotor*** differs from other types of commercial apparatus in

* Report of Committee on Resuscitation from Mine Gases; Technical Paper 77, U. S. Bureau of Mines, 1914.

Digitized by Google

hat the reversals of respiratory flow are controlled by the mechanism of the strument. It consists of a closely fitting face mask, a source of oxygen nd the reversing mechanism. It is so constructed that inspiration ceases hen the entering gas encounters sufficient resistance to cause the mechanism reverse and expiration to begin. This reversal is intended to result from e resistance due to completely filled organs of respiration.

Records of cases in which the pulmotor has been used are not convincing hat it is superior to or even the peer of the Schaefer method, properly applied. is claimed that two factors interfere with its successful use. In the first lace, as the reversal of respiratory flow is controlled automatically, there no assurance that inspiration may not be changed to expiration too soon, s the result of obstructions in the air passages which act upon the reversing echanism before a complete ventilation has taken place. It is possible to vercome this defect by manually controlling the operating mechanism and hus extending the inspiration to the proper limit. The second factor observed in connection with expiration by suction. The finer bronchi- les are provided with no cartilages to stiffen them, and when air is aaked from the trachea and from the larger bronchi, these bronchioles are kely to close before air can be drawn through them from the alveoli. urthermore, during the process of suction, the walls of the bronchioles and lveoli may collapse and stick together, rendering the subsequent inspiration ore difficult, and further decreasing the ventilation. The escape of air to the stomach has been observed to cause movements of the thorax which losely simulate respiration, while actually no air enters or leaves the ronchial tree.

**9. Pharyngeal insufflation*** is a method of mechanically applied rtificial respiration which has been recommended by the Commission on esuscitation as a satisfactory supplement to the prone-pressure (Schaefer) nethod in cases of suspended respiration. Inspiratory air enters through a ube inserted in the pharynx, and so constructed as to conform to the human natomy in order to prevent the escape of air through the mouth and nasal assages. An oxygen tank or a pair of foot bellows supplies the necessary ressure, and reversals of respiration are controlled by the operation of a espiratory valve, which can be conveniently held and operated with one and. This valve is essentially a three-way cock which, when the valve s in one position, will furnish communication between the source of pressure nd the pharyngeal tube, and when in another position, will allow a free xpiration to the atmosphere while the pressure lead is shut. In case a pecially constructed pharyngeal tube is not available, it is possible to use a lose-fitting mask, provided with a tube for connection to the valve. Air s prevented from entering the stomach by placing a heavy weight upon the bdomen; this may be reinforced by a belt, though a belt alone should not be lepended upon. A weight upon the abdomen may likewise render good ervice to a failing circulation by increase of blood pressure. In cases where t is found impracticable to use weights, the air may be drained from the tomach through a tube which furnishes communication between the stomach nd the outside air. This stomach tube passes through the pharyngeal ube, but interferes in no way with the process of insufflation. This machine s light and can be constructed at relatively small expense.

**10. Current tolerance of the human body.** It was announced many ears ago by Tesla, Elihu Thompson and D'Arsonval, that alternating currents f high frequency produced little sensation when passed through the human ody, compared with alternating currents of low frequency and equal trength. Tests have been made to determine the "tolerance current" of arious individuals at several frequencies. The tolerance current was rbitrarily assumed as the limiting current strength which the subject could take through his arms and body, without marked discomfort or distress.

It was found that for each individual, there is a marked increase of current trength which may be tolerated, as the frequency is increased from 11,000 o 100,000 cycles per sec. A man can tolerate only about 30 milliamperes t 11,000 cycles per sec. but can tolerate nearly half an ampere at 100,000 ycles per sec.† Although the tolerance current was found to increase

* See *Journal of American Medical Association*, 1913, Vol. LX, p. 1407.

Digitized by Google

very rapidly above 11,000 cycles per sec., the increase between 60 cycles and 11,000 cycles was much less rapid, ranging from about 5 milliamperes at 60 cycles to 30 milliamperes at 11,000 cycles.

## ELECTRIC HEATING AND COOKING

BY W. S. HADAWAY, JR.

*Electric Heating Engineer, Fellow, Amer. Inst. of Elec. Eng.*

**11. Field of application.** Electric heating apparatus is extremely economical of heat, producing it at the point and rate desired. Therefore electric heating is especially adapted to application in those places where heat is to be localized for a certain purpose, such as cooking, welding, industrial work, etc. When electric energy costs from $0.03 to $0.05 per kw-hr., it can compete with gas at from $1.00 to $1.50 per 1,000 cu. ft.

In those places where cost is a relatively unimportant item in comparison with convenience, such as on board ship, in street cars, sick rooms, etc., electricity can properly be used for heating rooms.

**12. Heat generation.** There are three common methods of converting electrical energy into heat; which are as follows: (a) the electric arc, which is used to obtain extremely high temperatures such as are required in furnaces; (b) the passage of an electric current through a resistor which is used in the construction of medium-temperature and low-temperature appliances such as the domestic heating devices; (c) the induction type of heater, used widely in electric welding machines, where the metal to be welded is the secondary, and also used in high-temperature furnaces.

**13. Heat transfer.** Heat energy lost by a body is expended by radiation convection and conduction.

**14. Radiation.** Radiated heat is transmitted or projected in straight lines from the radiator to any object at a lower temperature, without the intervention of matter. Thus the heat from the sun is radiated to the earth through the ether.

The quantity of heat radiated from a body is dependent upon the following: (a) the smoothness of the heated surface; (b) the form of the surface, such as flat, corrugated, etc.; (c) the location of the heated surface; (d) the temperature difference between the heated surface and the surrounding air.

**15. Coefficients of radiation.** The following table gives the radiation coefficients $K$ for various surfaces as established by Peclet. The general formula for loss of heat by radiation is:

$$\text{B.t.u.} = KN(T - T_1) \qquad (1)$$

where $K$ = radiation coef., $N$ = number of sq. ft. radiating surface, and $(T - T_1)$ = temperature difference in degrees fahr. This formula holds only for small differences of temperature.

Values of $K$

| Surface | B.t.u. per deg. Fahr. per sq. ft. per hr. | Surface | B.t.u. per deg. Fahr. per sq. ft. per hr. |

**16. Radiation between bodies of widely differing temperatures.** The table in Par. **15** is true only for differences in temperature not more than 10 deg. Fahr. (5.6 deg. cent.). For greater differences in temperature, a variable coefficient $K_1$, given in the following table, is used in the formula:

$$\text{B.t.u.} = K_1 K.N.(T - T_1) \qquad (2)$$

Digitized by Google

| Values of $K$ | | | | | |

| 150 | 1.57 | 300 | 2.27 | 450 | 3.50 |

**17. Convection.** Heat transfer from a body by convection is a form of conduction in which the heat is absorbed and carried away by the surrounding medium, which is in motion. Convected heat is mainly influenced by the following conditions: (a) the velocity of the passing air; (b) the extent of the friction between the body and the air, due to the surface condition; (c) the temperature difference between the air and the heated surface; (d) the location of the heated surface, whether at the top, bottom or side of the body.

**18. Conduction** of heat is simply the transference of heat through matter without visible molecular motion. Conduction of heat is comparable to the transmission of electric current through a conductor, under the following assumptions: (a) that the temperature difference is similar to the difference of potential; (b) that thermal resistance is similar to electric resistance. With these assumptions, the thermal resistance may be expressed as follows:

$$\frac{L}{\lambda_t A} \tag{3}$$

Where $L$ is the length of path, $A$ is the cross-section and $\lambda_t$ the thermal conductivity. For a table of thermal conductivities of various substances, see Sec. 4. The flow of heat which a given temperature difference will establish through a given thermal resistance equals the difference in temperature divided by the thermal resistance.

**19. Resistors.** One of the essential qualifications necessary in heating apparatus is that the operation of the electric heater be as rapid as possible. In this manner the losses are reduced and appliances of the highest efficiency and lowest operating cost are obtained. New resistance materials available in recent years have aided this development materially, in the respect that the alloys can be rated much higher, and thus answer the requirements of good, high-duty resistors.

These requirements may be stated as follows: (a) no oxidation; (b) high melting point; (c) high specific resistance; (d) low temperature coefficient of resistance; (e) no deterioration or aging due to repeated heating and cooling; (f) uniformity of cross-section; (g) freedom from impurities.

**20. The resistors most widely used at the present time** by manufacturers of heating devices, are comprised of nickel-chromium alloys (Sec. 4). These not only satisfy the requirements of withstanding oxidation and high specific resistance, but can be operated safely at high temperatures and without danger of burning out the unit. The German silver resistors become brittle after repeated heating and cooling. Copper-nickel is still used for low-temperature work. The materials of nickel steel oxidize in the open air, and are only used when protected by special cements or enamels.

Digitized by Google

**21. Electrical insulation.** The best form of insulation that can be used in the construction of electric heating devices is mica (Sec. 4). This is true because mica can withstand high temperatures better than any other material. The high cost of clear mica, however, has resulted in some cases in the use of micanite, sheet asbestos, special cements and enamels to advantage.

Among the insulators suitable for such high temperatures as are required in furnace work are, chalk, soapstone, lava, fire clay and quarts. Soapstone is one of the oldest insulators used in electric heating devices.

**22. Construction of resistor units.** There is no one type of the resistor unit adaptable to all forms of construction, so that a number of good constructions are at present in use. These are as follows: (a) exposed coils of wire or ribbon open to air and wound around insulating material; (b) wire or ribbon in form of coils or flat layers embedded in enamel, asbestos, cements, soapstone, mica and other non-conductors; (c) film of metal, fired on enamel, glass or mica; (d) metallic powder mixed with clay and compressed in forms, and crystallized silicon in tubes of glass; (e) incandescent filaments in vacuum.

**23. Room heating.** An empirical formula for energy required in rooms heated electrically (black-body radiation) is stated as follows:

$$\text{Watts} = \frac{\text{B.t.u. per hr.}}{3.41} = \frac{2.71\,(T - T_1)\,N}{3.41} \qquad (4)$$

where $T - T_1$ is the temperature difference in deg. Fahr. between the heated surface and the room, and $N$ is the number of square feet of radiating surface. One watt-hour (3.41 B.t.u.) will raise the temperature of 1 sq. ft. of common radiator surface approximately 1.26 deg. Fahr. (0.70 deg. Cent.).

**24. Car heating and ventilation.** The modern city cars with closed vestibules, tight window sashes, etc., so restrict the leakage of air that some means of artificial ventilation is highly desirable, especially in cases where heavy traffic is combined with low speed. Cars running at high speed can maintain sufficient ventilation through openings of moderate size. In 1909 the Chicago Board of Health carried out a series of experiments with various commercial systems of car ventilation and, as a result, the following standard requirements were formulated.

At least 38,000 cu. ft. of air per hr. must be supplied to each car. This air must enter at or near the floor line from as many points as possible, primarily to give a proper distribution, and also to prevent drafts. This air must be heated as it enters the car, and the foul air must be removed at or near the ceiling and from as many points as possible. The temperature in the car shall not be over 52 deg. Fahr. A temperature of 41 to 45 deg. Fahr. is considered high enough, as the passengers have on heavy clothing and overcoats. Some heat is required, however, because if the air is not warmed upon entering, it will be more readily noticeable as a draft, and as the passengers are not exercising, they will require a somewhat higher temperature than if they were walking in the outdoor air.

Assuming that a large pay-as-you-enter car is heated to 52 deg. Fahr. when the outside temperature is 0 deg. Fahr. it will radiate about 18,300 B.t.u. per hr. from the sides, floor and roof. One hundred passengers will generate 38,000 B.t.u. Subtracting from this the 18,300 B.t.u. radiated, it will be seen that the passengers will not only make up the heat radiated from the car, but will contribute 19,700 B.t.u. toward the heating of fresh air. If 38,000 cu. ft. of air are taken in at 0 deg. Fahr. 34,544 B.t.u. are required to raise its temperature to 52 deg. Fahr. Subtracting the 19,700 B.t.u. furnished by the passengers leaves 14,844 B.t.u. per hr., or about 4.3 kw-hr., as the amount of heat energy required to be furnished by resistance coils. Thus the cost of heating the car would be 6.4 cents per hr. assuming that energy costs 1.5 cents per kw-hr. at the car.

**25. Power Required to Heat Cars**

| Car length, ft... | 14 to 16 | 18 to 22 | 22 to 26 | 28 to 32 | 36 to 40 |
|---|---|---|---|---|---|
| Power, kw..... | 3.5 to 4 | 4 to 5 | 5 to 6 | 6 to 8 | 9 to 10.5 |

NOTE.—These figures represent the maximum power with heater switch "full on," and under average service in a latitude about like New York. The higher values of power apply to high-speed suburban roads.

**26. Heat Given off by the Human Body**

| | Authority | B.t.u. per hr. | | Authority | B.t.u per hr. |
|---|---|---|---|---|---|
| Infant | Rubner | 63 | Child 6 years | Barrel | 240 |
| Adult at rest | Rubner | 380 | Man 29 years of age in atmosphere whose temp. is 31 deg. Fahr. | Barrel | 610 |
| Adult at medium hard work | Rubner | 470 | Same, temp. 68 deg. Fahr. | Barrel | 440 |
| Adult at medium hard work | Rubner | 550 | Man, 59 years | Barrel | 510 |
| Adult in old age | Rubner | 360 | Woman, 32 years | Barrel | 480 |

Petten Kofer states that the mean heat radiated from an adult at 70 deg. Fahr. is 400 B.t.u. per hr., and 200 B.t.u. from a child.

**27. Advantages of electric heating.** The general advantages gained by electric heating are as follows: (a) the elimination of explosion and fire risk; (b) the absence of smoke and fumes; (c) the ease of variation, exact duplication and control of temperature; (d) the localization of heat where desired. These advantages result in a reduction of insurance rates, better working conditions, and a superior product.

**28. Cost of operating heating devices.** The cost depends entirely on two variables each of which has a wide range; first, the unit cost of energy, which is determined by local conditions; second, the efficiency of the apparatus, which depends upon its design.

The following results are given as the comparative charges for gas and electric cooking:

| | Elec. per kw-hr. | Gas per 1,000 cu. ft. |
|---|---|---|
| R. Borlase Matthews; Oct. 6, 1911; *Elec. Rev.*, London | $0.033 | $1.00 |
| W. R. Cooper; Inst. of Elec. Eng., Nov. 26, 1908 | 0.03 | 1.00 |
| Heating Committee; Ass'n. of Edison Illum. Co. (Sept., '07) | 0.025 | 1.00 |
| James I. Ayer; N. E. L. A. Report, May, 1904 | 0.0227 | 1.00 |

**29. A general rule for cooking** is to allow one-third kw-hr. per person per meal. The following table shows the result of comparative experiments on the cost of electric cooking for three persons extending over a period of three months, by W. R. Cooper, Institution of Electrical Engineers, September 25, 1908.

| Period 1901 | Kw-hr. | |
|---|---|---|
| | For one month | Per day |
| March 22–April 22 | 67.04 | 2.24 |
| May 1–May 31 | 63.55 | 2.19 |
| June 1–June 30 | 66.31 | 2.21 |

**30. Equipment of Hotel Moserboben.*** Boiler for soups and meats, a potato steamer and table range. Boiler—3 heats, 3 kw. capacity, 15 gal., boil water in 30 min. Potato steamer—1 kw. capacity, 10 gal., water jacket, 5 qt. water, boil water in 10 min. Table Range—4 plates, 12 in. diam., each 1.5 kw., 4 plates 8¼ in. diam., each 1 kw., total 11.2 kw. Large range—8 plates—2 roasting ovens, 3 kw. each, total 16.2 kw.

**33. Baking data.***
Electric Cooking and Heating in Hotels, *Electrician*, July 19, 1907.

| | Size oven, cu. in. | Lb. bread | Time, min. | Energy used |
|---|---|---|---|---|
| Gas | 6400 | 8 | 58 | 31 cu. ft. gas |
| Electricity | 6137 | 9 | 52 | 0.92 kw-hr. |

The United States Navy has adopted electric heating devices for cooking and baking on war-ships, finding that they are cheaper to operate, occupy less space, are cleaner, and give better results.

**34. Industrial heating.** In industrial trades, due to the large consumption of electricity, manufacturers can obtain a very favorable rate for electricity. In many industries it has been found cheaper to operate an isolated plant, using a dual system of exhaust steam and electric heating. The exhaust steam is used for low-temperature heating and electricity for high temperatures. In these isolated plants the cost per kw-hr. depends upon the load factor and the uses of exhaust steam, and varies from a minimum of less than 1 cent to approximately 2½ cents.

The following trades are using electrically heated devices on a large scale to advantage: hatting, laundry, newspaper, printing and publishing, candy, clothing, buttons and celluloid, paper-box, shoes, furniture, handkerchiefs, gloves, tin-can manufacturing, branding and many leather goods industries.

In many cases, even where the electricity charges are high, it has been proven that the total cost of production is cheaper by using electrically heated devices as compared with gas. The better working conditions, absence of exhaust gases, and control of temperature, have raised the efficiency of the workman and the machine, resulting in fewer products scrapped, and also, including rejected and accepted products, more articles produced per day.

## ELECTRIC WELDING

### BY OTIS ALLEN KENYON

*Consulting Electrical Engineer, Associate, American Institute of Electrical Engineers*

**44. There are three distinct processes of electric welding.** (a) the incandescent process; (b) the carbon arc process; (c) the metallic arc process.

### THOMPSON PROCESS

**45. Temperature distribution.** In making welds it is important that the temperature distribution over the face of the joint should be as uniform as possible. Alternating current assists in meeting these requirements as, on account of skin effect, the current density is greater near the surface than at the center, which tends to maintain an even temperature throughout the joint in spite of the radiation from the surface. On account of the necessity for uniform temperature distribution, it is impracticable to butt weld two pieces of different areas, as the smaller one will become much hotter than the large one. For this same reason it is also impractical to butt-weld large surfaces, as the current will not distribute itself uniformly over the section.

**46. The incandescent process (known as the Thompson process)** is primarily suited for manufacturing process where more or less standard welds are made. The principle of this process consists in connecting the joint to be welded in a low-potential alternating-current circuit and applying a definite mechanical pressure to the joint while the metal is at the welding temperature. The heating energy may be taken from any alternating-current system. The welding machine itself consists of suitable clamps for holding the pieces to be joined, and a means of applying pressure. The clamps, together with the joint, close the secondary circuit of a transformer, and these terminals are usually water cooled. Fig. 3 gives the average

Digitized by Google

power and time required to make welds of iron and steel by the incandescent process. It may be noted that the power in kilowatts and the time in seconds are numerically equal. Herman Lemp states that the energy required to bring iron to the welding temperature is approximately 7 h.p.-min. per cu. in. of metal.

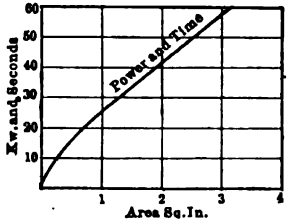

FIG. 3.—Power and time required to butt-weld iron rod by incandescent process.

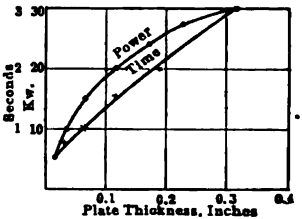

FIG. 4.—Power and time required to spot-weld steel plate by incandescent process.

**47. Spot welding.** To overcome the difficulties due to non-uniform temperature distribution, what is known as spot welding has been developed. Spot welding usually consists of punching the surfaces to be welded in such a way that a series of joints of equal and definite area are made between the two. Fig. 4 gives the average power and time required to make welds by the spot-weld process. Fig. 5 shows how a rod may be welded to a surface by this process; also how two flat surfaces may be welded together. The whole object of the spot-weld process is to reduce the welded joint to an area of definite and uniform dimensions.

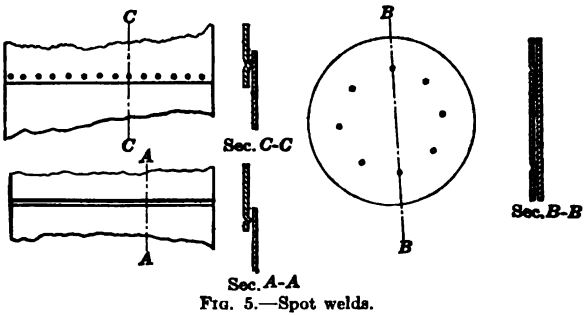

FIG. 5.—Spot welds.

A modification of the spot-weld principle is shown in the lower left-hand corner of Fig. 5 where instead of a series of spots we have a V-shaped depression in one of the plates which makes an edge contact with the plate to which it is welded. The current is then passed through the plate by means of a wheel which runs in the grove and exerts the necessary pressure for welding.

| 4.0 | 50,000 | 90 | 83.8 | 4,148 | 2.00 | 44,000 | 48 | 73.7 | 1947 | 1.000 | 49,000 | 23 | 82.1 | 1,039 |

NOTE.—The stock should be clamped in the machine so as to fulfil the following relations: Iron and steel: $l = 2d$; brass: $l = 3d$; copper: $l = 4d$, wherein $l$ is the distance between the inside face of the clamps and $d$ the diameter of the stock to be welded.

## CARBON-ARC PROCESS

### 49. Characteristics of Carbon Welding Arc

(C. B. Auel, Amer., Mach., Mar. 16, 1911)

| Arc length. (in.) | E.m.f. across arc and carbon (volts) | Current (amp.) | Length carbon (in.) |
|---|---|---|---|
| 6 | 101 | 300 | 1×6.5 |
| 5 | 98 | 350 | |
| 4 | 93 | 400 | |
| 3 | 86 | 605 | |
| 2 | 80 | 750 | |

Digitized by Google

**50. The carbon-arc (Bernardos) process** has been in use about 25 years. In this process the heat of the arc is utilised to bring the metals to be joined to the welding temperature, and a melt bar of the same material as the parts to be joined is introduced in the joint to fill the space between the pieces. (See Fig. 6.) In welding with a carbon arc, the parts to be joined are connected to the positive side of the circuit, and the carbon electrode to the negative side. A direct-current generator of about 125 volts and capable of furnishing 600 or 700 amperes is generally used. However, a constant-current generator with arrangements for varying the current from about 50 to 600 amperes is more economical. The carbon arc is long and behaves very much like a flame, therefore, it is necessary to manipulate it like a flame by giving it a circular motion, such as is done with the oxyacetylene flame.

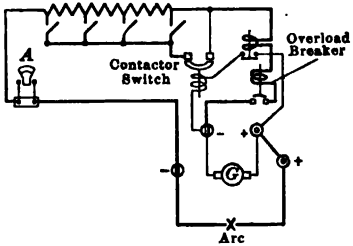

FIG. 6.—Connections for carbon-arc controller.

**51. Application.** The carbon-arc process is suited to work where large amounts of energy are to be developed in a short time, such as filling holes in castings and melting large masses of metal. As disadvantages the following may be mentioned: the likelihood of carbonization of the weld; the large area which is heated by the arc; the necessity for using both hands.

**52. Stresses due to temperature changes.** On account of the large area which is heated by the arc flame, it is necessary to exercise extreme care in order to avoid stresses and distortion due to temperature changes. Therefore, in many cases it is necessary to preheat the objects to be welded with a gas flame.

**53. Protection of operator.** The light and radiated heat of the arc are so intense that the skin and eyes must be protected. Therefore, since both hands are required to do the welding, it is necessary to provide the operator with a helmet; this helmet prevents him from examining the work carefully as it progresses.

**54. The carbon arc may be used for cutting steel,** such as sheet piling and structural steel of buildings, bridges, etc., which have to be cleared away. It can also be used for cutting cast iron.

**55. Continuous-current steel-cutting plant.** A plant used in San Francisco consisted of a 25-kw. continuous-current generator direct connected to a single-cylinder gasolene engine, both mounted on a truck. The operation required about 250 amp. at from 90 to 100 volts. A 15-in. I-beam was cut through in about 20 min., thus saving several hours' time.

**56. An alternating-current steel-cutting plant,** used in New York City obtained energy from a central station; four 20-kw. single-phase transformers were connected in multiple, the secondary e.m.f. being 50 volts. One side of the circuit was connected to the work by a wire bolted to the steel, while the other was connected directly to the carbon electrode. The carbon electrode is 1.25 in. in diameter and 0.75 in. long and is clamped between two copper plates each 5 in. square by 0.5 in. thick. A Dossert lug is used to make the connection, as a sweated joint is out of the question, because of the intense heat. As it is, the copper plates buckle after 15 hr., use and new ones must be provided. The operator must wear an asbestos mask and gloves to protect himself from the heat. The mask is fitted with double black glass goggles so as to permit the operator just to see the arc.

Tests on this plant show that it requires 650 amp. at 50 volts. In an 8-hr. day, 10 ft. of steel piling were cut (the cut varying in depth from 0.5 in. at the centre of a pile to 3.5 in. at the ends) the energy consumption being 256 kw-hr. Assuming energy costs $0.10 per kw-hr., it was found that this device saved over $10 per day, to say nothing of the value of the time gained.

Digitized by Google

**57. The arc can also be used for filling blow holes** in castings. The casting must first be heated to a dull red color in order to prevent the production of harmful stresses, then the arc is applied either by connecting one side of the circuit to the casting, or by deflecting against the casting, with a magnet, an arc formed between two carbons, the metal used to fill the holes being introduced in the arc.

## METALLIC-ARC PROCESS

**58. The metallic-arc (Slavianoff) process** was developed to avoid the introduction of carbon into the weld. In this process there is substituted for the carbon electrode an iron or steel pencil, which is melted by the arc and serves to fill the space between the pieces to be welded. The composition of the welding pencil is an important factor in determining the success of a weld. At present it is impossible to give specific information on this subject because those who have investigated it do not choose to reveal their results. However, the practice of those most successful, seems to be the employment of a commercially pure iron to which small percentages of other metals have been added, according to the character of the metal to be welded.

**59. Refractory-flux coating.** This process did not come into commercial use until the value of refractory-flux coatings on the welding pencil was discovered by Kjellberg in Sweden. In accordance with Kjellberg's invention the electrode or welding pencil is dipped in a paste containing suitable fluxing materials and a refractory base, and this mixture is then allowed to dry upon the electrode. The composition of welding fluxes is even more important than that of the pencils. Indeed in many cases it is possible to use commercially pure iron pencils and to insert the alloying metals in the flux. The composition of fluxes, like that of welding pencils, is jealously guarded by those who have investigated the subject.

The advantages of the refractory coating are: First, it applies the flux to the weld at a rate which adjusts itself perfectly to that of the melting of the welding pencil. Second, when welding overhead, it forms a tiny crucible which holds a small quantity of molten iron on the end of the pencil and allows the "pinch effect" (Sec. 19) of the current to squeeze the molten iron upward and into the weld.

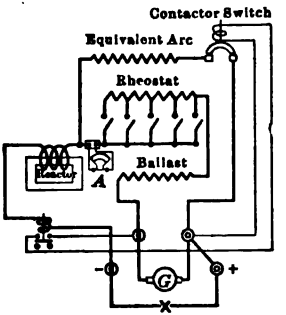

FIG. 7.—Metallic-arc controller for constant-potential generator. (The Elec. Weld. Co.)

**60. Equipment.** The metallic arc is short, varying from less than 0.125 in. to 0.187 in. and requires a pressure between 15 and 30 volts. The current depends upon the character of the work, varying from 50 amp. for light work to 170 amp. for very heavy work. The arc being short and of low voltage is very sensitive to changes in length; therefore it is desirable to design a welding circuit for a constant-current characteristic. In practice constant-potential generators of from 60 to 100 volts or more are used, the difference between the arc voltage and generator voltage being absorbed in rheostats. A single arc may be operated from a constant-current generator and the rheostats eliminated. However, if the generator is to furnish energy over a wide range of currents, rheostats must be provided for shunting the windings. Very recently there has been developed a constant-current machine, equipped with relays, which permits the operation of several arcs in series. This machine, as at present designed, meets the requirements of metallic-electrode welding and allows the adjustment of current from 60 amp. to 160 amp. without the use of heavy-current rheostats. When a constant-potential generator is used for welding (Fig. 7), any number of welders up to the capacity of the machine may draw energy from it. However, on account of the necessity of maintaining a suitable arc, it is necessary to connect a ballast resistance in series with each arc,

Digitized by Google

thus wasting at least 60 per cent. of the total energy. With the constant-current generators, no energy is thus wasted.

**61. Method of procedure.** In the metallic-arc process, the metals to be joined are clamped in position and connected to the positive side of the circuit. However, it is also possible, with a properly designed pencil, to weld satisfactorily with the pencil connected to the positive side. The edges of the joint are beveled (Fig. 8) either from one or both sides of the angle, the bevel being so chosen as to permit the insertion of the pencil to within less than 0.125 in. of the surface to be welded.

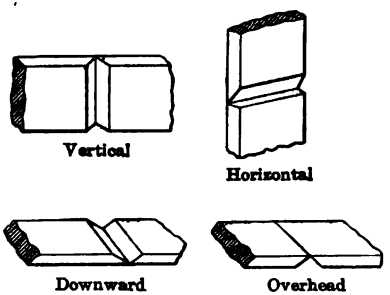

FIG. 8.—Conventional arc-welding positions.

**62. The cost of metallic-arc welding** includes the following factors: welding pencils, fluxes, labor, energy and fixed charges. In general it may be said that the pencils and fluxes should be about the same in a given case as the corresponding expense for the carbon-arc, and the oxy-acetylene processes. In all three cases the labor is skilled, and is paid at about the same rate. Therefore, the labor cost of welding depends on the speed

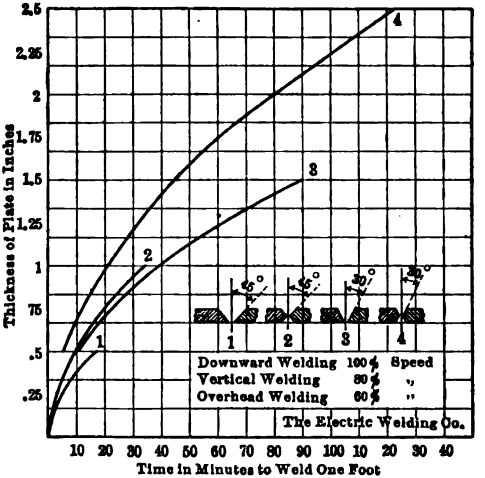

FIG. 9.—Time required to weld seams of various thicknesses by metallic-arc process.

(see Fig. 9). For thin plates, the oxy-acetylene process is faster than the electric arc. However, for sizes above 0.125 in. the arc is faster, therefore the labor item is less. The cost of energy depends on local conditions and can be accurately calculated for any given case from the data here given.

Digitized by Google

In comparing arc-welding costs with oxy-acetylene-welding costs, the cost of electric energy is balanced against that of oxygen and acetylene.

**63. Advantages.** The extreme localisation of heat in the metallic-arc process is an enormous advantage, especially where large masses of metal are concerned, as it minimizes stresses due to expansion and contraction with the practical result that preheating need not be resorted to nor must the joints be more open at one end than at the other to allow for expansion, as is the case with hot-flame and carbon-arc processes. Another advantage of the metallic arc is that the operator uses only one hand for welding, leaving the other free to manipulate a glass screen. This he holds before his face when the arc is on, and lowers each time the arc breaks in order that he may examine the work and closely control its quality.

**64. Strength of weld.** Experience shows that with a metallic arc, welds can be made in which the strength of the joint is the same as that of the metal itself and even greater. However, on account of inferior work that has been done by unskilled welders, engineers are inclined to avoid arc welding except in cases where it can be subjected to test before putting it into service. If some method of inspection could be developed whereby the quality of a finished joint could be determined without damaging it, welding would undoubtedly displace riveting in a great many structures, and thus an enormous saving in labor and materials be accomplished.

**65. Porosity test.** Wherever the character of a joint is suitable, its porousness may be tested by applying kerosene to one side. Kerosene will penetrate a porous joint that is so tight that water under high pressure could not penetrate it. In this way the soundness of welds may be tested and a really unsound weld will reveal itself under a few minutes' application of kerosene.

**66. Literature.** The May, 1913, *Bulletin* of the New York Public Library gives a list of works relating to electric welding, covering the period between 1786 and 1912, inclusive, comprising several hundred articles and books in English and foreign languages, as well as references to the most important patents.

## ELECTRICAL EQUIPMENT FOR GAS AUTOMOBILES

**BY JOHN C. BOGLE**

*Engineer, McMeen and Miller; Associate, Amer. Inst. Elec. Engineers*

### BATTERIES

**67. Type adaptable to requirements.** It is standard practice to employ the pasted-plate lead cell for gas-car service. The advantageous features of this type of cell are: economy of space and reduction of weight, together with a low internal resistance and the possibilities of discharge at a high rate for a short interval. The last-mentioned advantage obtains in the case of battery systems which include provisions for electric starting.

The battery should be of rigid construction, capable of withstanding the severe vibration to which it will be subjected in service. The outer box should be of excellent workmanship. It has been thought desirable, in some cases, to fill the space between the outer box and the inner jar with some yielding plastic or compound. Jars are constructed of hard rubber having relatively high tensile strength and some flexibility.

Plates are designed for least possible internal resistance and for maximum product of life and capacity. Separators of wood or hard rubber are usually inserted between adjacent plates; these should be perforated or otherwise so constructed that they will interpose no appreciable increase in internal resistance.

**68. Methods employed in charging.** If the battery system serves merely for ignition and car lighting, it is usual practice to charge the cells independent of the car equipment. If the car equipment includes electric starting devices, the battery will receive its charge from a direct-current generator in the car. Charging on removal from the car must be attended with precautions observed in connection with any battery (see Sec. 20). In addition, however, separate precautions should be observed in case the battery is to be left out of service for any considerable length of time. Under

Digitized by Google

these conditions it should receive attention and charge at least once a month. When the battery is to be put back into service it should first receive an overcharge for several hours at the normal rate.

**69. Freezing.** Care should be taken in cold weather to insure that the electrolyte is not allowed to freeze. Following is a table of freezing temperatures (deg. Fahr.) corresponding to various specific gravities. For reduction of battery capacity with decreasing temperatures, see Sec. 20.

| Specific gravity | Condition | Temperature |
|---|---|---|
| 1,290 deg. | Fully charged..... | − 100 deg. |
| 1,260 deg. | ¾ charged..... | − 60 deg. |
| 1,225 deg. | ½ charged..... | − 38 deg. |
| 1,160 deg. | ¼ charged..... | 0 deg. |
| 1,125 deg. | Completely discharged.. | + 13 deg. |

**70. Location in car.** The most desirable location, in point of accessibility, is upon the running board; however, in some of the larger ampere-hour capacities, this location cannot conveniently be maintained, and the battery is either slightly underhung or placed beneath the seat. By suitable arrangement of the rows of cells a variety of groupings may be secured, and the box fitted into an accessible place. Accessibility is highly important; otherwise, it is extremely doubtful whether the battery will receive proper attention.

**71. Choice of ampere-hour capacity** is influenced by the practical duties which devolve upon the battery. For use exclusively for car lighting, the problem is relatively simple and depends strictly upon the lamp load in amperes and the predetermined length of time allowed for burning lamps (Par. **88**). The capacity required for starting is discussed in Par. **77**.

**72. Ratings of lead batteries for lighting and for combined lighting and starting service.** The following is taken from the report of the Standards Committee, Society of Automobile Engineers, January, 1914.* "Lighting batteries shall be rated at the capacity in ampere-hours of the battery when discharged at a 5-amp. rate to a final voltage of 1.8 per cell, the temperature at the beginning of the charge being 80 deg. Fahr. Batteries for combined lighting and starting service shall have two ratings of which the first shall indicate the lighting ability and be the capacity in ampere-hours of the battery when discharged continuously at a 5-amp. rate to a final voltage of 1.8 per cell, the temperature of the battery beginning such charge being 80 deg. Fahr. The second rating shall indicate starting ability and shall be the rate in amperes at which the battery will discharge for 20 min. continuously to a final voltage of not less than 1.65 per cell. The temperature of the battery beginning such charge to be 80 deg. Fahr."

## ELECTRIC STARTERS

**73. Process of electric cranking.** The starting of gas-car engines by electric motors, depends for its success upon the possibilities of obtaining enormous current discharges from storage batteries, these discharges necessarily extending over as short a time as possible. When the battery current is applied, the electric motor armature transmits its motion to the fly-wheel or crank-shaft of the engine, rotating it in order to accomplish the requisites necessary for engine starting. These requisites include compression of gas in the cylinders, suction of fuel, and ignition.

In the early development of auto-starters, engine-starting speeds were as low as 24 rev. per min. At present, cranking speeds of 100 rev. per min. and some much higher are considered good practice. Such speeds are not realized if, under operating conditions, the battery voltage is low. Examples of capacities common with 6-volt systems may be cited; these battery sizes range from capacities of 80 to 160 amp-hr., figured on a 10-amp. discharge rate, and the majority of installations range from 100 to 120 amp-hr. capacity. These figures include provision for car lighting.

* *Trans.* Soc. Auto. Eng., Jan., 1914.

Digitized by Google

**74. Battery discharge rate during cranking.** From the curve of Fig. 10,* it will be seen that if a battery is discharged at the 20-min. rate, an amp-hr. capacity will be realized with an approximate value only 30 per cent. of that obtained at the normal 8-hr. discharge rate. This means that a battery with a normal rating of 120 amp-hr. will furnish only 36 amp-hr. if allowed to discharge completely in 20 min., and the current will be in the neighborhood of 110 amp. if maintained uniform throughout this period. Compare this figure with the result of a test, shown in Par. 76.

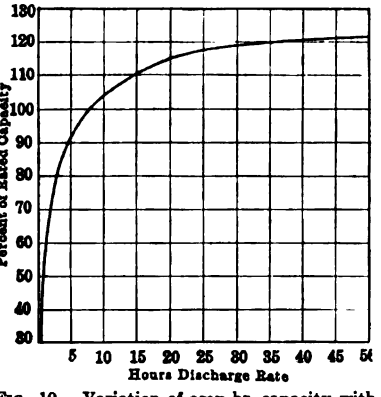

FIG. 10.—Variation of amp-hr. capacity with different discharge rates.

**75. The ampere "draw" during the cranking period** depends upon the operative voltage, the engine dimensions, the degree of compression, the number of cylinders, the friction, and upon certain exigencies such, for example, as obstruction in any part of the starting mechanism. The "draw" with 6-volt systems will usually be about 80 amp. for the lighter cars, and will not greatly exceed 140 amp. for the heaviest. Some 6-cylinder pleasure cars draw as high currents at starting as large 4-cylinder trucks. The proper value of ampere draw can only be determined accurately as the result of exhaustive tests, which take into consideration all possible rigors to which the equipment may be subjected in service.

**76. Typical starting-test data.**† Commercial starter turning dead engine of Model 36-B, Buick. A 6-volt, 120-amp-hr. (on 10-amp. discharge rate) battery was used. Car had been run about 2,000 miles, and engine was warm at time of test.

| Time | Volts per cell | Ampere draw | Rev. per min. | Specific gravity |
|---|---|---|---|---|
| 3:00 P.M. | 2.00 | 95 | 120 | 1300 |
| 3:05 P.M. | 1.99 | 91 | 116 | 1295 |
| 3:10 P.M. | 1.96 | 95 | 116 | 1280 |
| 3:15 P.M. | 1.93 | 97 | 116 | 1280 |
| 3:20 P.M. | 1.88 | 102 | 112 | 1275 |
| 3:25 P.M. | 1.84 | 103 | 112 | 1270 |
| 3:30 P.M. | 1.80 | 105 | 112 | 1265 |
| 3:35 P.M. | 1.72 | 110 | 112 | 1255 |
| 3:38 P.M. | 1.52 | 110 | 100 | 1250 |
| 3:39 P.M | Stopped | | | |

**77. Battery requirements for starting service.** A rough rule for battery requirements may be stated, namely: that the capacity of the battery in ampere-hours shall be numerically equal to the ampere draw necessary to turn the engine after it has once been started. This figure is suggestive of the S. A. E. rating for batteries (Par. 72).

**78. The momentary discharge rate at the instant of starting** is dependent on the **breakaway torque** of the engine, which consists chiefly of

* *The Automobile*, Feb. 6, 1913; page 421.
† Vesta Accumulator Co., April, 1914.

Digitized by Google

static friction and inertia. This current surge seldom exceeds from three to four times the ampere draw (Par. 75) except where sleeve-type engines are being started. In the latter case the momentary discharge will possibly be at a rate of eight times the ampere draw. It is to be doubted whether the momentary discharge rate will prove the determining factor in the choice of battery capacity, when all things are considered.

**79. Duration of the cranking period.** The specified 20-min. period (Par. 72) is for purposes of comparison, and, of course, is never met in service. The length of time required for starting is a function of the efficiency of carburation, the engine cranking speed, the number of cylinders, and the general good repair of the car. The following test was made in February, 1914, by the Royal Automobile Club, London, on a commercial starter operating at 24 volts.

The device was submitted for the test fitted to a 20-h.p. Ford car. The dimensions of the engine were 95 mm. × 102 mm. The volume swept by the piston was 723 cu. cm., and the cubical contents of the compression space was 209 cu. cm. The engine of the car was started, on six consecutive days, two hundred and fifty times per day.

| Day | No. of starts | Total time taken for starts |
|---|---|---|
| 1 | 250 | 13 min. 18 sec. |
| 2 | 250 | 11 min. 22 sec. |
| 3 | 250 | 13 min. 32 sec. |
| 4 | 250 | 11 min. 41 sec. |
| 5 | 250 | 11 min. 37 sec. |
| 6 | 250 | 11 min. 3 sec. |

The engine was switched off and was not run between starts. The first start each day (cold) took somewhat longer (a maximum of 14.4 sec.) than the others, which were practically instantaneous. At the close of every day the car was run for half an hour to charge the battery.

**80. An automatic cut-out** is provided for applying charging current to the battery when the generator speed has reached the charging value, and for disconnecting the generator from the battery when the speed falls below this value. Automatic cut-outs are usually adjusted to operate at car speeds of from 12 to 15 miles per hr.

The device is simply a reverse-current relay, taking several forms, one being illustrated in Fig. 11. The potential coil of this relay is connected permanently across the generator terminals, and when the generator has reached the predetermined voltage, the coil is sufficiently energized to close the relay contacts. Current then flows through the series winding of the relay to battery, strengthening the pull due to the potential winding. Should the generator slow down below the predetermined charging speed, the generator voltage will fall below the battery voltage and the reversed current in the series winding of the automatic cut-out will deenergise the core and allow the armature to drop away, thereby disconnecting the generator from the battery.

The cut-out is not for the purpose of opening the circuit when the battery is fully charged and the engine still continues to run. Indeed, in the operation of gas cars it will not be necessary to provide equipment for performing this operation, as it will be found almost impossible to charge the battery continuously at a high rate, because the car will seldom travel at high speeds for intervals of any appreciable duration.

**81. An overrunning clutch** is provided to transmit the motion of the starting motor to the crank-shaft, and to prevent the transmission of crank-shaft motion to the starting motor when the engine is running under its own power or is being cranked by hand.

**82. Charging control.** The rapid development of the electric starter during the years 1913 and 1914 has been due to a sudden demand made by the public for this auxiliary. Chief among the problems has been the application of a simple, efficacious device to insure satisfactory rate of charge. It should be understood that one of the main factors governing design has been the technical ignorance of the ultimate user. Thus we have a storage battery subjected to extraordinary service and in the hands of an operator wholly unversed in proper battery maintenance.

Digitized by Google

One of the first automatic controllers was the so-called speed governor. This was in reality a centrifugally operated clutch connecting the generator element with the engine driving it, and so arranged that at the higher speeds the fly-balls would relieve the frictional adhesion between parallel surfaces, and the slippage, thus automatically adjusted, would maintain a constant generator speed and potential. The speed governor is in disfavor at the time of this writing (March, 1915), due to its rapid depreciation in service.

Another class of charging controllers includes those employing a vibratory contact, connected as a recurrent shunt on the generator field rheostat; in other systems, the vibrator has been used to shunt the magnetic circuit or to oppose to the main field flux the counter magnetomotive force of a differential winding; any of these methods operates by varying the effective flux threading the armature.

The present tendency seems to be toward a reduction of the number of moving parts. There are several starters on the market which limit the charging current either by a differential field compounding or a correctly

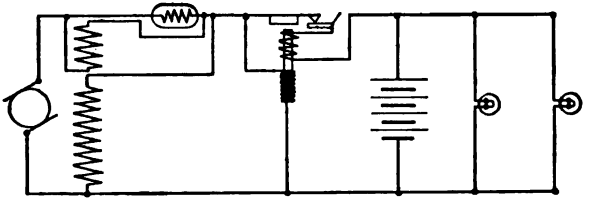

FIG. 11.—Typical charging controller and automatic cut-out.

gaged armature reaction. A starter of this class is illustrated in **Fig.** 11. Here a ballast coil or series resistance of iron wire is inserted in one of the leads from the generator. The shunt field is connected outside the ballast coil, and a differential field is shunted across the ballast coil. The effect of the differential compounding is to limit the field strength and the charging current.

**83. Constant charging current vs. constant potential.** If constant charging current is maintained, the generator voltage will have to increase slowly as the charge progresses, in order to overcome the rising e.m.f. of the battery. The resultant variation of generator voltage is objectionable, however, because it shortens the life of the lamps; it is not considered practicable to employ a lamp regulator such as may be found in train-lighting systems (Par. **298**), because of the added complexity.

If constant generator voltage is maintained, the battery charge will be a tapering one, since the battery e.m.f. ranges from 1.7 volts per cell at com plete discharge to 2.2 volts per cell at full charge. Necessarily the charging current will be excessive when the battery is exhausted; the discharge may be excessive at times, also, and the combined effects are likely to shorten the life of the cells.

**84. Grounded and ungrounded systems.** The wiring of electric apparatus on gas cars should be as simple as possible in order not to confuse the operator who is presumed to be unversed in electric circuits. To carry this idea further, some manufacturers utilize the metal framework of the car as a ground return. Though the simplicity of this arrangement presents an obvious advantage, the difficulty of maintaining a multiplicity of ground connections militates against such practice in the judgement of some manufacturers who prefer the use of the two-wire system.

**85. Single-unit, two-unit, and three-unit systems.** As in all rapidly developing arts, competition allows no standardization of operating method. In order that each system may have distinctive design, the manufacturers of starters approach a common objective from widely differing directions. One point of differentiation lies in the number of rotational

Digitized by Google

units employed in the processes of battery charging, engine starting and ignition. Some systems embrace a motor for starting, a separate generator for battery charging, and a high-tension magneto (Par. 90) for ignition purposes; these are known as "three-unit systems." An arrangement comprising a starting motor, a separate generator, and some form of battery ignition is termed a "two-unit system" (Fig. 12).

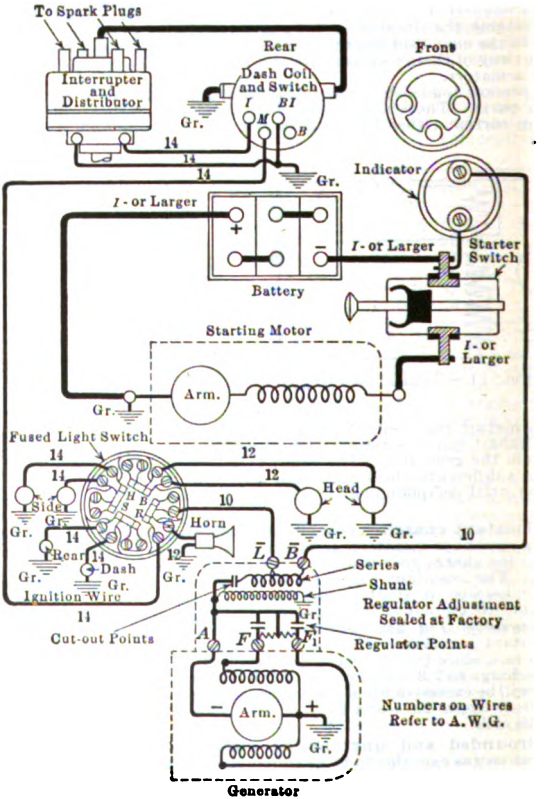

FIG. 12.—Grounded two-unit 6-volt system.

Several manufacturers have built starting systems where but one rotating unit is employed for battery charging and engine starting. The machines used for this service often possess somewhat unique windings. In several instances, two armature windings are employed, one for motor duty and the other for generator duty. Another more recent starter provides a single

Digitized by Google

unit equipped with two commutators; these commutators are connected in series for charging and in parallel when the machine is operating as a motor.

The wiring connections of a typical single-unit system are shown in Fig. 13.

The mechanical construction of the several units should be such as to demand little or no attention from the operator. Easy access should be afforded for repairs.

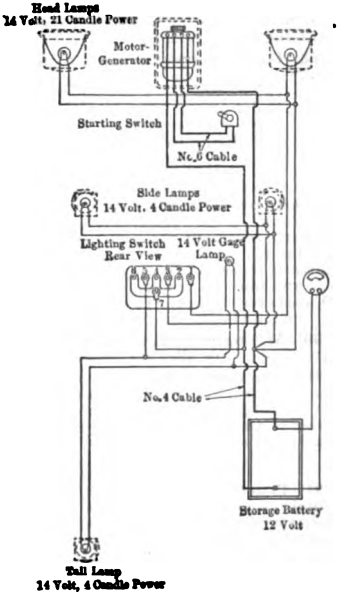

FIG. 13.—Single-unit, two-wire, 12-volt system.

## LIGHTING

**86. Reflectors** are of many shapes, and perform the same function as the backing of any ordinary headlight. It is essential for efficient use that they focus properly, and that the beam have proper alignment with the direction of car motion. Some lamps are provided with a mechanism by which the bulb may be either advanced or retracted until the proper focus is obtained. Proper alignment is secured by focusing the ray to a pencil beam and then aligning the lamp by resetting the props. A focusing lamp is shown in Fig. 14.

In some cities a "glare ordinance" restricts the use of blinding rays from head lamps. This difficulty has been overcome by the use of translucent screens, by an auxiliary lamp of smaller size located in the same reflector, by interposed obstructions to the beam, and by backing the bulb with a small shroud of low reflecting power.

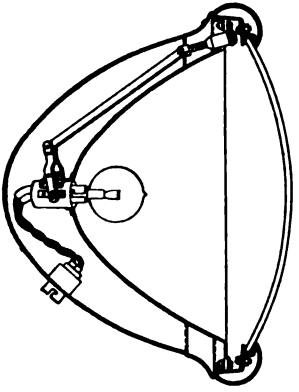

FIG. 14.—Focusing lamp.

**87. Wiring for lighting systems** must be installed with a view toward permanence of insulation and contact. Oil will depreciate rubber insulation, hence automobile wire is cloth-covered. If a grounded or a one-wire system is used, care must be taken to secure a perfect and lasting ground on the metal frame of the car. It should be remembered that the carrying capacity of wire for a given candle-power must be considerably higher than is found in standard 110-volt systems of distribution. Simplicity in the arrangement of leads is essential, for repairs are likely to be made by operators absolutely uninformed regarding the simplest electrical circuits.

Lamps are usually controlled from a multi-point switch located within easy reach of the operator. Ordinances of certain cities demand that the

Digitized by Google

tail-lamp switch be so arranged that it is impossible to turn it to the "off" position from the car seat, thus forcing the operator to get out of the car for this purpose. A device, consisting of a relay properly connected, permits switching on the tail lamp from the seat, but necessitates leaving the car for extinguishing the lamp.

**88. Candle-power and wattage of automobile lamps.** The efficiency of low-voltage tungsten lamps, such as are used in the lighting of gas cars, closely approximates 1 watt per c-p. The following table will show the sizes usually adopted for automobile lighting:

| | |
|---|---|
| Head lamps | 15 to 21 c-p. |
| Tail lamps | 2 to 4 c-p. |
| Side lamps | 6 c-p. |

15 watts represent the power consumption of two side lamps and one tail lamp.

30 watts represent the power consumption of two head lamps and one tail lamp.

45 watts represent the power consumption of two head lamps, two side lamps, and one tail lamp.

60 watts represent the power consumption of two head lamps, two side lamps, one tail lamp, one dome lamp, two pillar lamps, and one gage lamp.

**89. Arrangement of lighting units** is suggested by the preceding paragraph. See also Fig. 13.

**90. The source of energy** may be a storage battery which is charged upon removal from the car, the storage battery used in connection with an electric starting system, or the magneto. In the last case, the lamps will be extinguished when the engine stops; consequently, this system may be considered a make-shift.

## IGNITION

**91. Processes involved in ignition.** Ignition of the mixture in the cylinder should occur in such manner that the combustion of gas takes place when the piston is at the head of its stroke. There is a perceptible lag of time from the commencement of the process of sparking until the charge is completely fired. This interval depends upon the rate of gas combustion, the inductive lag, and also the inertia of the vibrator, if such a device be used. At low engine speeds the travel of the piston during this interval is relatively slight. At higher speeds, however, the effect of this delay is to retard the spark until the piston has completed a considerable portion of its downward travel, and in this case some corrective measure is almost imperative. See Par. **92**.

Proper starting of the process involved in firing the charge necessitates that an electric contact be made and then broken at the exact instant required. Adjustment of the mechanism driving the contact, in order to secure best ignition results, is known as **timing**.

The energy source is either a battery or a magneto. In all but the low-tension system (Par. **93**), currents of a few milliamperes are caused to cross an air-gap within the cylinder. One terminal of this air-gap is grounded on the engine. The lead from the other terminal passes through an insulating and gas-tight bushing, called a **spark plug**, to the source of high-tension energy.

The spark points are separated 0.4 or 0.5 mm. The voltages across the gap may very roughly be estimated at about 20,000 volts.

**92. Variation of spark.** The time interval or lag from the operation of the contact breaker to the complete firing of the charge in the cylinder is practically constant at all speeds. On the other hand, the travel of the piston during this interval is proportionately increased as the speed increases. The process of ignition, then, must be commenced at a more advanced position at the higher speeds. If a high-tension magneto system is used, it is desirable that the primary circuit be broken when the current is at its maximum value. The characteristic e.m.f. curve of a magneto, particularly at low speeds, is decidedly pointed, which narrows perceptibly the range of spark variation which may be profitably accomplished. This difficulty, however, may be obviated by rotating the field magnets to correspond with the change in the point of break at the contact breaker. Where battery ignition is used in connection with the single-spark system, a somewhat wider range of spark variation may be realized.

Digitized by Google

The spark variation may be accomplished manually, or, by means of a governing apparatus, the process may be made automatic. This relieves the operator of the care and attention bestowed on the spark lever, and, in addition, accurately determines the proper position of the spark for all engine speeds.

**93. Low-tension (make-and-break) system.** The spark may be made within the cylinder by the action of a spring which breaks the contact made by a device driven from a cam mechanism which is positively connected to the engine. The circuit leading to the terminals of this contact include either a battery or a low-tension magneto in series with a simple reactance. The sparking action is simply the inductive kick of the reactance coil when a steady current temporarily flowing through it is suddenly broken. The size of the spark depends upon the value of current built up in the reactance during the time of contact; this current value varies with the engine speed. At high engine speeds a reduced intensity of spark is thus realised, and a heavier spark is obtained at the lower speeds, which is desirable.

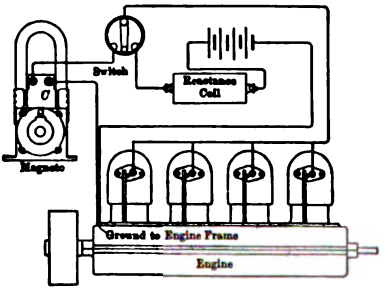

FIG. 15.—Low-tension (make-and-break) system.

The timing of ignition is secured by the adjustment of the cam or cams. Fig. 15 shows the arrangement of a low-tension system of ignition, offering a choice of magneto or battery and coil at the will of the operator. In the former case, the magneto, as here shown, embodies all the reactance necessary. An arrangement of this nature provides an auxiliary source of energy, whereby, if starting with ignition supplied from a magneto is insufficient at the low cranking speed, ignition may temporarily be supplied from the battery.

**94. Multiple-vibrator system.** Where more than one cylinder is used it is possible, by supplying duplicate ignition units (a separate unit for each cylinder), to secure firing which is approximately synchronous. In Fig. 16 may be seen four separate induction coils, each supplied with its own vibrator. The primary circuit of each one of these coils is completed by a contact maker, which at the proper time (here indicated by the position of a cam), closes the primary circuit of the coil corresponding to the cylinder which is to be fired, and, by the action of a vibrator, causes a spark in that cylinder. Synchronised ignition for four or more cylinders with this method, can be only approximate at best. It is impossible so to attune the vibrators that they will respond equally to the action of the timer. The time lag, mentioned in Par. 91, may vary for each of the several cylinder equipments. The effect of this is improperly timed firing, and the smoothness and economy of the engine as a whole is greatly reduced. It is due to these difficulties that multiple-vibrator ignition is losing in favor, and is being rapidly replaced by several other systems.

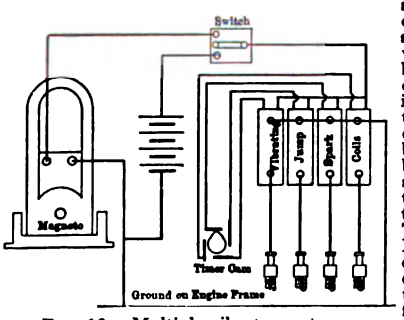

FIG. 16.—Multiple-vibrator system.

Digitized by Google

**95. Master vibrator with multiple-coil system.** The master vibrator is an auxiliary piece of apparatus used principally to convert a multiple-vibrator system into one more nearly synchronous. Essentially it consists of a single vibrator connected in that primary lead from the battery which is common to all coils. In addition, certain features of refinement have been added which ordinarily do not appear in the separate vibrators of the multiple-vibrator systems. In Fig. 17 a master vibrator is shown connected to a four-coil ignition arrangement. A master vibrator can be installed in any accessible place in the car, and may be connected, with few changes, to an existing multiple-vibrator system; however, all vibrators on the individual coils must be short-circuited. The source of energy, as in the multiple-vibrator system, may be either a battery or a low-tension magneto.

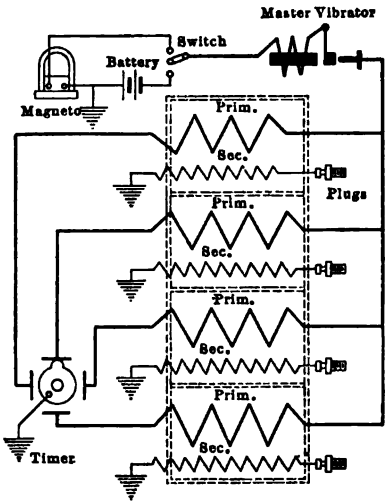

FIG. 17.—Connections of master vibrator.

**96. Single coil with distributor.** In many of the modern types of car, ignition is accomplished by means of a single coil whose secondary is connected successively to the spark plugs of all cylinders by means of a device which is known as a **distributor**. The required energy may be supplied from a high-tension magneto or a battery and coil.

**The high-tension magneto** may be of several designs, each maker claiming certain advantages for his own method. In one type (Fig. 18), current is first generated at a low voltage, and then led out to the primary of a coil. From the secondary of this coil, high-tension current is brought back to the distributor which is mounted on the magneto and connected with the magneto shaft through suitable gearing. The primary circuit is normally closed through the armature of the magneto and the coil. This circuit is opened by a contact breaker, also located on the magneto. Leads extend from the distributor to the spark plugs of the various cylinders. Another type of high-tension magneto contains the induction coil as an integral part of the armature. The armature thus carries

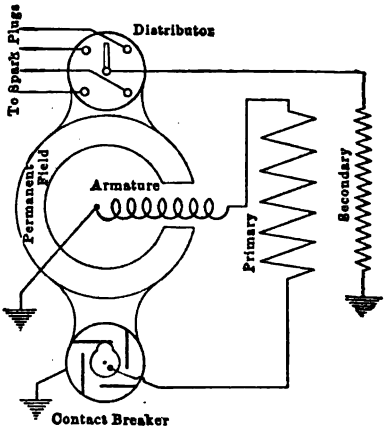

FIG. 18.—High tension magneto with separate induction coil.

Digitized by Google

two coils, one of few turns and one of many turns. The former or primary winding includes in its circuit the contact breaker, and the secondary winding is led to the distributor which is located on the magneto. High-tension magnetos are coupled positively to the engine in order that the proper relation may be preserved between magneto and engine.

Where a battery is used with the single-coil distributor system, it is usual practice to employ what is known as a **single-spark contact maker and breaker.** Such a device is shown diagramatically in Fig. 19. It will be seen that in this system the circuit is closed for a certain definite percentage of each revolution of the timer. As the engine speed increases, this duration of contact will be preceptibly shortened, consequently the primary current will build up to a smaller value, and when this current is broken, the resultant spark will be smaller, even though the speed of break is reasonably constant for all speeds. A refinement which has been added to this system, is an automatic regulator for securing the same length of break at all except the very slowest speeds. It is argued in favor of this kind of battery ignition, that a quick break, properly timed, results in a rapid combustion of the gas and the greatest pressure upon the piston at the beginning of the power stroke.

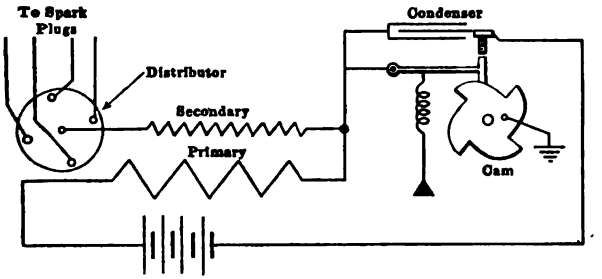

FIG. 19.—Single-spark system of battery ignition.

**97. Battery versus magneto.** Prior to the advent of recent improvements in battery starting and lighting systems, the magneto system of ignition was decidedly in public favor. But the very rapid adoption of battery starting and lighting systems has resulted in considerable controversy over the relative merits of battery and magneto ignition systems. The most important advantage claimed for the magneto was reliability; it also consumes but a small portion of the engine output, never becomes exhausted and never requires recharging as batteries do. The last-named advantages disappear in large degree when the magneto system is compared with the modern battery ignition systems in which the batteries are under charge almost continuously while the engine is in operation. It is also claimed that the magneto is less likely to suffer complete failure than a battery which may become short-circuited and give out completely. On the other hand, battery ignition produces greater spark intensity at the lower engine speeds than the magneto system, and certain experts have claimed that this feature makes the battery system decidedly superior. Another advantage which is claimed for battery ignition is the increased range of spark adjustment (Par. 92).

## THAWING WATER PIPES

**BY H. B. GEAR, A.B., M.E.**

*Engineer of Distribution, Commonwealth Edison Company,*

*Member, American Institute of Electrical Engineers*

**98. Advantages of electrical method.** The thawing of frozen water pipes by the use of electrical energy has become quite common in the northern

Digitized by Google

states. During unusually long-continued periods of weather when the temperature is averaging 10 deg. Fahr. and lower, the frost reaches such a depth in the earth that service pipes and occasionally the smaller water mains become frozen. Service pipes of less than 2 in. in diameter may be readily thawed by passing electric current through them in sufficient quantity to raise the temperature of the pipe above the freezing point. This permits the water to pass around the central core of ice and if pipes are kept open the flow of water from the mains completes the thawing process within a short time after the flow has begun. The thawing of water by the use of electric current is obviously far cheaper than by other methods, as no excavation is necessary and as very little remains to be done after the flow of water has been established.

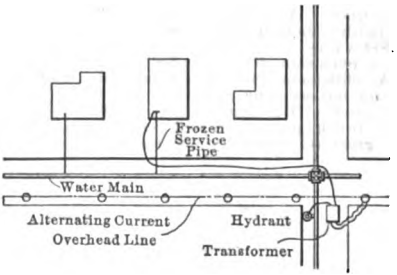

FIG. 20.—Use of transformers for thawing.

**99. The methods by which the thawing of pipes have been accomplished** are various and involve the use of both direct and alternating currents. The use of direct current is permissible only where there is a separate generator of ample capacity available, or a network of capacity sufficient to deliver 500 to 1,000 amp. Where the supply is drawn from a separate generator the control of the flow of current is readily accomplished by the field rheostat. Where the supply is drawn from a low-tension, direct-current network the voltage must be reduced by the use of resistance coils. With alternating-current service, it is customary to use a special pipe-thawing transformer, having a variable impedance, or a combination of standard transformers so connected as to give the proper voltage and current. The most common pipe-thawing problem is illustrated in Fig. 20, where the service pipe running from the street main to the house is frozen. In order to

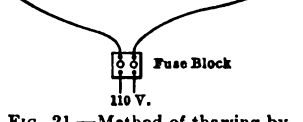

FIG. 21.—Method of thawing by inserted wire.

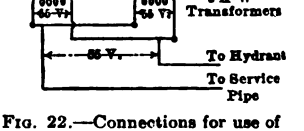

FIG. 22.—Connections for use of standard transformer.

pass current through the service main, the circuit is completed as shown in the illustration from the transformer through the street hydrant, water main and service pipe and back to the source of supply. Where a hydrant is not readily accessible the circuit is sometimes completed through the water piping system of an adjoining building. In connecting to a service pipe it is desirable to disconnect the house piping in order to prevent stray current from passing across to gas piping or grounded electric circuits. Fires have been started in some cases where this precaution was not taken and the electric-service companies in many cities require that the water piping be disconnected from the service before the current is turned on. In cases where the street main becomes frozen, current must be circulated between two

Digitized by Google

adjoining hydrants. Such cases, however, are comparatively rare, as freezing does not take place in sufficient amount to stop the flow of water.

**100. Another method of thawing pipes,** using a small amount of energy, is shown in Fig. 21. With this scheme a piece of rubber-covered wire is thrust into the end of the pipe and a current of about 20 amp. slowly melts the ice. A disc of insulating material centres the wire and prevents it from making contact with the pipe. This method is only applicable where the pipe is straight and where the end is accessible.

**101. Power capacity required.** In thawing ordinary house services which are not over 1¼ in. in diameter, it has been found that a transformer capacity of about 30 kw. is ample to start water flowing in from 15 to 30 min. Where standard transformers are used, the connection shown in Fig. 22 has been quite generally employed; this affords about 55 volts and from 350 to 500 amp. Standard transformers may be safely overloaded 50 per cent or more for 15 min. during the cold weather in which this kind of work is done.

The thawing of a 6-in. (15.24 cm.) main, 1,700 ft. (518 m.) in length in the East River at New York required the use of 750 kw. for 36 hr. In this case the pipe was laid in the bed of the river and was surrounded by salt water having a temperature of about 30 deg. Fahr. It was very difficult to raise the temperature sufficiently to thaw the ice inside, as the heat was carried away so rapidly by the moving water around the pipe. The accompanying table gives data on the amount of current and the length of time required to thaw frozen water pipes by electricity. ("Proceedings of American Water Works Association," 1912. *Eng. and Cont'g*, Feb. 12, 1913.)

| Size pipe (iron)*, in. | Length, ft. | Volts | Amperes | Time required to thaw, min. |
|---|---|---|---|---|
| ¾ | 40 | 50 | 300 | 8 |
| ¾ | 100 | 55 | 135 | 10 |
| ¾ | 250 | 50 | 400 | 20 |
| 1 | 250 | 50 | 500 | 20 |
| | | | | Hours |
| 1 | 700 | 55 | 175 | 5 |
| 4 | 1,300 | 55 | 260 | 3 |
| 10 | 800 | 62 | 400 | 2 |

* To thaw out lead pipe, the current must be increased 50 per cent.

## MARINE APPLICATIONS OF ELECTRICITY

**BY H. A. HORNOR, B.A.**

*Fellow, American Institute of Electrical Engineers, Member, Illuminating Engineer Society, Member, American Electro-chemical Society*

### MERCHANT MARINE PRACTICE

**102. Rules for installations.** In general the electrical construction on merchant vessels must comply with the requirements of the classification society under the rules of which the vessel is constructed. Such societies are established in all the large maritime countries. The American Bureau of Shipping and Lloyd's Register of British and Foreign Shipping are the societies under which most of the merchant vessels of this country are built. In addition, the Navigation Laws of the U. S., and the Pilot Rules, issued by the Department of Commerce, must be carefully followed. For certain inland vessels, especially those plying to and from New York City, the National Board of Fire Underwriters specify and inspect the installation. To cover detail requirements and special operating features the vessel owner also provides a general specification both for use in obtaining a price as well as for an instrument of guarantee. These rules and specifications give a wide latitude to the engineer, and in many cases the finished installation more than covers the requirements. This is due to rapid advance in the art.

**103. Lighting circuits.** The distribution of energy is the same as in a two-wire system on land. Feeders are led from the switchboard to distribution cabinets, and branch leads are thence distributed to groups of

Digitized by Google

lamps. Not more than 660 watts are assigned to one branch line. The usual allowable voltage drop to the farthest outlet is 3 per cent.

**104. Running lights.** In accordance with law, every vessel carries the following navigating lights: (a) masthead; (b) port; (c) starboard; (d) stern; and (e) range. A special feeder is carried to a tell-tale board located in the pilot house, and from this board separate branch lines communicate with each running light. In the event of failure of the lamp in any running lantern, both a visual and an audible signal is indicated by the tell-tale. There are several methods employed to accomplish this purpose, but care in selecting a system need only be exercised as regards ruggedness of construction and the prevention of corrosion.

**105. Lighting fixtures.** For those places in the vessel subjected to the action of steam or to mechanical injury, and where the outlet would be exposed to the weather, a special water-tight or steam-tight fixture is provided, and frequently a substantial guard is placed over the glass globe. In this country it is the practice to screw the glass globe which enshrouds the lamp, into the metal base of the fixture, permitting it to seat itself upon a soft gasket of rubber insertion. In other countries a flange is cast on the bottom of the glass globe and a ring of metal compresses the globe upon the gasket. Steam-tight fixtures are made in several models to adapt them to certain locations and to facilitate installation. Fixtures for oil-carrying vessels differ slightly from the ordinary steam-tight fixture, the principal difference being that in the former case the globe is cemented to a metal ring which makes a tight screwed joint with the base; practice among the owners of oil vessels does not agree as to their use. Fixtures for living spaces are generally selected by the owner, and are similar to those in vogue on land except that they must be designed for mounting on a flat block and must permit ample room in the base for connections. Recently china fixtures (Beleek) have been introduced in lieu of metal for passenger quarters. The advantages are incorrodibility and cleanliness.

**106. Lamps.** At the present time carbon-filament incandescent lamps are usually installed, but the tendency to use metallic filament lamps is gradually increasing. The successful use of wire-drawn tungsten lamps in railway car lighting is having its effect upon the rapid introduction of this type of lamp on shipboard; in addition to this, the smaller lamps at 110 volts permit a wider distribution with the same amount of copper.

**107. Methods of illumination.** The application of modern methods of illumination does not progress rapidly in this class of work. Conservatism plays a large part in abating any radical departures from present practice. A recently completed excursion steamer was largely equipped with indirect and semi-indirect fixtures, but in making such applications this type of vessel must not be confused with ocean-going vessels, which must so be fitted that such appliances will not be affected by the rolling of the ship.

**108. Motor circuits.** Feeders are led directly from the main switchboard to a double-pole switch and cut-out placed in the line to protect the starting box and motor. The conductors must be designed to care for the starting current, especially if the circuit is so fused. The cut-out switch and the double-pole switch are not necessary for motors of 0.25 h.p. or less.

**109. Motor controllers.** Starting panels, similiar to those of land practice in their electrical features, but usually enclosed in a non-water-tight sheet metal box, are provided for all motors of capacities below 10 h.p.; for larger capacities, drum-type controllers are employed. The latter are protected either by separately mounted circuit-breakers or by specially designed contactors likewise enclosed in a sheet-metal box. This box must be made completely water-tight if mounted on an exposed deck.

**110. Motors.** Ordinarily land motors of regular commercial design are accepted and installed, but such practice is not deemed advisable from the standpoint of the engineer. Motors should be fully enclosed if located in exposed places or in the machinery spaces. Careful consideration should be given to the design of the bearings, especially the guards which prevent oil from travelling along the shaft and into the armature windings. The spaces in a vessel are usually crowded, and therefore the design should provide easy means for overhauling. Although not a universal rule, it would be conservative to specify that all motors should be built with horizontally split frames.

Digitized by Google

**111. Searchlights.** This apparatus, because of the comparatively large current consumed, is considered as furnishing part of the power load. The searchlight is served through a separate switch on the main switchboard, and the arc voltage is adjusted by an external variable resistance. Provision is made on the switchboard whereby the voltage of the searchlight feeder may be observed by use of the generator voltmeter. The searchlight may be managed from the pilot house by either direct hand control or remote electric control. In order to insure against the ill effects of radio-telegraph induction it is necessary that exposed leads to searchlights be either encased in pipe or wrapped with wire. In both cases the outer steel covering must be well grounded to the hull of the vessel. Searchlights are useful in picking up buoys in harbor channels and, in some trades, are very necessary for loading and unloading at night. For freight vessels or for passenger and freight vessels of 4,000 tons carrying capacity or over, the searchlight should not be less than 18 in. in diameter.

**112. Electric radiators.** For certain service, such as the coastwise traffic of the Pacific coast, electric air heaters find a suitable application. Where the temperature varies but a few degrees, as in this instance, passenger steamers can thus be comfortably heated without exceeding proper temperatures. For attractiveness some vessels carry luminous radiators in the staterooms and lounging rooms, and tubular air heaters in the passageways and in the rooms less frequented. These appliances must be designed to undergo hard service, must be properly fused, arranged for mounting on bulkheads, and should be sufficiently guarded to prevent inflammable materials from being cast upon them.

**113. Engine telegraph system.** For the maneuvering directions between the pilot house and bridge and the engine room, mechanical signals are employed. This system consists generally of transmitters, located one in the pilot house and one on the bridge, connected by low-brass wire and triple-link chain passing over brass pulleys to a receiver in the engine room. A reply system assures that the signal has been properly received. Occasionally an electrical attachment is made from the engine-room receiver to the reversing shaft of the engine whereby a false signal may be immediately made known. The transmitter dials are electrically illuminated. Various models to suit the propelling machinery are manufactured.

**114. Miscellaneous mechanical telegraph and bell pulls.** Other telegraphs for the purpose of docking the ship, steering, indicating the rudder angle, and for adjusting the mooring lines, are exactly similar to the engine telegraph instruments except that the dial orders are suitably changed. As an emergency precaution mechanical bell-pulls are installed near the engine telegraphs, connecting with a gong and a jingle bell in the engine room. As an auxiliary to any means for operating the main steam-whistle valve, mechanical pulls are located on the bridge and in the pilot house.

**115. Telephone speaking tubes and call-bell system.** The law requires that for vessels in which the distance from the pilot house to the engine room is greater than 150 ft. a telephone must be installed in addition to, or in place of, the voice tube. For shorter distances speaking tubes are used giving communication between important places in the vessel. It is compulsory to install either a speaking tube or a telephone between the wireless room and the bridge. Other points of communication are merely for convenience and differ with the desires of the owner. In both passenger and freight vessels, annunciators are located in the main pantry and push buttons are installed in all staterooms, messrooms, saloons, etc. In living quarters remote from the bridge and not provided with watchmen on continuous duty, alarm gongs are installed; these are actuated by a push button located in the pilot house. This is a requirement of law.

**116. Fire-alarm system.** All vessels are not equipped with such a system, and the systems that have hitherto been installed have not proven altogether satisfactory. Such systems usually consist of electrical contacts which are closed by the melting of a fuse of soft metal, and merely indicate the presence of fire. Two systems are on the market to-day which more nearly approach satisfactory service. In one of these not only is warning of the exact location of the fire given, but live steam is admitted to the origin of the fire by means of a direct lead of pipe.

**117. Submarine signals.** Large cast-brass bells, rung either by electric, air or wave power, are submerged beneath the lightships that beacon the

Digitized by Google

coast, or may be suspended from a buoy which serves the same purpose. On both the starboard and port bow down in the forehold of a sea-going vessel are placed two tanks filled with brine. A diaphragm transmitter is placed inside each tank and is connected to telephone receivers located in the pilot house.* A double set of batteries are included to avert interruption to the service. Submarine signals can then be easily detected for a range under favorable conditions of at least 6 to 8 miles by this electrical perception of water vibration when the bell is struck. As there is a receiving station on each side of the bow, it can also be determined whether the vessel is approaching the port or the starboard side of the beacon. Experiments are now being made to render practicable the use of high-frequency impulses through the water, so that full communication can be established between vessels. For description of Fessenden Submarine Oscillator see *Trans.* A. I. E. E., 1914.

**118. Electric-whistle operator.** This device consists of an electromagnet operating a sensitive steam valve directly connected to the main steam whistle. By means of a clock movement the whistle may be blown automatically as well as at will. A telegraph key is also provided so that code signals may be given from the whistle. With an additional contact disc on the clock movement and an external switch, automatic signals can be given from a ship alone in a fog, as well as complying with the law when towing another vessel.

**119. Radio-telegraphy and radio-telephony.** All systems which are explained elsewhere (Sec. 21) and which are applicable for shipboard installation, are, of course, subject to the selection of the owner. The points of care of installation are very minor except the serious one of obtaining positive and sufficient ground connections. The effects upon the rigging of the vessel are such as to require careful grounding of all stay lines, etc., and, as mentioned under searchlights (Par. 111), all exposed conductors must be properly encased. This property of radio-telegraphy must also be considered in connection with the type of electric installation adopted.

**120. Generating plant design.** The generator is direct-connected to a special marine-type engine or to a turbine. The special features of design relate to reductions in weight and space. The manufacturers are prepared to supply generating sets suitable for this purpose, built with non-corrosive parts and proper arrangement of steam connections for ship installation. The generator frame is usually split horizontally, and easy access is afforded to the commutator. For both reciprocating-engine and turbine drive, forced lubrication is preferred. The present accepted voltage is 110 volts, and direct-current compound-wound generators are used. The prime mover must be able to exhaust either into the feed-water heater, the main or auxiliary condenser, or into the atmosphere. Owners do not agree as to the advantages of the two types of prime mover. Some object to the high rotative speed of the generator which in certain small sets is as high as 5,000 rev. per min.; others prefer the ease of operation and the reduction of upkeep of the turbine in comparison with the reciprocating engine.

**121. Generating plant operation.** Except in very large passenger and freight vessels, the dynamos are located in the engine room and are therefore under the direction of the engine division. Since they form one of the many auxiliaries it becomes evident that they must be reliable, rugged, and able to operate with little attention. There are reciprocating engines now manufactured which combine the gravity-feed and forced-lubrication systems in such manner that the apparatus is reasonably "fool proof" as far as the oiling is concerned. On the generator end, if of open construction, a sheet-metal guard is placed over the commutator so that it is protected from mechanical injury. Incidentally this avoids the danger of any one being thrown against it in passing. These sets usually operate under favorable conditions, without undue noise, and the regulation is within 2 per cent.

**122. The cost of marine generating sets** is not much higher than that of ordinary commercial sets of the same capacity. The average price is approximately $60 to $80 per kw.

**123. Switchboards.** Regular commercial practice is followed as far as general design and apparatus is concerned. Compactness is necessary

* Fay. *Proc.* A. I. E. E., 1912

Digitized by Google

so that the board may be mounted as near a bulkhead as possible. Owners differ as to the method of connections, some desiring that the generators be run in parallel; others preferring that each feeder be provided with a double-throw switch and that separate bus bars be provided for each generator. This is more a question of operation than one of engineering, but with the conditions as described in Par. 121 it would seem more desirable to keep the generators on separate bus bars, should no electrician be carried.

**124. Conduit and moulding.** The special requirement for any marine installation is that the conductors be so protected that grounds will seldom occur and that the water-tightness of the vessel will not be impaired. All of the above cited rules require a heavy insulation of rubber and furthermore require that the completed installation must show approximately one megohn of insulation resistance. Beyond these rules the owner usually specifies the highest quality of wire upon the market. As it is customary to use enamel-lined conduits, double-braided wire is installed in conduits and single-braided wire in mouldings. In a combined conduit and moulding installation, conduits are run on exposed decks, in cargo holds, machinery spaces, galleys, pantrys, crew's quarters, etc. Water-tight junction boxes for branch connections and steam-tight fixtures are used on such lines. In the living quarters, mouldings matching the woodwork are provided, all connections being carefully made and laid in the moulding. When conductors pass through steel beams or bulkheads the hole is bushed with hard rubber. When conduits pass through water-tight decks or bulkheads a brass stuffing tube is fitted at the bulkhead; this tube is packed with red lead and flax, forming a water-tight joint.

**125. Flexible cables and conduit.** Flexible cables with or without a lead covering are sometimes used in lieu of mouldings. The flexible cables are strapped on the structure, have the advantage of being readily overhauled, and, if the insulation is properly selected, reduce the amount of inflammable material.

**126. Steel braided armored cables.** There is at present on the American market a design of steel-armored cable similar to that used for some time past in foreign countries. This material supersedes both conduits and mouldings, as the lead-covered steel-armored cable is perfectly water-tight and sufficiently protected for exposed spaces; the armored cable without a lead sheath is applicable for living spaces where it may be safely run behind panel work or in decorative mouldings. As mentioned above, this type of installation besides having the important characteristic of reducing grounds to a minimum also makes a perfectly safe installation for heavy wireless telegraph outfits. The only change necessary in fittings is that stuffing tubes must be added to the water-tight branch junction boxes.

## NAVAL PRACTICE

**127. Lighting system.** All governments strive to obtain for their naval vessels the very latest and best developments of the art. This desire precludes standardization to any great extent. The methods of distributing light, the type of lighting fixtures, and the problems of illumination are all being carefully studied; advances in the art are rapidly adopted. In general the fixtures are heavier than in ordinary practice, and the materials, as specified, are more closely inspected. In the United States Navy, the standard lamp is rated at 123 volts, and metallic-filament lamps are now in service. Arc lamps are no longer used, having been superseded by the 250-watt tungsten lamp.

**128. Motor system.** Motors and their controlling equipments are elaborately specified, tested and inspected by the United States Government. Copies of these specifications as well as all apparatus and material furnished the United States Government may be procured upon application to the Navy Bureau concerned. Within recent years the motor load on a battleship has very greatly increased both in capacity and importance. This augmentation has caused some governments to increase the generator voltage to 220, still retaining direct current. Such auxiliaries as the anchor windlass, requiring 300 rated horse-power, and the steering gear which requires approximately a like amount, illustrate the above statement.

Digitized by Google

**129. Signalling system.** Although the lighting and power systems are large and important, they are not more important than the interior communication in a battleship. Every device that human ingenuity can devise is called into requisition, and its operation and efficiency are carefully observed; if it is of value it is regularly employed. Systems of signals connect the important points for use in navigating the ship, in transmitting general orders, and in the firing of the guns. Mechanical signals parallel all important electrical signals.

**130. Generating plant.** The U. S. Navy has adopted as standard a direct-connected horizontal steam-turbine generator set operating at a standard direct-current voltage of 125.* Reliance is placed on a strict interpretation of the specifications to produce a perfect machine with as small a weight and as high an efficiency as the manufacturer can guarantee. Nations differ as to the proper number of dynamo rooms and to the number of machines which should be contained in them. The U. S. Navy prefers to-day two rooms with two dynamos in each room. Switchboard practice likewise varies in the different countries. Some of the foreign powers use steel for mounting the various switching devices, but the U. S. Navy now specifies special composition. In some naval vessels the generator control switchboard is located in the dynamo room, and in other vessels it is combined with the distribution switchboard located in an adjacent compartment.

**131. Wiring.** Many of the foreign nations have for several years been using steel-armored, lead-covered cables and recently the U. S. Navy has adopted a similar system. Previous practice in the U. S. Navy was generally to install conduits and to use open wires only in those places not subject to mechanical injury. The appliances are all specially standardized, specified, and inspected, and are in every way more rugged and of better metal than in the ordinary merchant service.

In some installations the material and apparatus may be delivered as the work proceeds, but precautions are essential when the installation of steel-armored cables is undertaken. In such an installation the cables are laid, instead of pulled into conduits. This consideration together with the fact that it is not wise to expose the loose end of the cable for any length of time, requires that all apparatus and material be fully delivered before starting the installation. In ordering wire for shipboard installation it must be remembered that the length of wire on the standard reels of the manufacturer may vary greatly, increasing the cost of material due to the waste in cutting off the proper length. It has been found desirable and economical to order wire in positive lengths, placed upon reels marked with the feeder or main number as shown on the approved drawing.

## MISCELLANEOUS

**132. Cost of electric plant on typical vessels.** Actual costs of such installations are not obtainable and would not be of material value. Estimated flat costs for different types of vessels are here given as a guide.

| | |
|---|---|
| Tug boat, 50 lamps, 3 kw | $1,100 |
| Ferry boat, 300 lamps, 20 kw | $3,000 |
| Freight vessel, 150 lamps, searchlight, 20 kw | $5,000 |
| Oil tanker, 150 lamps, searchlight, 20 kw | $7,500 |
| Passenger & freight vessel, 1,200 lamps, searchlight, heating system, 150 kw | $27,000 |
| Battleship, 3,000 lamps, 1,500 kw | $1,100,000 |

## APPLICATIONS OF ELECTRICITY IN THE UNITED STATES ARMY

**BY EDWARD D. ARDERY**

*Captain, Corps of Engineers, United States Army*

**134. General applications.** Aside from the usual applications to illumination and the operation of machinery, electrical energy is employed in the Army for communication, operation of searchlights, maneuvering seacoast guns, operating ammunition hoists, blasting, exploding mines and firing guns.

**135. Energy supply.** A central generating plant would be the most economical arrangement, but might be paralyzed by a single well-directed shot. To provide for such an emergency, a reserve supply is necessary. Where reserve energy supply is not already provided for in other ways at seacoast forts, it is current practice to install 25-kw. gasoline generating sets in or near the batteries. Commercial supply also is used when available. On account of the development of the gasoline sets, the use of storage batteries in fortifications is being discontinued; these batteries were formerly required for supplying the telautographs, but are now employed only in connection with the telephone systems.

**136. General specifications for power plants in fortifications.** The National Coast-Defense Board, in 1906, recommended: (a) that the electrical energy used for fortification and defense purposes be furnished by an adequate steam-driven, direct-current central power plant, all machinery to conform in type to approved commercial standards; (b) that each battery or group of batteries be equipped with gas-driven or oil-driven direct-current generators, installed as a reserve to the central plant; (c) that the energy supply of searchlights be provided by self-contained units unless the searchlights are in close proximity to the central plant; (d) that the torpedo casemates be supplied with energy from independent sources for submarine-mine purposes; this arrangement should constitute an integral part of the submarine-mine defense; (e) that alternating current energy, when essential, should be obtained from the direct-current distribution system, using for the purpose a suitable converter; if, however, it is found more economical, this energy may be obtained from a separate alternator; (f) that the central-station output, when not needed for fortification service, may be used for garrison purposes, provided that the latter load does not require too large an increase in the size and number of units; (g) that, should the garrison service require an alternating-current distribution system, the energy should be supplied from the central plant, either through a suitable converter or from alternators installed for this special purpose in the central station; (h) that uniformity of types and accessories should be adhered to as closely as possible.

**137. Protection of distribution.** Considerations of economy, efficiency, and protection against hostile fire require that the greater part of the electrical communications be either subterranean or submarine. Conductors are sometimes laid underground in trenches roofed with plank for protection. Such conductors should be lead-covered and armored, the armor being served with a jute yarn in some cases. Lead-covered, unarmored cable, without jute on the lead covering, is suitable for conduit construction.

**138. Wiring specifications.** The wiring rules formulated by a Board on Standardisation of Wiring for Seacoast Batteries are as follows: (a) conduits should not be employed for local distribution in emplacements where their use can be avoided; (b) all wires leading out from the emplace-

Digitized by Google

ment switchboard should be exposed in so far as possible; (c) armored cable should be used for all exposed wiring, and lead-covered cable should be used in conduits; (d) all branch lighting circuits in emplacement distribution will be of No. 12, A.W.G.; (e) exposed wires will be supported on ceilings or walls with cable hangers, to permit the application of preservative coatings; (f) snap-switch and plugging-in boxes introduce more points where grounds may occur, and should be used only where they are absolutely essential; (g) a branch lighting circuit may carry a maximum current of six amperes; (h) all fixtures for inside or outside lighting about emplacements should be of approved water-tight types. Due to the effect of alkalies on the lead covering of cable, concrete conduits are no longer installed. Condensation and other sources of dampness in the seacoast fortifications render particular care necessary to prevent grounds.

**139. Special illumination of range-finding instruments.** The cross wires and range scales of position-finding instruments are illuminated by electric lamps; emergency lamps are supplied with energy from dry cells. Oil and gas illuminants have been found unsuitable for this service.

**140. Searchlights** are used in the coast defenses for signaling; for discovering and illuminating the enemy's ships; for bewildering his pilots; and for rendering his searchlights ineffective by means of fixed beams from the shore, which the enemy's beams cannot easily penetrate. In land operations the searchlight functions are similar. The searchlights now standard are the so-called 60-in. (1.5 m.) and the 36-in. (90.0 cm.), although some 30-in. (75.0 cm.) and 24-in. (60.0 cm.) are still employed. The mirrors are ordinarily of glass, parabolical in shape, and with silvered backing. A 25-kw. gasoline generating set is furnished for operating each 60-in. (1.5 m.) searchlight.

The ranges at which targets may be satisfactorily illuminated by a 60-in. (1.5 m.) searchlight are as follows: with very clear atmosphere, 10,000 yd. and sometimes farther; with average atmosphere, 6,000 yd. to 8,000 yd.; through slight haze or rain, 3,000 yd. to 4,000 yd.; in medium haze or gray dawn, 1,000 yd. to 2,000 yd.

Remote control of searchlights may be effected by use of a synchronous-motor controller, using 110 volts at the training motors, and may be accomplished at a distance of 10,000 ft. (3.048 km.).

**141. Characteristics of Searchlight Arcs**

| Size of light (in.) | Current (amp.) | Volts across arc | Size of carbons in inches | |
|---|---|---|---|---|
| | | | (positive) | (negative) |
| 24 | 50 | 48 | ~ 1 by 12 | 0.75 by 7 |
| 30 | 80 | 50 | 1.125 by 12 | 0.875 by 7 |
| 36 | 130 | 60 | 1.25 by 12 | 1.0 by 7 |
| 60 | 175 | 65 | 2.0 by 15 | 1.375 by 12 |

The life of a pair of cored carbons for use with a 60-in. (1.5 m.) searchlight is 5 hr.

**142. Signaling by searchlight** may be accomplished by day or night by exposing and occulting the beam with a shutter, thus sending a series of dots and dashes that are visible, in ordinary weather, for a distance as great as 10 miles (16.09 km.) at sea. At night the beam may be traversed, turned on the clouds, or reflected from a water surface. In elevating for signaling, care must be taken that the angle is not such that hot particles of carbon will fall on the mirror. If the searchlight is depressed too far, the heat may damage the mirror. If used in cold weather, the mirror should be heated and cooled gradually, because rapid expansion or contraction may cause the silvering to flake.

**143. The Ardois system** is a vertical display of four lights, manipulated by a keyboard. Red and white lights represent dots and dashes, respectively.

**144. Telephone and telegraph.** The telephone is extensively used in the army, particularly in connection with the range-finding and fire-control system of the coast artillery. In field operations it plays an important

Digitized by Google

part in the transmission of information, orders, etc. The telegraph is of less importance, and is used in the same manner as in commercial practice.

**145. Buzzer.** This apparatus consists of an interrupter and an induction coil supplied with energy from a few dry cells. In operation the buzzer is used as a transmitter for the purpose of signaling; the frequency of the current is such as to produce a high note in a telephone receiver at the far end of the signaling circuit. Leaks, bad connections, and high resistances, any one of which would cripple a system employing Morse instruments, merely affect the loudness of the signals in the receiver. Each transmitting station is equipped with a telegraph key and a telephone transmitter, and may be used either for telegraph or telephone communication.

**146. Wireless telegraphy** (radio) is readily adaptable to military purposes, and for ordinary distances can take the place of the telegraph, making it particularly useful in field operations. In Alaska, on account of the frozen soil, satisfactory grounds are sometimes difficult to obtain. The Signal Corps has developed portable radio sets that may be transported on mules, on a wagon, or on an aeroplane. High frequency, quenched-spark circuits are used. Both silicon and perikon detectors are employed. The generator of the pack set is driven by hand, but a storage battery can be used. The wagon set is larger and of higher efficiency than the pack set. For aeroplanes the generator is operated by a friction drive from the engine. In the absence of a ground connection, a counterpoise is used. Receiving is rendered difficult on account of the noise of the engine.

**147. Handling of guns.** For enabling seacoast guns to be traversed by power, motors are attached to some of the gun carriages. When, at drill, the guns on disappearing carriages are tripped into battery without being subsequently fired, the retracting to the loading position may be done by motors. Retracting motors can also be arranged to elevate or depress the muzzle of the guns when being aimed.

**148. Firing of seacoast guns** may be accomplished electrically or by pulling a lanyard. To guard against accidents in electrical firing, there are usually three breaks in the circuit. Two are closed automatically: one when the breech-block is properly locked, and the second when the gun has moved properly into battery; the third is a contact which is manually closed at the firing pistol or switch when all is in readiness. Energy may be supplied from dry cells or an electric exploder.

**149. Ammunition hoists** are used for raising projectiles from the magazine level to the loading-platform level of some of the larger guns; these hoists consist of endless sprocket chains, with carrier arms attached, operated by electric motors. To avoid accidents, the motors cannot normally be reversed, but the projectiles can be lowered by hand. The powder charges may be handled on similar hoists.

**150. The velocity of a projectile is measured** by firing it through two targets *t*, Fig. 23, separated by a known distance. An electric circuit is broken at each target, and the elapsed time between breaks is determined with a Le Boulengé Chronograph (*b*, *d*, *r*). The velocity of gun recoil can be similarly determined.

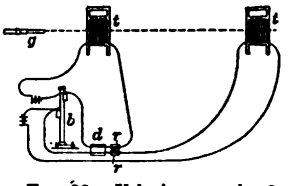

FIG. 23.—Velocity recorder.*

**151. Targets.** The face of the self-scoring target for rifle practice is divided into segments of armor plate, which the rifle bullet cannot penetrate. Held against the backs of these sections by springs are one or more spindles. A bullet striking a segment causes the spindle or spindles abutting against that segment to jump backward, closing an electrical contact; this causes a number representing the value of the hit to appear in a corresponding place on a miniature-target annunciator at the firing point. Dry cells furnish the energy required for operation. Each segment has a separate circuit, but with a common return.

**152. Electrical caps, or fuses** (Fig. 24) contain fulminate of mercury, with a platinum bridge, *p*, imbedded in the fulminate; heating the bridge by passage of an electric current through it causes the ignition. Caps stored

*Lissak, O. M. "Ordnance and Gunnery;" New York, Wiley and Sons, 1908.

Digitized by Google

in a damp place deteriorate rapidly. With less than 0.25 per cent. moisture, the caps will not explode dynamite, although they may themselves explode. For simultaneous ignitions, caps are usually connected in series; however, owing to non-uniform sensitiveness, one or more may explode and break the circuit before the bridges of the others have become sufficiently heated. Where several caps are to be exploded, and where sufficient energy is available, it is best to connect them in parallel. When detonating with electric fuses, the Laflin and Rand Exploder No. 3 is ordinarily used. Its rated capacity is 12 fuses, but it is best to attempt not more than 6. The leads should be insulated, though this is not imperative, as fuses have been fired with bare leads in fresh water. The wire should be of copper, of a size not smaller than No. 18 A.W.G., where the distance is 500 ft. (152.4 m.).

FIG. 24.—Exploder.*

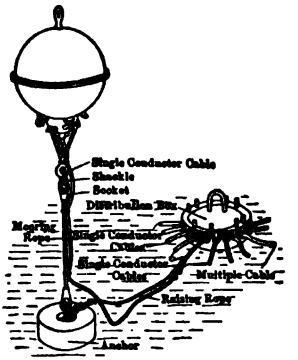

FIG. 25.—Buoyant mine.*

**153. Mines** (Fig. 25) are of two general classes, land and submarine. The former consist of charges of explosive below the surface of the ground. By means of electric fuses and leads these can be fired at the will of the operators. Submarine mines contain charges of high explosive which it is desirable to explode as near as possible to the hull of the enemy's ships. Such mines may be anchored on the ground under water, or may float below the water surface. The inside mechanism of the mines is so designed as to allow of frequent and safe testing of the fuses after the mines have been planted.

To prevent deterioration of cable intended for submarine mine work, the cable reels are stored under water in tanks, the ends only of the cable remaining above the water surface.

**Electrical firing** may be effected as follows: (a) when the mine is struck by a ship, the power circuit being inside and rendered operative by the jar or tipping; (b) at will from the shore, either with or without an electrical signal from the mine; (c) automatically by contact, provided a switch on shore is closed at the time, the circuit being finally completed by the striking of the floating mine-case, or of the floating buoy in the case of ground mines.

The subject of **electric blasting** is well described in a work entitled "Electric Blasting Apparatus and Explosives," by Wm. Maurice (The Electrician Printing & Pub. Co., Ltd., London).

## ELECTRICITY AND PLANT GROWTH

**By JOHN E. NEWMAN**

*General Manager, The Agricultural Electric Discharge Co., Ltd.*

**155. General.** In the eighteenth century a Scotchman subjected myrtles to the discharge from a frictional machine and reported that they were benefitted. Since his time there have been many experiments, but they may all be divided into two main classes, as follows: (a) those aiming to influence the plant by changes in the atmospheric electrification; and (b) those in which currents are passed through the soil about the plants. The records of these experiments show that, generally speaking, where artificial discharges of electricity to the air over the plants take place, favorable results have been recorded; where the method has been that of passing currents through the soil, the results are contradictory.

**156. The first systematic experiments** on any important scale are those of the late Prof. Lemstrom, of Helsingfors University, Finland, who carried out experiments on a field scale in Finland, France, Germany and in England (at Durham University). In the course of his trials, he experimented with almost all the common vegetables and cereals as well as with strawberries and raspberries. His method was to suspend a network of fine iron wires, spaced about 4 ft. apart, 16 in. above the plants to be electrified. These wires were provided with points like barbed wire, and had to be raised as the plants grew. While the results showed a definite increase, from 20 per cent. to 45 per cent. in the case of most crops, the method is impracticable for work on a large scale. The close network of wires about 1 ft. above the crop and the numerous posts necessary, seriously interfere with the ordinary cultivation of the ground and make horse or steam cultivation impossible. Nor can an influence machine be considered practical from an engineering standpoint.

**157. In the Evesham experiments,** commenced in 1906 (and still being carried on) by the writer, in cooperation with Mr. R. Bomford and Sir Oliver Lodge, the following arrangements were adopted and have been followed essentially in subsequent installations in different parts of the world, including the plant now being worked by the Department of Agriculture at Washington. Over the area to be electrified is erected a wire network consisting of thin galvanized steel or bronze wire run at an average height of 15 ft. above ground (this being assumed as that clearance which would allow a loaded harvesting wagon to pass underneath), the wires being 10 ft. apart and carried as span wires between stout telegraph wire, on insulators mounted on posts planted 71 yd. apart in parallel rows 102 yd. apart. Thus 21 poles will do for 20 acres, or roughly a pole to an acre.

**158. The potential at which the network is charged** varies from 50,000 to 75,000 volts. This corresponds to the potential at which the network is actually charged by an average thunderstorm, and at this pressure the discharge on a quiet day is distinctly audible. What we have is practically a leaky condenser, with the air as the dielectric; and this condenser must be kept charged.

**159. Source of energy.** The current to charge the network is provided by an induction coil, the negative high-tension pole of which is earthed and the positive high-tension pole connected to the network through from 3 to 5 **Lodge valves** in series. The valves will allow positive electricity to pass through them in one direction only, and negative electricity to pass through them only in the other direction. Any value of direct-current voltage up to 250 may be employed, or alternating current may be used, with some decrease in efficiency.

**160. A motor-driven mercury gas break,** able to run about 1,000 hr. without being cleaned out, is used; it is equipped, when necessary, with an automatic hydrogen generator.

**161. The power absorbed by the coil when charging** a network of 25 acres is about 300 to 500 watts, and the small break motor and ventilating fan motor absorb another 100 watts.

**162. The best length and time of application of the current is**

Digitized by Google

still a matter for experiment and may possibly vary with different crops or in different climates, but so far it appears as if an application of from 4 to 6 hr. per day gives better results than a longer period.

**163. Effect of moisture in soil.** It is not yet possible to accurately predict the results which will follow electrification, but it can be said that its application is probably useless in dry regions, and that the most favorable results will follow where there is ample moisture in the ground.

**164. Results of application.** The process has been applied thus far chiefly to wheat, potatoes, sugar beets and strawberries.

**Wheat,** during eight successive years (1905–1911), in three fields on Mr. Bomfords farm at Evesham, England, has given an average increase of 21 per cent. in weight of grain, and also an increase of straw which it has not been possible to measure. The only year in which no increase resulted was 1911, which was a year of great drought in England, and the yield during this period from both electrified and control areas was only 16 bu. per acre.

**Potatoes** have shown more irregular results, affording, at an installation at Dumfries, Scotland, increases of 20 per cent. to 25 per cent. in two seasons, and showing no difference in a third. In the last case, the control and electrified plots were arranged in a chess-board pattern, and were of moderate size. Subsequent tests showed that one or other of the control plots was usually being electrified unintentionally. In the two years during which positive results were secured, there was but one control and one electrified plot.

**Outdoor strawberries** have shown a small decrease, or no difference, which is contrary to the results obtained with forced strawberries in pots in greenhouses. This result may be due to the dwarf-growing habit of the plant, although it should be noted that the control and electrified areas in this case also were arranged chess-board fashion, and that the yield from the whole field was above the average. The electrified fruit was markedly sweeter than the unelectrified.

**Sugar-beets** at several European installations have displayed increases of 20 per cent. or more, with a considerable increase in the sugar content of the roots.

## WINDMILL ELECTRIC PLANTS

**BY FRANK F. FOWLE, S. B.**

*Consulting Electrical Engineer. Member, American Institute of Electrical Engineers*

**166. Wind velocities** are customarily recorded, in the stations of the U. S. Weather Bureau, by means of the Robinson anemometer which integrates the total wind movement. The records of the Weather Bureau should be consulted for definite data on wind movement in any particular locality. The measured or indicated wind velocity, as recorded by the Weather Bureau, is not the true velocity, but

$$\log V = 0.509 + 0.9012 \log v \qquad (5)$$

Digitized by Google

where $V$ is the true wind velocity and $v$ is the actual velocity of the cup centres in the anemometer. See *Electrical World*, Vol. LVI, Oct. 27, 1910, pp. 995 to 1000. As a rule, the measured or indicated velocity is the one implied in discussions of velocity and pressure.

**167. Wind movement** is recorded in miles, and is virtually the integration of the instantaneous velocities for a given period or the total distance a given particle of air would move in that time. Tables of wind movement per day or per month have been prepared and published for various localities; many of these can be found in the government publications. Such information is very essential to any careful study or forecast of the probable performance of a windmill in any specific locality.

**Wind pressure** and its relation to wind velocity is a subject which has received much study by many investigators. The Weather Bureau formula is

$$P = 0.004\left(\frac{B}{30}\right)V^2 \qquad \text{(lb. per sq. ft.)} \qquad (6)$$

where $B$ is the barometer reading in inches of mercury and $V$ is the indicated velocity in miles per hr.

**168. Available work in air currents.** The total aerostatic head of a moving gas, at any given point, is the sum of the pressure head and the velocity head. Since the aerostatic gradient changes but slightly between areas of high and low pressure, it is sensibly constant in passing any given locality. Therefore the total available work stored in the moving gas is represented by the velocity head, or energy of momentum.

**169. Windmill characteristics** are shown in Figs. 26 and 27, plotted from the test data on a 16-ft. aermotor (steel mill) taken from Par. **172**. It is obvious from Fig. 26 that both the speed and the load torque increase

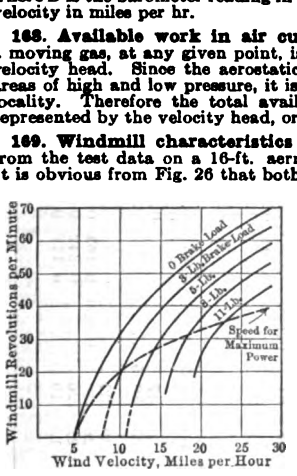

FIG. 26.—Speed curves of 16-ft. Aermotor.

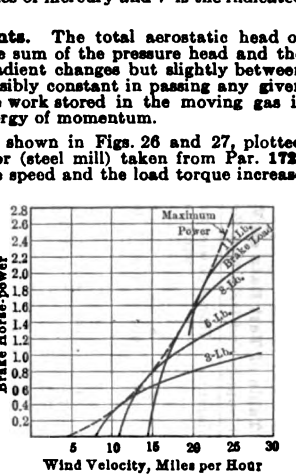

FIG. 27.—Power curves of 16-ft. Aermotor.

with the wind velocity, for maximum output; this is made even clearer by the maximum power curve in Fig. 27. Maximum output therefore requires that the load on the mill, under variable wind velocities, shall have the characteristic of increasing torque with rising speed, in a certain definite manner for any given mill.

**170. Efficiency.** The 12-ft. aermotor (Par. **172**) in a 9-mile wind, at maximum power, had an efficiency of 26 per cent.; this value was computed from the basis of the total wind area of the wheel (12-ft. circle). In a 14-mile wind the efficiency was 23 per cent. Maximum efficiency always occurs with maximum power or output.

**171. Windmill governors.** Practically all forms of vertical mills are equipped with a form of device which throws them partially or wholly out of the wind, when the wind velocity exceeds a certain value. The effect is to prevent excessive or dangerous speeds in high winds or gales.

**173. Comparison of different types of windmills.** Murphy's tests led him to the conclusion that steel wheels are superior to wooden wheels; also that curved sails are superior to flat sails. Furthermore, a relatively small number of large sails will give higher efficiency than a large number of small sails, of equal total area. Steel mills are commonly employed except along the seacoast or in very damp climates, where corrosion is likely to give more than ordinary trouble.

**174. Example of useful work performed in a given period.** Based on the records of mean wind movement at Dodge, Kansas, from 1889 to 1893, Murphy estimated (Water Supply and Irrigation Paper No. 42, Part II, page 118) that steel mills (aermotor) would give the following performances.

| Size of mill | Horse-power-hours per month | | |
|---|---|---|---|
| | Mean | Maximum (April) | Minimum (November) |
| 12-foot..... | 338 | 461 | 245 |
| 16-foot..... | 488 | 671 | 351 |

**175. Height of tower.** The mill should always be placed well above surrounding objects such as trees or buildings, at least 30 ft. On account of competition, the tower weights are kept as low as possible and for this reason steel towers sometimes lack stiffness; wooden towers are usually less objectionable in this respect. It is almost always economical to place the mill at an elevation of 50 ft. or more above the ground, not only to avoid obstacles to free wind movement, but also because wind velocities are known to increase somewhat with the elevation.

**176. Generators** for windmill electric plants are referred to in Sec. 8, Par. **186** and **189**. A shunt-wound machine, with variable-speed drive, requires an automatic regulator for maintaining constant voltage. The differential type of winding, applied to a machine for charging storage batteries, tends inherently to regulate for constant output with variable-speed drive.

**177. Automatic battery switch.** In order to connect the generator to the storage battery when the speed and the terminal voltage are sufficiently high, and to disconnect the generator when the speed and the voltage fall too low for charging, an automatic switch is employed whose functions are controlled by the terminal voltage of the generator.

**178. Storage-battery reserve.** The necessary reserve capacity in the storage battery, for any given installation, can be determined only by a careful study of the records of wind movement at the place in question. If the periods of calm occur frequently and last for any considerable time, it will pay to consider a gasolene engine for stand-by instead of the extra battery capacity required.

**179. Data on Cost and Capacity of Windmill Electric Plants**
(A. V. Abbott)

| Diam. of wheel (ft.) | Horse-power in 16-mile wind | Total cost of installation | Required capacity of battery (amp-hr.) | Watt-hours delivered per day from battery* |
|---|---|---|---|---|
| 12 | 0.21 | $249 | 5 | 280 |
| 16 | 0.41 | 415 | 10 | 551 |
| 20 | 0.79 | 606 | 32 | 1,762 |
| 30 | 2.40 | 1,344 | 103 | 5,640 |
| 40 | 4.42 | 2,000 | 190 | 10,390 |
| 50 | 6.88 | 3,190 | 294 | 16,170 |
| 60 | 10.00 | 4,179 | 427 | 23,500 |

* Assumed dynamo efficiency, 50 per cent.; battery efficiency, 45 per cent.; assumed daily charge, 8 hr.; wind velocity, 16 miles per hr., for 8 hr. per day.

Digitized by Google

**180. Cost of complete plants.** The data on cost of complete windmill electric plants given in Par. 179 was adapted from a more elaborate table of data in A. V. Abbott's "The Electrical Transmission of Energy," third edition (D. Van Nostrand Co.), New York, 1904, page 649. These figures include the windmill, tower, generator, storage battery and regulator, completely installed. The cost per h.p. is very high, ranging from several hundred dollars upward; however, upon comparing these values of h.p. with those given in the table in Par. 172, it will be seen that the former are rather low. Therefore better results can be expected with steel mills of the most efficient type.

**181. Comparative economy.** In general the windmill electric plant, in the present state of the art, cannot compete with energy supplied from central stations and its field is therefore restricted to rural districts and isolated regions. The annual operating expense, including interest, depreciation, taxes, repairs, oil and attendance, will probably range from 16 per cent. to 20 per cent. of the first cost. The charges for the electric plant will be reduced somewhat if the mill is used for other purposes, such as sawing wood, grinding grain and feed, pumping water, etc. One prominent manufacturer of power windmills considers that a satisfactory electric plant, mill included, cannot be installed for less than $1,000 and regards the gasolene engine as more satisfactory in small plants. The introduction of the low-voltage tungsten lamp has improved the prospects, however, for the windmill-driven plant.

While such plants have not been generally adopted as yet in this country, where as a whole fuel is still plentiful and cheap, much progress has been made in Europe, especially in Germany, where there are several notable windmill installations of considerable size.

It is sometimes the practice with large mills to employ two generators, one of small capacity for use in light winds and one of large capacity for use in moderate winds, while both can be used in heavy winds. A gasolene engine is frequently less expensive as a reserve or stand-by source of energy than a storage battery, especially for long periods of calm.

**182. Literature on windmill electric plants.** The literature on the subject is rather meagre and is scattered through many technical periodicals and publications. The following references are regarded as useful to anyone desiring further information.

## OZONE PRODUCTION

**BY MILTON W. FRANKLIN**

*Engineer Ozone Department, General Electric Company; Fellow, American Institute of Electric Engineers*

**183. General properties.** Ozone is a colorless gas, in ordinary circumstances, possessing the odor of chlorine, or of moist phosphorus. In great thicknesses or under pressure the color is blue, and when liquefied it

Digitized by Google

becomes a dark blue mobile liquid with highly magnetic properties. The chemical formula is $O_3$ and the molecular weight 48; the critical pressure is 125 atmospheres and the critical temperature, −103 deg. cent. It is an endothermic compound and the heat of formation is nearly 33,380 g-cal. per mole. At ordinary temperatures it is relatively stable but it decomposes in contact with organic, or in general, oxidizable matter, and spontaneously at 260 deg. cent. It is practically insoluble in water, 1.5 to 10 mg. per liter being the limits of solution at temperatures of from 2 deg. to 28 deg. cent., according to Maufang.

**184. Formation.** Ozone may be formed in various ways, which are: (a) by chemical action; (b) by electrolysis; (c) by the electrostatic field; (d) by ultraviolet rays; (e) by the radioactive elements; (f) by incandescent solids: (g) and by the evaporation of water. Only the production by the electrostatic field has been developed commercially. The theory of this method is not fully understood but it is probable that ionisation by collision takes place, with consequent dissociation of the oxygen which on recombination furnishes aggregates of ions consisting of molecules with an attached extra atom. Within working limits, in commercial ozone generators, the production is roughly proportionate to the electrostatic intensity above a certain critical value, and with alternating currents, to the frequency employed.

**185. Chemical analysis.** Treadwell and Anneler, in 1905, checked all previous results and finally established the correctness of the method of chemical analysis which is now in general use. This depends on the following reactions:

$$2KI + O_3 + H_2O = 2KOH + I_2 + O_2 \qquad (7)$$

$$2Na_2S_2O_3 + I_2 + 2KOH + H_2SO_4 = Na_2S_4O_6 + 2NaI + K_2SO_4 + 2H_2O \qquad (8)$$

In practice these reduce to the following volumetric equation:

$$1{,}000 \text{ c.c. } N/10\,Na_2S_2O_3 = O_3/20 = 48/20 = 2.4 \text{ gm. } O_3 \qquad (9)$$

The sample of ozonized air of measured volume is drawn through a neutral solution of KI and titrated with $Na_2S_2O_3$ or it may be collected in a calibrated flask and shaken with the neutral KI solution. The mixture of KI and $I_2$ is acidified with an equivalent of $H_2SO_4$ before the titration. It is customary to denote the amount of ozone in terms of gm. per cu. m. of air and to reduce the readings to spt.

**186. Ozone generators** have been made in various forms. The essential principle in all cases is the juxtaposition of two or more discharging surfaces so as to form a condenser with an air gap which may or may not be furnished with a dielectric element. The discharging surfaces may be smooth or armed with points, and if smooth they may be flat or curved. Ozonators without dielectrics generally possess rotating electrodes, so that they are in relative motion in order to avert sparking which favors the formation of nitrogen oxides and the destruction of ozone already formed. The great majority of successful ozone generators have smooth electrodes and dielectrics, and are divisible into two types, the cylindrical and the plate.

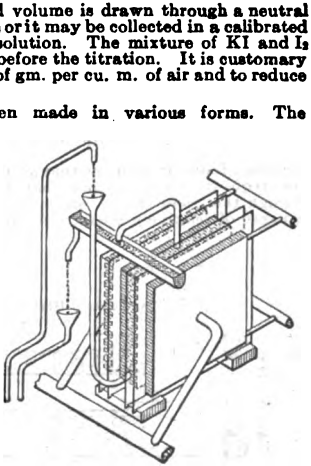

FIG. 28.—Plate ozonator.

**187. A typical form of plate ozonizer** is shown in Figs. 28 and 29. The two outer plates are pierced at the centre, and the ozonized air is aspirated through tubes inserted in the holes. The air enters at the peripheries of the plates and passes through the field to the centre. Cooling is effected by means of flat rectangular water boxes in contact with the two outer plates, and with a similar box in contact with and between the two inner plates. The two outer boxes are earthed; the inner box is insulated and forms

Digitized by Google

the high-potential element of the ozonator. The boxes are all furnished with circulating water, that in the inner, high-potential box being introduced and removed by allowing the water to fall through the air a distance sufficient to ensure against wasteful electrical leakage. The whole structure is commonly contained in a glass retaining case into which suitable dry air is introduced. The advantage of this type of ozonator is that as the field is produced between the two glass plates, the labor necessary to keep the machine clean is nominal. The disadvantages are as follows: difficulty of assembling and taking apart, high potential required, complexity of the cooling system, large space occupied and danger of shut down of the whole system through the failure of one unit.

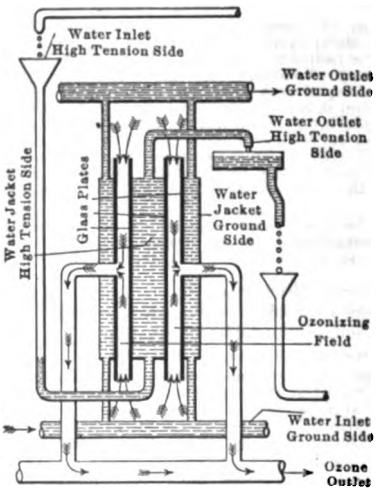

FIG. 29.—Plate ozonator.

**188. Operating voltages.** Commercial ozonators are commonly operated on voltages ranging from 5,000 to 20,000 and at frequencies of from 50 to 500 cycles per sec., and are used in connection with transformers. Special high-frequency generators are generally furnished in all but the smallest installations, for the capacity of an ozone generator is almost proportional to the frequency employed.

**189. Refrigeration of air supply.** An essential to successful and economical ozonizing is dry dense air and consequently most installations, excepting very small ones, include a means for refrigerating the air. It has been found in practice that air cooled to about zero Centigrade possesses the requisite dryness, and that further cooling is uneconomical because, though the yield of the ozonator is increased, this is secured only at the expense of relatively greater cost for refrigeration.

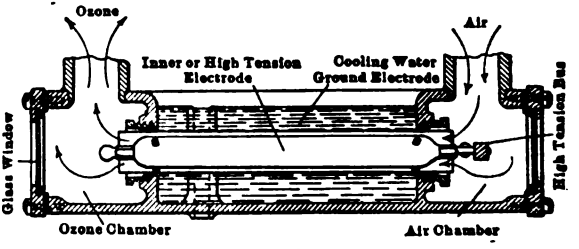

FIG. 30.—Tubular ozonator.

**190. Tubular ozonizers.** A representative tubular unit is shown in Figs. 30 and 31. This consists of a cast-iron frame with two closed bulkheads connected together by the ozone tubes in much the same way as in a water

Digitized by Google

tube boiler. Within these tubes, which are of glass, the cylindrical high-potential electrodes are placed coaxially. The outer tubes are immersed in water which forms the ground element, while the inner high-potential elements are connected to the circuit by means of suitable contacts on a bus bar whichis carried into the air header through insulating bushings. The air is introduced into the rear header and passes through the tubes to the front, whence it passes into the ozone collecting pipe. This machine requires cleaning from time to time, but the operation is simple and quickly performed. The door of the ozone header is removed, the inner electrodes are drawn out and the tubes are cleaned with a swab.

The advantages of the tubular osoniser are compactness, relatively low voltage (about one-half that of the plate machine), readiness with which it may be assembled and taken apart, simplicity of the cooling system, and facility with which one or more units may be inserted or taken out.

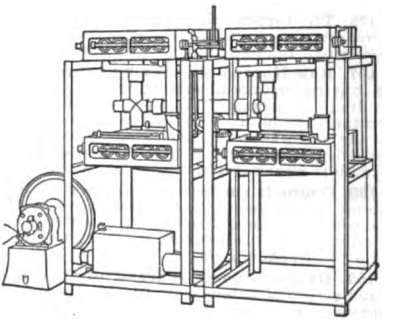

FIG. 31.—Tubular osonator.

**191. Concentrations and yields.** For most industrial purposes the concentration should be in the neighborhood of from 1 to 3 g. per cubic meter of air, although in some special cases it may be as high as 5 g. It is rarely found expedient to operate at greater concentrations. The average yield is about 50 g. per kw-hr., and although much higher yields are claimed from time to time for certain types of generators, these have not been attained in commercial operation.

**192. Oxidising effect of ozone.** The applications of ozone are dependent upon the fact that it is a powerful oxidising agent, and that it oxidises most substances at temperatures far below those at which they are capable of combining with ordinary oxygen.

**193. Ventilation.** Ozone is used in ventilation chiefly on account of its power of destroying organic odors. It has been shown that it is capable of oxidising the odors arising from various animal and industrial activities, for instance those of valerianic acid, butyric acid, skatol, indol, decayed foods, fish, tanners' scrap, manure, etc. The causes of distress in vitiated air are heat moisture and crowd odors. It is not believed that the organic excreta causing the latter are poisonous, although admittedly objectionable. Prof. Bass recently has conducted experiments on school children, which have established the fact that the addition of about one part of ozone in a million parts of air determines the difference between tolerable and intolerable conditions, when the air supply is very small.

**194. Bactericidal power.** It was at one time supposed that on account of the very great bactericidal power of ozone it would prove valuable in disinfecting the air of dwellings and factories, but it has been shown that in breathable concentrations it has little effect on the dry bacteria in the air; this, however, is immaterial, as it is now generally conceded that the dried bacteria in the air are not concerned in its vitiation nor in disease transmission. In suitable concentrations ozone may be used for disinfecting and deodorising rooms that have become contaminated or infected.

**195. Water purifications.** The purification of potable water constitutes the most important application of ozone, in point of magnitude, up to the present time. The advantages of the method are the non-poisonous nature of the reagent; its insolubility which ensures against an excess remaining in the water; and the fact that besides rendering the water sterile, it removes all taste and odor which might be due to organic defilement.

Digitized by Google

Water, to be ozonised, ordinarily requires filtering to remove the bulk of the organic matter, about 97 per cent. being thus eliminated. The ozone is relied upon to destroy the bacteria smell, taste and color which may persist after the filtering, which need be only roughly done. The ozone is introduced into the water under pressure and is caused to become intimately mixed with it by suitable mechanical means, such as agitation or forcing it through the interstices between broken rock or the like, or through sieves.

The cost of water purification by ozone is given by Erlwein as ranging from about $6.75 to $7.50 per million gallons, which includes all expenses such as interest and depreciation, and maintenance. The amount of ozone used, ranges from about 2 g. to 15 g. per 1,000 gal.

**196. The technical applications of ozone** are very numerous and are increasing daily in number. Oils, fats, tallows and waxes may be bleached, deodorised, rendered tasteless and otherwise purified by means of ozone.

**197. Raw linseed oil may be converted into a good drying varnish by having ozone blown through it.** At ordinary temperatures this results in bleaching of the oil and in increased viscosity. At elevated temperatures the oil darkens and it may be completely dried so as to be useful for the manufacture of linoleum. Raw menhaden oil may be clarified, deodorised, bleached and greatly thickened in the same manner. Raw cotton-seed oil is bleached and deodorised besides being rendered viscous.

**198. Ozone is successfully applied to bleaching** cotton, linen and silk fabrics. It possesses great advantages over chlorine in that it is non-poisonous and need not be mixed in vats which suffuse the buildings with fumes. The use of ozone averts the necessity for handling, storing the bleach, and mixing the chlorine bleaching liquors.

**199. Ozone is used successfully for drying oil varnishes,** as in the manufacture of patent leather. If it is mixed with varnish, the latter dries quickly and evenly throughout its thickness, and if varnished surfaces are exposed to ozone it causes the formation of a protective surface while the underlying layers harden more slowly.

**200. Ozone is applied to the cold-storage industry.** For many substances there exists a critical temperature below which they may not be stored without danger of damage, and above which bacterial proliferation and other putrefactive causes result in deterioration. It is difficult to maintain these critical temperatures in rooms, the doors of which are being opened and shut constantly, and it has been found that with the aid of ozone all deleterious processes may be suppressed even though the temperature rises several degrees above the critical point.

**201. In the brewery, ozone is becoming widely used.** It is useful in sterilising and drying the casks and in providing water of unsurpassable quality for the purpose of brewing. Recent researches have shown that it increases the power and activity of yeast.

**202. Purification of sewage.** It has been proposed to apply ozone to the purification of sewage, and while this is a subject of much experimentation, so far no instance of successful application has been recorded.

# RADIOACTIVITY AND THE ELECTRON THEORY

BY EDWIN P. ADAMS, PH.D.

*Professor of Physics, Princeton University*

## RADIOACTIVITY

**203. The radioactive elements** are those whose atoms spontaneously break down, or disintegrate, with the expulsion of electrically charged particles; these particles are of two kinds, forming the $\alpha$ and $\beta$ rays.

**204. The $\beta$ rays.** These are made up of negatively charged particles, carrying the elementary charge: $e = 1.6 \times 10^{-20}$ expressed in absolute c.g.s. electromagnetic units. They are projected with velocities within a wide range of limits, some approaching within 1 per cent. of the velocity of light. The mass of these particles cannot be determined directly, but the ratio of the charge to the mass can be measured. The results show that the $\beta$ particles from all radioactive substances are identical. According to the theory of a

Digitized by Google

moving charged particle, its effective mass should increase with its velocity, but only appreciably when its velocity approaches that of light; a particle moving with the velocity of light would have an infinite mass. This prediction of theory is borne out by experimental results. The ratio of charge to mass for particles whose velocities do not exceed $3\times10^9$ cm. per sec. is found to be $1.77\times10^7$ in absolute c.g.s. electromagnetic units. Thus the mass of a single $\beta$ particle is $10^{-27}$ grams. The $\beta$ particle is the smallest known mass.

**205. The $\alpha$ rays.** These are formed of positively charged atoms of helium, carrying a charge double that of the elementary charge carried by the $\beta$ particles. They are projected with definite velocities from the different radioactive substances, varying from $1.45\times10^9$ to $2.22\times10^9$ cm. per sec.

**206. The $\gamma$ rays.** In addition to the $\alpha$ and $\beta$ rays, which are formed of charged particles, radioactive substances also emit another type of radiation, the $\gamma$ rays. According to theory, when a rapidly moving charged particle is accelerated, either positively or negatively, an electromagnetic pulse spreads out from it. It is probable that the $\gamma$ rays are made up of a succession of these pulses, arising, mainly, from the sudden liberation and sudden stopping of the $\beta$ particles. There is evidence that the $\alpha$ rays also produce $\gamma$ rays.

**207. The $\delta$ rays.** When an $\alpha$ particle is ejected from an atom, the residue is negatively charged. It must move in a direction opposite to that of the $\alpha$ particle so that its momentum is equal to that of the particle. The $\delta$ rays are formed of the residues of the atoms after expulsion of $\alpha$ particles.

**208. Effects produced by the rays.** The $\alpha$, $\beta$, and $\gamma$ rays produce both photographic and ionising effects. To show the former effect, a photographic plate is exposed to a radioactive substance. It is found to be affected just as if it had been exposed to light. The ionising effects are shown by their rendering air a conductor of electricity. The neutral molecules of air are split into positive and negative ions through the action of the rays. When a potential difference is applied, these ions travel in opposite directions, thus setting up an electric current. The photographic effect is caused mainly by the $\beta$ and $\gamma$ rays and the ionising effect by the $\alpha$ rays.

**The ionising effect is employed to measure the "activity" of a radioactive substance.** Metallic uranium is taken as a standard, and by an activity of 100 times, is meant that the substance produces 100 times the effect of an equal weight of metallic uranium in rendering air a conductor of electricity under the same conditions.

**209. Radioactive disintegration.** The atoms of any radioactive element break down according to the law $N = Ne^{-\lambda t}$. $Ne$ is the number of atoms initially present, $N$ the number after a time $t$ has elapsed, and $\lambda$ is a constant which has a definite value for each radioactive substance. External conditions are found to have no effect on the rate of disintegration. For example, the same value of $\lambda$ is found whether it be measured at the temperature of liquid air or at the high temperature of an electric furnace. Thus radioactive disintegration is a phenomenon of an altogether different kind from any known chemical change.

**210. Radioactive elements.** Of the chemical elements that have long been known, only uranium and thorium have marked radioactive properties. There is considerable evidence that rubidium, potassium and sodium are also radioactive, but to a much less degree. In fact it is not improbable that all the elements are radioactive, the rate of disintegration of all but a few of them being too slow for detection. The phenomenon of radioactivity must be regarded as evidence of the instability of the atoms of the elements. The most unstable atoms are those belonging to the most radioactive elements. There is an enormous difference in the rate of disintegration of the different radioactive products. For example, uranium decays to half its initial amount in $5\times10^9$ years, while actinium $A$ requires but 0.002 sec. for half of it to disappear.

There are three known series of radioactive elements, the uranium series, the thorium series, and the actinium series; it is not improbable that the last two series, as well as the first, have uranium as their parent. In each of these series, any member arises from the previous one by a radioactive disintegration, accompanied by the expulsion of an $\alpha$ or a $\beta$ particle, resulting in the formation of an atom of a different kind. In the uranium series is

Digitized by Google

found radium, the best known of the recently discovered intensely radioactive elements. There is some evidence that the final member of this series is lead.

**211. Radioactive equilibrium.** A series of radioactive elements is in equilibrium when just as much of any one of the intermediate products is formed in a certain time as disintegrates in the same time. In the uranium series, the constant $\lambda$ of the disintegration of uranium itself has a value such that $5 \times 10^9$ years elapse before a given amount of uranium decays to half its initial value. Thus millions of years are necessary for the uranium series to come to equilibrium. In most uranium minerals the equilibrium condition is satisfied, so that there is a definite relation between the amounts of uranium and radium contained in them. It is found that the amount of radium associated with 1 g. uranium is $3.4 \times 10^{-7}$ g.

**212. Heating effects.** The continual emission of particles projected with high velocities from radioactive substances results in heating effects. The kinetic energy of the particle is transformed into heat. The $\alpha$ particles produce about 90 per cent. of the heating effect; while their velocities are lower than those of the $\beta$ particles, their mass is so much greater that the kinetic energy of an $\alpha$ particle is many times greater than that of a $\beta$ particle. One gram of radium in equilibrium with all of its products sets free approximately 118 cal. of heat per hr.

**213. Radioactive minerals.** The principal source of radium and the other strongly radioactive elements of the uranium and actinium series is the mineral pitchblende, which is an oxide of uranium. From this radium may be separated by chemical processes, its behavior being the same as that of barium from which it is separated by fractional crystallization. Carnotite is another uranium mineral, but of rarer occurrence. The principal source of the elements of the thorium series is monazite sand.

**214. Uses of radium.** Aside from its great scientific interest, the only important use of radium is as a therapeutic agent. Many cures of cancerous growths have been reported to result from its application.

**215. Mesothorium,** one of the members of the thorium series, is coming to be employed widely as a therapeutic agent. It has the advantage over radium of being easier to obtain. It is found in the residues left in the manufacture of thorium salts used in making Welsbach gas mantles. But it is far less permanent than radium. While 2,000 years must elapse for a given amount of radium to decay to half its amount, a given amount of mesothorium is reduced one-half in less than 6 years.

**216. Determination of physical constants.** The study of radioactive phenomena has resulted in the most reliable determination that we have of certain important physical constants. Some of these are given in the following table:

| | |
|---|---|
| The elementary electric charge | $1.59 \times 10^{-20}$ |
| Number of molecules in 1 c.c. of a gas at 0 deg. Cent. and 760 mm. pressure of mercury | $2.7 \times 10^{19}$ |
| Mass of the hydrogen atom | $1.65 \times 10^{-24}$ g. |
| Number of atoms of hydrogen in 1 g. | $6.0 \times 10^{23}$ |

**217. Bibliography.**

RUTHERFORD.—"The Radioactive Substances and Their Radiations." New York, G. P. Putnam's Sons, 1914.

## THE ELECTRON THEORY

**218. The electron.** The electron theory is built upon the observed wide distribution of electrons or corpuscles and their capability of accounting for many otherwise unexplained phenomena. Electrons are identical with the beta particles; the latter term is used to denote them when they appear accompanying radioactive disintegration. Electrons appear also under the name of cathode particles, when they are projected from the negative electrode, or cathode, by an electric discharge through a gas at low pressure. Ultra-violet light falling upon the surface of a metal sets electrons free; they are also liberated from incandescent solids. Whatever their origin, all electrons appear to be identical in nature. Their velocity of projection depends upon the circumstances under which they appear, but the ratio of their charge to their mass is the same for all except for the highest velocities of

Digitized by Google

projection; this ratio diminishes with increase of velocity according to the same law in every case. The conclusion is forced upon us that the electron is the one common constituent of all matter. We cannot go so far as to say that matter is built up wholly of electrons, for some means has to be found for holding the electrons together against their mutual repulsion. For this purpose, positive electricity is assumed, but our knowledge of this is meagre compared to our knowledge of negative electricity. The electron may be regarded either as a particle of matter charged with negative electricity, or as a particle of electricity endowed with mass in virtue of its motion.

**219. Interpretation of electric phenomena in terms of the electron theory.** In a conductor, in addition to the electrons contained in the atoms, which, in part, form the atoms, it is assumed that there are free electrons which pursue zigzag paths among the atoms. When the conductor is all at one potential there is no more tendency for these free electrons to travel in one direction than in any other. But when a difference of potential is applied to the conductor there is a force acting on the electrons driving them in a direction opposite the force, since they are negatively charged. Thus there is a drift of electrons in one direction, and this drift constitutes the electric current. An electric current, therefore, is to be regarded as a flow of electrons. In a perfect insulator, there are no free electrons but only those contained in the atoms. Thus there can be no continuous flow of electrons, *i.e.*, an electric current, in an insulator, under a constant electric force. When an electric field is applied to an insulator, the electrons inside the atoms move from their normal equilibrium positions until the forces of the external electric field balance the forces on the electrons arising from the atoms. There is thus a momentary flow of electrons inside the atoms and this constitutes the displacement or dielectric current. The displacement of the electrons from their normal position inside the atoms under the influence of an external electric force constitutes the polarization of the insulator.

**220. Thermoelectric effects.** The free electrons inside a conductor may be considered as moving about exactly as the molecules of a gas. They thus exert a pressure corresponding to the pressure of a gas on its enclosure. This electronic pressure varies for different metals so that if two different metals are in contact there will be a greater pressure of electrons on one side of the junction than on the other. Suppose now that we have a closed circuit consisting of two different metals, with, therefore, two junctions. Let the two junctions be at different temperatures. As in the case of gas pressure, the higher the temperature the greater the pressure. So there will be a greater pressure driving the electrons from, say, metal $A$ to metal $B$ at junction 1, than from $A$ to $B$ at junction 2. There will thus be a steady flow of electrons around the circuit, constituting the thermoelectric current.

**221. Magnetic effects on the electric current.** An electron in motion constitutes an element of an electric current. So that if a magnetic field is applied, there will be a force acting on the electrons in a direction perpendicular to both the direction of motion of the electron and the magnetic field, and proportional to the sine of the angle between them. Suppose now that in a metal plate there is an electric current from left to right, and therefore a flow of electrons from right to left. Let the plate be placed in a uniform magnetic field perpendicular to it, the electrons will then be acted upon by forces in a direction perpendicular to their motion, and they will therefore traverse shorter distances measured in the direction of their drift between collisions with the atoms of the metal, and thus the resistance of the metal will apparently be increased. This effect, which is observed in all metals, is especially marked in bismuth, and is made use of in measuring magnetic fields; the increase of resistance of bismuth is a measure of the strength of magnetic field.

**222. Hall effect.** If, in the case just considered (Par. 221), the ends of a wire be joined to two points at the ends of a line on the plate, which line is perpendicular to the direction of the current, a current will flow through this branch circuit when the magnetic field is applied. This is the "Hall effect," and may be explained by the bending of the paths of the electrons by the magnetic field which drives them through the branch circuit. According to this view, the Hall effect should have the same sign for all metals, *i.e.*, with the primary current kept in the same direction and the magnetic field in the same direction, the secondary current through the branch circuit should flow

Digitized by Google

in the same direction whatever metal is used. This is found, however, not to be the case. It is probable that the assumptions made are of too simple a nature; that the more complicated structure of a metal must be considered, which is itself affected by the magnetic field.

**222. Magnetism.** In order to account for the magnetic properties of bodies it has been found necessary to consider the electrons contained in the atoms. We may consider the atoms as containing electrons circulating in closed orbits. It is a fundamental theorem in electromagnetism that a small closed current is equivalent, as far as its external effects are concerned, to a magnetic particle perpendicular to the plane of the current. An electron circulating in a closed orbit is equivalent to a current flowing in a closed circuit. So that if each atom contains a single circulating electron, it will be itself a magnet, *i.e.*, it will have a resultant magnetic moment. But it is necessary to suppose that the atoms contain many electrons, and so it may happen that the magnetic moments of the different circulating electrons will neutralise each other, in which case the atom will have no resultant magnetic moment. When this is the case, the theory shows that the effect of an external magnetic field is to modify slightly the electronic orbits in such a way as to make the atoms exhibit a diamagnetic property. On the other hand, the magnetic moments of the different electrons may not neutralise themselves so that the atoms have a resultant magnetic moment. In this case the atoms show a paramagnetic property. The effect of the external magnetic field is to orient the atoms in the same sense, and the substance as a whole becomes magnetised.

**224. Electrons in optical theory.** The electron theory has had its greatest triumphs in the field of optics. Let us consider first the part electrons play in the emission of light. According to our present view, light waves are of an electromagnetic nature. There is no difference between a train of light waves and a train of electromagnetic waves produced electrically except in wave length. The limitation as to the dimensions of the apparatus used in producing electric waves leaves a wide interval between the longest light or heat waves and the shortest electric waves. An electron circulating in an atom in a circular path is a generator for electromagnetic waves. The known order of magnitude of atomic size, and the known value of the charge and the mass of the electron enable us to calculate the wave lengths of the light so generated. The result is something of the order of magnitude of the known wave lengths of visible light. This in itself is an important result as it is the only mechanism known which leads to estimates of this magnitude.

When an incandescent gas is placed in a magnetic field it was discovered by Zeeman that some of the spectral lines become split up into a number of components. One frequent case is that of the splitting up of a single line into two or three components, depending upon whether the magnetic field is along the line of sight or perpendicular to it. This is accounted for by the change in the electron orbits produced by the magnetic force. An electron in motion behaves just as an element of a linear current; so in a magnetic field there is a force upon the electron at right angles to the motion and to the magnetic field. This force has the opposite direction for an electron moving in the opposite direction. The electrons circulating in one direction inside the atoms will thus have the radii of their orbits increased, and those circulating in the opposite direction, diminished. The frequency of the light emitted depends upon the radius of the orbit. Thus a spectral line, which corresponds to a definite frequency when no magnetic field is applied, splits up into two or three lines in a magnetic field. In addition, it is found that the two outer components are circularly polarised in opposite directions, which is what this theory demands. The distance between the spectral lines may be measured, and from this the ratio of charge to mass may be deduced. The results of this wholly independent method of determining the ratio of charge to mass, are so close to the values obtained for the cathode particles and the beta particles from radioactive substances, that there is little doubt but that the centres of light emissions are electrons—the same as the cathode and beta particles.

# ROENTGEN RAYS

BY EUGENE W. CALDWELL, M.D.

**226. Discovery.** In December, 1895, William Conrad Roentgen, then Professor of Physics at the University of Wurtsburg, announced that while experimenting with the vacuum tubes of Lenard, he had discovered a new form of radiation which he called X-ray, because its exact nature was unknown.

**227. Properties.** These rays differ from the cathode rays previously discovered by Lenard in having greater penetration and in not being deflected by magnets.

Roentgen found that these rays would pass through materials opaque to ordinary light and set up fluorescence in crystals of barium platinum cyanide. He found that they could not be sensibly refracted or reflected by any materials available; that they were not deflected by a magnetic field; that they penetrated different materials in a ratio approximately inversely proportional to the atomic weights, and that they acted like light on the silver salts used in photography.

**228. Transparency of Various Substances to X-rays**

**229. Secondary rays.** Roentgen showed that rays similar in all respects to X-rays but of comparatively small quantity were set up in most materials when X-rays passed through them.

**230. Characteristic rays.** J. J. Thompson has shown that when X-rays strike metallic plates such as copper, silver, lead, etc., new rays are set up at the metal surfaces, having penetrating properties peculiar to the metal

Digitized by Google

from which they arise and independent of the penetration of the rays producing them.

**231. Theory.** The exact nature of the X-ray is still under discussion. The most commonly accepted hypothesis is that it is a disturbance of the luminiferous ether similar to visible light, but having much shorter wave length than ultra-violet light.

**232. Conditions necessary for production.** When an electrical discharge is passed through a vacuum tube exhausted to a Crookes vacuum (much higher degree of exhaustion than in the tubes of Hittorf, Geissler and Lenard) X-rays are produced wherever the cathode stream is arrested by the walls of the tube or metallic objects therein.

**233. Cathode stream.** The cathode stream is believed to be a discharge of negatively charged electrons from the surface of the cathode.

**234. X-ray tubes.** The so-called focus tube, in which a concave cathode focuses the cathode stream upon a flat metallic target is the one used in practice. The construction of these tubes is a highly developed specialty of the glass blowers' art.

**235. Penetration or quality of X-rays.** (Soft and hard rays.) The penetrating quality of X-rays depends chiefly upon the potential difference maintained between the terminals of the tube, and upon the nature of the metal forming the target. For ordinary medical uses tubes are made with platinum- or tungsten-faced targets and are operated at from 60 to 90 kilovolts. Low penetration ("soft") rays are produced at 25 to 30 kilovolts, and are largely absorbed by the glass wall of the tube and by soft tissues of the body. High penetration ("hard") rays produced at 90 or 100 kilovolts may be detected after passing through steel ½ in. thick.

The potential difference at terminals of tube and the penetration of rays, increase with increase of current strength in tube but not in the same ratio. The resistance of the X-ray tube depends upon many factors among which are: (a) the degree of vacuum maintained (the resistance increases with high vacuum); (b) the distance between the nearest points of the two electrodes. With other conditions constant the resistance will be higher when the electrodes are near each other. The resistance will be higher when by long use the occluded gases have been exhausted from the surfaces of the electrodes.

**236. Regulation of tubes.** The regulation of the quality of the ray is usually effected by varying the degree of vacuum of the tube. This is accomplished in one of several ways.

(a) **By use of the osmosis regulator (Villard).** A silvered palladium tube 1 or 2 mm. in diameter sealed into a glass bulb, when heated to red heat becomes porous to the hydrogen in the flame and allows the gas to pass into the bulb, reducing the vacuum.

(b) **Certain crystals,** such as sodium and potassium hydrate and sodium formate, are sealed into auxiliary bulbs which can be heated either by application of flame externally or by passage of an electrical discharge through them.

(c) **The D. McFarlan* Moore mercury-seal air valve** has been developed by Baker and Bauer for X-ray tubes. A small plug of porous material is sealed by being covered with mercury. When it is desired to introduce air into the tube the mercury is momentarily displaced from the porous plug.

(d) **Coolidge tube.** In this tube the vacuum is as perfect as it is possible to make and no current can be passed through until thermal ions are liberated by heating the cathode which consists of a spiral of Tungsten wire. The tube begins to take current at about 600 volts. The strength of current which may be passed depends solely on the number of thermal ions available, and is practically independent of the voltage. The *quantity* of rays is regulated by varying the temperature of the cathode which determines the strength of current that may be passed through the tube. The heating of the cathode is effected by passing through the tungsten spiral a current of about 4 amp. from a battery of about 10 volts. The penetration of the rays is varied by adjusting the voltage across the terminals of

* D. McFarlan Moore, *Proceedings* Am. Institute Electrical Engineers, April 26, 1907.

Digitized by Google

the tube. The operation of this tube is radically different from that of the tubes which are dependent upon gaseous ions.

Earlier attempts to produce tubes operating on this principle were made by Wehnelt and Lilienfeld.

**237. The electrical generating apparatus** must be capable of maintaining a potential difference of 60 to 80 kilovolts across the terminals of the tube. For ordinary fluoroscopy 2 or 3 milliamperes will suffice, but for rapid Roentgenographic work as much as 100 milliamperes may be used. The induction coil with interrupter is still in common use. For powerful discharges needed in short radiographic exposures, electrolytic interrupters of the Wehnelt or Caldwell type are preferred. For Roentgenoscopy and for therapeutic uses, mechanical interrupters of the vibrating type, rotary breaks or the mercury-jet interrupters are better. (See Sec. 6.) The so-called "interrupterless" machine consists of a high-tension transformer operated in connection with a synchronous rotary rectifier which transmits the peaks of the high-tension secondary discharge to the terminals of the machine always in the same direction. For operation with direct current the rotary rectifier is usually mounted on an extension of the shaft of a rotary converter which supplies the alternating current to primary of transformer. With alternating-current supply the high-tension rectifier is rotated by a small synchronous motor.

Influence machines or so-called electrostatic machines of the Holtz and Wimshurst type may be used, but these are not so reliable or so powerful as induction coil or transformer with rectifiers.

**238. Measurement.** It is customary to measure the current passing through the tube, with an ordinary milliampere meter of d'Arsonval type mounted on an insulating support and having one terminal connected to the metal case. The potential difference across tube terminals is estimated by length of equivalent spark gap. Electrostatic voltmeters may be used for this purpose. There are several more or less commonly used empirical units for both quantity and penetrating quality of X-rays.

**239. Penetrometers.** There are several of these which depend upon the relative degree of transmission of the ray by two dissimilar metals such as aluminum and silver, the silver being especially pervious to the softer rays. The Benoist penetrometer consists of a series of steps of aluminum of varying thickness arranged around a thin disc of pure silver. Reading is made by observing what thickness of aluminum absorbs the same amount of X-rays as the thin disc of silver. In the Wehnelt penetrometer the principle is the same but the aluminum is in the form of a wedge. The electroscope and electrometer have long been used as indicators of penetration. The "Qualmeter" of Bauer is an electroscope provided with the empirical scale of Benoist or Wehnelt. It is connected to the negative terminal of the tube.

The measurement of quantity of X-ray is usually made by comparing, with a standard scale, the change in color produced in a chemical test piece which has been exposed to the rays.* Stern in 1903 proposed to use strips of bromide paper for measuring the dose of X-ray; the strips were developed, after exposure, for a standard time in a standard developer and then compared with a color scale. The Kienboeck quantimeter which appeared a few years later is essentially the same device. Sabarand and Noiré use discs coated with barium platinum cyanide which turns darker when exposed to X-rays.

**240. Principal uses.** The applications of X-rays in medicine and surgery for diagnosis and treatment overshadow all others in importance. Other uses for X-rays are: (a) detection of pearls in pearl-bearing mollusks; (b) customs examination of baggage for detection of smuggled articles; (c) sterilization of tobacco and foodstuffs to prevent hatching of eggs of worms or other parasites; (d) detection of flaws in metals; (e) the sterilization of testes and ovaries of criminals; (f) distinguishing between real and spurious diamonds, the real diamonds being more nearly transparent than the imitation.

**241. Roentgenography.** The so-called X-ray photography for medical or surgical diagnosis should not be undertaken by electricians or photographers. The safe interpretation of Roentgen ray shadows is difficult, and

* S. Stern, *Journal of Cutaneous Diseases*, Dec. 26, 1907.

Digitized by Google

requires special training. Their resemblance to photographs makes them misleading to the inexperienced.

**243. X-ray burns.** The so-called X-ray burns may be acute, *i.e.*, developed from a single prolonged exposure, or they may be chronic, developing gradually as a result of repeated small exposures which, individually, would produce no noticeable effect. The acute burn seldom appears before five days after the exposure and sometimes as late as three or four weeks later. The reddening, blistering and sloughing observed in ordinary burns and due to death of tissue, are present. All X-ray injuries are especially slow in healing. The chronic type resembles the senile keratosis (the horny skin produced by the sun and wind on the faces and hands of old people). These chronic keratoses are classed as precancerous, and when once established are prone to increase and develop into cancerous growths without further exposure.

In the ordinary application of the ray for diagnosis or treatment the danger to the subject is little, but physicians working daily around X-ray tubes must observe caution to escape injury.

To protect the patient, screens of aluminum from ½ to 3 mm. thick are interposed to cut out the rays of low penetration which would otherwise be absorbed by the skin.

The tubes are shielded by being enclosed in chambers composed of metal or lead glass.

The controlling devices are placed behind screens of lead from 2 to 5 mm. thick and provided with lead-glass windows. Protective aprons and gloves, composed of rubber cloth impregnated with lead or bismuth salts are worn by the operator. Eye-glasses or spectacles of lead glass are sometimes used.

**243. Treatment of injuries.** The treatment of X-ray injuries is very difficult and tedious. Surgical removal with skin graft may be necessary. It is extremely important to avoid the use of irritating or stimulating ointments such as the much advertised skin remedies.

The chronic keratoses may be destroyed by freezing with liquid air or carbon dioxid snow, by burning with high-frequency sparks, or by exposure to the rays of radium. These agents all produce a destruction of tissue following by sloughing. Of these, radium is by far the least painful.

**244. Nomenclature.** The terminology of the subject is unsatisfactory. The following terms have been formally adopted by Roentgen societies of England, Germany and United States.

ROENTGEN —Root-word (pronounced rent gen).

ROENTGEN RAY—A ray discovered and described by Wilhelm Konrad Roentgen.

ROENTGENOLOGY.—The study and practice of the Roentgen ray as applied to medical science.

ROENTGENOLOGIST.—One skilled in Roentgenology.

ROENTGENOGRAM.—The shadow picture produced by the action of the Roentgen ray upon a sensitized plate or film.

ROENTGENOGRAPH.—(Verb.) To make a roentgenogram.

ROENTGENOSCOPE.—An apparatus for examination with the fluorescent screen excited by the Roentgen ray.

ROENTGENOSCOPY.—Examination with the Roentgenoscope.

ROENTGENOGRAPHY.—The art of making roentgenograms.

ROENTGENIZE.—To apply the Roentgen ray.

ROENTGENIZATION.—Application of the Roentgen ray.

ROENTGENISM.—Untoward effect of the Roentgen ray.

ROENTGEN DIAGNOSIS.—Therapy—Treatment dermatitis: (self-explanatory).

# LIGHTNING RODS

**BY ERNST J. BERG, SC.D.**

*Prof. Electrical Engineering, Union College*

*Fellow A. I. E. E.*

**245. Source of atmospheric electricity.** Among the many theories propounded that of Dr. George C. Simpson* appears perhaps most rational. In brief he concludes from laboratory experiments with drops of water in air that when such drops are broken up in smaller drops the water becomes positively and the air negatively charged. This fact used in conjunction with Lenards proof that drops larger than 0.2 in diameter are unstable when falling through air and that drops smaller than 0.2 in diameter attain a velocity less than 18 miles per hr., form the basis for the following brief explanation quoted in Dr. Simpson's words.

"It is exceedingly probable that in all thunderstorms ascending currents greater than 18 miles an hour occur. Such currents are the source of large amounts of water which cannot fall through ascending air. Hence at the top of the current, where the vertical velocity is reduced on account of the lateral motion of the air, there will be an accumulation of water. This water will be in the form of drops which are continually going through the process of growing from small drops into drops large enough to be broken. Every time a drop breaks a separation of electricity takes place, the water receives a positive charge, and the air a corresponding amount of negative ions. The air carries away the negative ions, but leaves the positively charged water behind.

"A given mass of water may be broken up many times before it falls, and in consequence may obtain a high positive charge. When this water finally reaches the ground it is recognized as positively charged rain. The ions which travel along with the air are rapidly absorbed by the cloud particles, and in time the cloud itself may become highly charged with negative electricity. Now, within a highly electrified cloud there must be a rapid combination of the water drops, and from it considerable rain will fall; this rain will be negatively charged, and under suitable conditions both the charges on the rain and the rate of the rainfall will be large.

"A rough quantitative analysis shows that the order of magnitude of the electrical separation which accompanies the breaking of a drop is sufficient to account for the electrical effects observed in the most violent thunderstorms. All the results of the observations of the electricity of rain described above are capable of explanation by theory, which also agrees well with the actual meteorological phenomena observed during thunderstorms."

**246. Importance of lightning protection.** Statistics show that in this country, between 700 and 800 persons are annually killed by lightning, and about twice as many seriously injured.† The efficiency of lightning rods for farm houses in the middle west can be judged from statistics gathered by Mr. E. W. Kellogg‡ who concludes that for an equal number of houses rodded and not rodded, the fires due to lightning are approximately 15 times greater with the buildings not rodded than with those which are rodded.

**247. Nature of the discharge.** Sir Oliver Lodge first suggested that there are at least two distinct kinds of discharges, one of which is relatively quiet and which results from the gradual breaking down of the air between the object struck and the charged cloud and another which is a violent secondary discharge caused by a primary discharge in the vicinity.‡ The first kind follows the well-known laws familiar to the electrical engineers—laws that deal with more or less permanent conditions. The nature of the discharge is governed by the resistance, inductance and capacity of the path. The path itself is almost certain to be the rod on account of the conducting streamers above it. The second kind is more complex, and the laws that it follows are less thoroughly understood. There is no conducting path above the rods because there may have been no potential difference between them

* Proceedings of the Royal Society, Series A, Vol. LXXXII, p. 169.

Digitized by Google

and the surrounding air before the discharge. Thus the rods may readily be missed, and the discharge may enter any portion of the roof and find its way to the ground through the building. To guard against these contingencies it would seem that the entire roof should be of metal, or at least largely covered by metal network.

Prof. Flemming has compared the first with the slow combustion of gun powder placed in a room and carefully lighted, the second with detonating powder. In the first case the heated air and gases of combustion are readily guided through the chimney and do no harm; in the second case no matter how large the chimney is, enormous pressures will exist in all directions. The reason for this is that, while the inertia of the air normally is very small and it can readily be displaced, it becomes tremendous when sudden forces are applied; in fact, during the very first instant the air acts as a solid.

**248. Electrical constants of lightning rods.** While the number of oscillations of a lightning discharge in clouds or between clouds and earth is entirely unknown and may perhaps even be zero, it seems necessary that the discharge originating in the vicinity of the rod and carried in the rod must be of very high frequency. In the passing of high frequency currents, energy is expended as heat at the surface of the conductor and as electric radiations in the surrounding space. The ohmic resistance, which depends upon the conductivity and the cross-section of the rod, is of practically no importance; even the shape of the conductor, which is of much importance with frequencies from 100 to 100,000 cycles, possesses relatively little importance at still higher frequencies.

The same applies to the inductance of the conductor—it is also practicably independent of the kind of material or its cross-section. It is evident that, provided the lightning discharge in the rod is a high-frequency oscillation, from an electrical point of view it matters really very little whether copper or iron, flat or round, stranded or solid conductors are used, although there is a slight advantage in flat ribbons at all but the highest frequencies. The object of the lightning rod is to present a path for the discharge, a path offering much less obstruction than any path through the building. If the ohmic resistance were all important this could well be done by using a very large copper rod, but at these very high frequencies the obstruction or impedance is measured in tens or even hundreds of ohms, whereas the ohmic resistance may be but a small fraction of an ohm.

**249. Electrical characteristics of lightning itself.** The greatest number of lightning discharges take place inside clouds or between adjacent clouds. These discharges involve usually rather moderate voltages, and while interesting are hardly within the scope of this paper. The knowledge of the nature of lightning discharges from cloud to earth is, however, of greatest importance in studying the efficiency of lightning rods. Unquestionably such discharges take place not only at moderate voltages, but also at voltages which are exceedingly high; the latter being true when the charged cloud is separated from earth by a layer of more or less dry free air.

Under these extreme conditions the distribution of potential may be fairly uniform, and the air may be charged to its breakdown point all through its mass, in which event the potential difference would be exceedingly great. The maximum value of the discharge current may also be very great, reaching several thousand if not hundreds of thousands of amperes, as may be judged from the consideration of the following simple case. An area on the surface of the earth 100 ft. square is subjected to the discharge of a cloud, also 100 ft. square, at a distance of 1,000 ft. In this case the capacity is approximately 0.000027 microfarads, a very small capacity indeed, something like that of the smallest Leyden jar. If the electric stress as assumed were uniformally distributed throughout the air space separating cloud and earth, and if the disruptive strength of air is 30,000 volts per cm., a potential of 912,000,000 volts would exist between cloud and earth just before the stroke. The electric charge, that is, the amount of electricity stored, would be 0.025 coulombs, a very small value when considered by itself. The energy stored would, however, be great on account of the high difference of potential. It would be 11,200 kw-secs., corresponding to the energy of almost a pound of dynamite. This energy is expended in heat and electric radiation, partly in the stroke before it reaches the rod, partly in the circuit of the rod. The higher the frequency the greater is the relative amount radiated. With a small copper rod the energy radiated at 1,000,000

Digitized by Google

cycles is perhaps 50 times as great as that converted to heat in the rod. Whether, however, the energy is radiated or directly converted to heat is not so material. In either case the maximum current in the rod may be enormous and depends upon the frequency of the discharge. With a lightning discharge this may be from 100,000 to perhaps 5,000,000 per sec., in which case the maximum value of the current is from 15,000 to 750,000 amp., it being proportional to the frequency. Steinmetz* has shown that the impedance or total obstruction of the high frequency conductor is about 0.1 ohm per ft. at 100,000 cycles, 0.5 ohm per ft. at 500,000 cycles, 1 ohm per ft. at 1,000,000 cycles, and 2.5 ohms per ft. at 5,000,000 cycles. Thus the maximum drop of potential per ft. of lightning rod would be 1,500 volts at 100,000 cycles, 9,000 volts at 250,000 cycles, 37,000 volts at 500,000 cycles, 150,000 volts at 1,000,000 cycles and 1,880,000 volts at 5,000,000 cycles.

**250. Relation of frequency to other factors.** While in every discharge almost an infinite number of frequencies undoubtedly are represented, it is probable that one is preponderating. Were it permissible to consider that the frequency in the discharge after it reaches the rod is governed only by the electrical constants of the rod, the wave length would be somewhat more than four times the height of the rod. This would mean with an ordinary dwelling, with a rod of say about 50 ft., about 5,000,000 cycles. If on the other hand the effect of the rod is hardly noticeable and the frequency is governed by the distance between cloud and earth, the frequency will be much lower, say 250,000 cycles, with a distance of 2,000 ft. between the cloud and earth.

In the first case the drop in potential per ft. is about 2,000,000 volts, in the second case only 9,000 volts. The first case gives an idea of the conditions of a secondary stroke. It is of very high frequency and may be the result of the discharge of the air immediately surrounding the rod rather than the entire air between cloud and earth. The discharge area is in this case difficult to estimate; it may be quite limited or it may be quite great.

Assuming again an area of 100 ft. square and calculating the voltage and capacity, it is found that the capacity is increased in the same proportion as the voltage is decreased; therefore the charge and maximum vale of the current remains unchanged. The maximum value of the current would be, say 750,000 amp., and the drop per ft. of rod about 2,000,000 volts.

It is evident that only a very small part of such discharge would travel through the conductor, and that the main discharge would jump several feet in the air rather than travel 1 ft. in the conductor. (The drop in potential of 2,000,000 volts per ft. corresponds to 2 ft. striking distance between parallel planes and perhaps 10 ft. distance between projecting masses of metal.)

The second case is approached when a lightning discharge takes place from cloud to rod after a conducting path has been prepared by means of streamers. It is the first, the quiet type of lightning mentioned in the beginning of the paper.

**251. Advantage of multiplicity of rod.** A single lightning rod may be expected to take care of low frequency discharge from cloud to earth, but is entirely inadequate to cope with a violent secondary discharge, even if it struck the rod instead of the building proper.

One lightning rod, while offering some protection, may be considered, under abnormal conditions, entirely inadequate to cope with the situation. If the buildings were grounded by ten rods the condition would be much improved, and the lightning discharge would probably be confined to the system of rods.

**252. Installations.** Experience seems to have settled beyond reasonable doubt, that, if properly installed, lightning rods afford considerable protection. A large number of instances might be quoted, but suffice it here to mention only one. Before equipping the buildings of The University of Illinois with rods, three fires were caused by lightning; since that time, though the number of buildings has been greatly increased, there has been no damage from lightning. It should be remembered, however, that a rod faultily installed may make matters worse than would be found where no rods were used. Assume, for instance, that a large building is equipped with a high but broken rod having poor joints or a high resistance to ground, say several hundred ohms, which undoubtedly sometimes is the case. Such a rod could serve the function of equalizing the potential between cloud and earth almost

* "Transient Phenomena." McGraw-Hill Book Company, Inc.

Digitized by Google

as effectively as a good rod, and were there only a sufficient number of them it is conceivable that the neutralisation of potential would be so complete as to make a flash discharge practically impossible. A building having one rod only, however, is considered at present. The rod is assumed as projecting considerably above the building. If the electric tension is great, unquestionably streamers are emitted, the air above the rod is made fairly conductive and thus the discharge is invited. The question is then: How can such a rod take care of the discharge? It has been shown how the discharge current frequently is very large and while the ohmic resistance of the rod is practically immaterial as long as it is at all reasonable, it must not approach or exceed the normal value of the impedance. In a rod, say 30 ft. long, the ohmic resistance of even the smallest practicable iron conductor is a fraction of an ohm only and the impedance is perhaps 30 to 75 ohms, depending upon the height and frequency of the discharge. It is easily seen that a poor joint may have many times this resistance; therefore, when the discharge encouraged by the streamers from the defective rod strikes the building it finds the rod entirely inadequate to cope with the situation. The voltage drop in the rod is so great that it is far easier for the current to split up in a number of paths and enter through the building than to confine itself to the rod. An apparent paradox thus exists. The rod should have good joints, should have good ground connection, and should be mechanically secure against breaking; although the shape of the rod, its metal or its general dimensions are rather immaterial.

**253. Location.** The rods should always be placed outside of the building and it is indeed a question whether the vertical part of the system, that is, the rod proper, should not be some little distance from the wall and possibly even insulated therefrom. They should be placed a considerable distance from gas pipes, stove pipes, water pipes and balconies or places where persons might be during a storm.

**254. Material and construction.** Lodge's experiments and theory show conclusively that there is no advantage in copper over iron. Copper may have mechanical advantages under certain conditions, for instance in cities where the atmosphere is charged with soot and a variety of fumes. Galvanized iron has the advantage of cheapness, with a possible electrical superiority. While flat conductors have a very slight advantage, it appears too small to be considered seriously. A round wire or a pipe can be handled conveniently, and seems preferable. In the installation of the rods, sharp bends should be avoided as much as possible. There is little or no advantage in using large and expensive copper conductors or cables; a size mechanically satisfactory is likely to serve all electrical purposes. Expensive sharp points offer little advantage over ordinary rather blunt points. The rods may advantageously terminate in a number of points projecting only a short distance above the part to be protected.

**255. The ground connection** should be of low resistance, and therefore the rods should preferably terminate in moist soil. "Salting" the ground may be an advantage, but experience with such grounds is not sufficient to warrant its adoption unless an occasional inspection is made. In many cases excellent connection can be made by driving a galvanized gas pipe a few feet into the ground. In installing the rod, allowance for expansion and contraction should be made. Gas pipes should not be connected to lightning rods, nor should the rods be placed in too close proximity to them.

**256. Precautions.** A building having its windows and doors open, affords opportunity for the entrance of air, perhaps ionized air made conductive by a previous discharge. It is, therefore, safer to keep the house closed during a violent storm. It is also well to keep away not only from the rod but from chimneys, kitchen ranges, metal pipes, etc.

The damage by lightning in cities is relatively small, and so far the modern sky scraper, with its vast amount of steel, appears to be lightning proof.

## ELECTROSTATIC MACHINES

**BY OTIS ALLEN KENYON**

*Consulting Electrical Engineer, Assoc. Amer. Inst. Elec. Eng.*

**257. Classification.** There are two fundamental types of electrostatic generators, namely, those in which the e.m.f. is generated by contact of

Digitized by Google

two unlike substances and those in which it is generated by electric induction; the former are called frictional machines and the latter are called influence machines.

**258. Frictional machines.** In a circuit composed of unlike materials there exists a difference of electric potential at the junction of these materials. However, from the law of the conservation of energy, no electricity will flow in the circuit unless energy from an external source is applied thereto. In frictional machines the energy which produces the flow of electricity is supplied by the heat due to mechanical friction.

**259. Electrical Series***

(Riess)

| Positive | Negative |
|---|---|
| Fur, human hair | Glass, porcelain, wood, metals, rosin, sulphur. |
| Glass | Zinc—tin amalgam on leather (sure). |
| Fur, wool, linen, silk, paper, metals | Rosin, sealing wax, sulphur, shellac, amber (sure). |
| Diamond, topaz, thummer-stone, quarts, calcareous spar, mica, polished glass. | Wool, linen, silk, leather. |
| Glass, silk | Metals. |

**260. Theory of frictional machines.** When two unlike bodies are rubbed together, the energy applied is partly stored by the establishment of a dielectric field and partly dissipated as radiated heat. The dielectric field established while the two bodies are in contact causes electricity to flow to the surface of the bodies, a positive charge being collected at one extremity and a negative charge at the other. The energy thus stored, in watt-seconds, is numerically equal to the product of the strength of the dielectric field, in volts, and the quantity of electricity transferred, in coulombs. The energy thus imparted to the dielectric field may be manipulated so as to raise the e.m.f. to a point limited only by the dimensions and insulation of the machine. For instance, in the case of two bodies in contact as at *a*, Fig. 32, the quantity

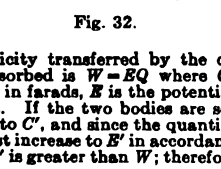

Fig. 32.

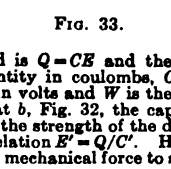

Fig. 33.

of electricity transferred by the dielectric field is $Q = CE$ and the energy thus absorbed is $W = EQ$ where $Q$ is the quantity in coulombs, $C$ is the capacity in farads, $E$ is the potential difference in volts and $W$ is the energy in joules. If the two bodies are separated as at *b*, Fig. 32, the capacity is reduced to $C'$, and since the quantity $Q$ is fixed, the strength of the dielectric field must increase to $E'$ in accordance with the relation $E' = Q/C'$. However, $E'Q = W'$ is greater than $W$; therefore, it requires mechanical force to separate the bodies.

**261. Construction of a laboratory type of friction machine** is shown in Fig. 33. A glass plate, $P$, is rotated in the direction shown by the arrow and the rubbing surface, $R$, which is made of leather coated with an amalgam (a good amalgam recommended by Kienmayer is $1Sn + 1Zn + 2Hg$), rubs against the glass plate generating a dielectric field which conveys the negative electricity toward the terminal $T_1$ and the positive electricity to the opposite

* The substances at the left are each supposed to be rubbed with any one of the substances given at the right and in the same row.

Digitized by Google

side of plate $P$. At the comb $C$ the dielectric flux is so dense that the air is rendered conducting and electricity passes between $P$ and $T_2$. Thus the tendency is for positive electricity to be transferred to $T_2$ and the negative electricity to $T_1$. The energy for this transfer of electricity is generated by the friction between $R$ and $P$, and the potential of the machine depends upon its own dimensions and its insulation.

**263. Experiments by Reiss* disclose the relation between e.m.f. and friction.** The results are given briefly as follows: a flat metallic cylinder, 1.575 in. (40 mm.) in diameter, covered with leather, was set upon an ebonite plate and drawn by an insulated handle over the surface, the charge being measured with a sine electrometer. The disc was drawn 1.18 in. (3 cm.) in one place; it was then set in another place and drawn 1.18 in. (3 cm.) again and so on, eight times, with the following results:

| Number..... | 1 | 2 | 4 | 8 |
|---|---|---|---|---|
| Charge..... | 1 | 1.45 | 1.7 | 1.93 |

Next the disc was drawn 9.45 in. (24 cm.) without stopping and the same result (1.93) was obtained. It was also found that there was maximum value beyond which the charge was not increased by drawing the disc farther.

**263. Influence machines.** The second type of machine, based on the principle of electric induction, and commonly known as the influence machine, operates as follows: a conductor thrust into a field of dielectric flux will have an e.m.f. generated in it which will cause a certain quantity of electricity to flow, and store a corresponding amount of energy. Fig. 34 shows two bodies, 1 and 2, connected to a battery $B$ as a source of e.m.f. The e.m.f. establishes a dielectric field between the bodies, drawing energy from the battery and storing it in the electric circuit. The energy stored is $W = C(E/2)$, wherein $C$ is the capacity, and $E$ the e.m.f. of the battery. Now if two bodies, 3 and 4, connected conductively, are inserted into the dielectric field, the capacity $C$, which is inversely proportional to the length of the dielectric will be increased, and the value of the dielectric flux correspondingly increased, thus drawing more energy from the battery and storing it in the system. Electromotive force will be generated in the bodies 3 and 4 which will tend to start a flow of electricity, and will transfer a quantity of electricity to the outside surface of the plates, sufficient to absorb the increase of energy stored in the system. If while in this position the two bodies are separated by severing the connecting link, the electricity will be unable to return to its state of equilibrium and the energy stored will remain bound. In order to utilise this energy, the bodies must be removed from the electric field of 1 and 2, and, now that each has a field of its own, mechanical energy equal in value to that stored in the bodies will be required to remove them. When the bodies are removed, the capacity of 1 and 2 will return to its original value, and the extra energy called forth for the placing of 3 and 4 in the field will be returned to the battery.

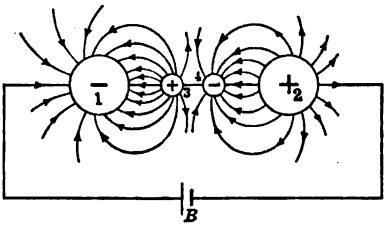

FIG. 34.

**264. Excitation of influence machines.** The influence machine does not employ a battery to maintain the e.m.f., but is given an initial charge of e.m.f., after which it is self-exciting. It will be noted that in this method a certain amount of electricity is stored in the bodies 3 and 4, and that the

* "Wiedemann Annalen," Bd. I, p. 1052.

Digitized by Google

value of e.m.f., and therewith the value of the energy can be changed at will by varying the capacity between them; an increase in capacity corresponds to a decrease in energy or motor action and *vice versa*.

**265. The Toepler influence machine** is shown schematically in Fig. 35; $S$ is a fixed glass plate with two segment-shaped pieces of paper, $p_1$ and $p_2$ (called field pieces) fastened on the back (shown dotted); $P$ is a glass plate mounted on an axle and can be rotated by a belt not shown in the sketch; on the plate, $P$, are mounted a number (8 in the sketch) of tin-foil discs, called carriers, each disc being armed with a small brass button which makes the contact with the various brushes; $b_1$ and $b_2$ are called appropriating brushes and are connected with the field plates $p_1$ and $p_2$, respectively; $n$ is the neutralising rod and carries a brush at each extremity; $c_1$ and $c_2$ are metallic combs connected to the terminals, $T_1$ and $T_2$, of the machine. The Toepler machine is very reliable and is self-exciting regardless of weather conditions. By connecting a number of pairs of plates in multiple the load capacity of the machine can be increased.

**266. The polarity of the Toepler type of machine** is not always the same, depending on how the charges are distributed when it starts. Tests for polarity should be made, where it is of importance. The flame of a Bunsen burner will be attracted by the negative pole.

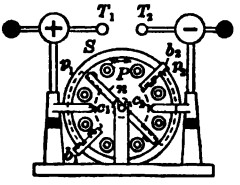

FIG. 35.

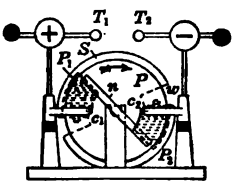

FIG. 36.

**267. The Holtz machine** is shown schematically in Fig. 36. $S$ is a stationary glass plate on the back side of which are mounted two paper field plates, $P_1$ and $P_2$; small blunt tongues project through slots, $w$, in the glass plate $S$ and nearly touch the rotating plate $P$. The rotating plate, $P$, is a plain glass plate covered with a coat of varnish; $c_1$ and $c_2$ are metallic combs connected to the terminals, $T_1$ and $T_2$. The rod, $n$, is a neutralising rod and carries a comb at each end.

**268. The operation of the Holtz machine** is as follows: The terminals $T_1$ and $T_2$, are put in contact and the machine started. One of the field plates is given a charge (let $P_1$ be charged positively). This charge will draw negative electricity to the comb, $c_1$, which will leak across to the glass plate, $P$. Passing around to the other side of the machine this negative charge on plate $P$ attracts a positive charge from the plate, $P_2$, to the other side of the plate, leaving $P_2$ negative. Now the negative charge on $P_2$ draws positive electricity from $c_2$ which neutralises the negative charge and leaves both sides of the plate negatively charged. Upon coming to the other side the positive charges on both sides of the plate draw negative electricity from the field plate, $P_1$, neutralising the charge on the lower side of $P$ and completing the cycle. The neutraliser, $n$, serves to keep the machine from reversing its polarity and losing its excitation.

The Holtz machine is sensitive to atmospheric conditions and should be enclosed in a tight compartment for satisfactory results. The compartment can be heated or some moisture-absorbing agent can be used to keep the air dry. The polarity of the machine can be determined by observing the character of the sparks at each pole; at the negative pole the sparks between the comb and the plate are broad and occur in bunches giving a bluish light, while at the positive pole they appear as single points of light.

**269. Effect of operation under air pressure.** Influence machines can be greatly increased in e.m.f. by enclosing them in an air-tight case and operating them under air pressure. As discussed in Sec. 4, the dielectric

Digitized by Google

strength of air is increased by raising the pressure, therefore higher e.m.fs. can be generated without causing the air to break down and neutralise the charges. Tests on an experimental machine* gave the following results:

| | | | | |
|---|---|---|---|---|
| Pressure, lb. per sq. in. | 0.0 | 15 | 30 | 45 |
| Spark length, in. | 2.5 | 5 | 7 | 8 |

## ELECTRIC PIANO PLAYERS

### BY OTIS ALLEN KENYON

*Consulting Electrical Engineer, Assoc. Amer. Inst. Elec. Eng.*

**270. The Tel-Electric piano player** is the name that has been given to one of the most successful types of electromagnetic piano player that has been developed. In this system the keys of the piano are operated by a bank of electromagnets situated immediately beneath the keyboard, thus interfering in no way with the usual manual operation of the instrument. The electric impulses which operate these magnets are produced in a separate apparatus that may be situated at any distance from the instrument that is to be played.

**271. Operation.** The Tel-Electric player is so designed as to operate either automatically, or subject to manual control. In operation, a roll of music is inserted in the carriage and the starting switch closed. Once started, the music roll, which is driven by a motor, is drawn through the transmitter, thus actuating the playing magnets according to the pattern of the music sheet. At the end of the selection, the roll is automatically reversed and wound back into its case and the current cut off.

**272. The music roll** consists of sheet brass into which a pattern has been punched. This roll forms the selective means which determines the sequence of the magnets that operate the keys and the pedals, and also the strength of the current through these magnets.

**273. There are three general types** of this player now on the market. The first is known as the "Tel-Electric," which is a sixty-five note player, and operates the keyboard of a piano from the second "*A*" in the base to the last "*C* sharp" in the treble. The various degrees of expression are controlled by a resistance bank, there being a resistor for each individual magnet. The **expression control** device permits the required length of the resistor to be introduced in each individual magnet-circuit, the changes in the amount of resistance being effected practically instantaneously. With this complete control of each individual note and the pedals, the melodies and rhythms are played with practically perfect expression.

The second type of player is denoted as the "Telelektra." It controls eighty-eight notes, or the entire keyboard of a piano, and produces even more perfect control of expression than does the Tel-Electric. With this player it is possible to get as many degrees of expression as a piano virtuoso can produce. Any variety of contrast between the melody and accompaniment is possible. In the Telelektra, the current for the operating magnets is varied, partly by the resistance method and partly by vibrating contacts, the rate of vibration being regulated by the music record. At zero vibration full current passes, and as the rate of vibration increases the value of current decreases in direct proportion to the time of contact. The control of the number of vibrations of these contacts is so perfect and so nearly instantaneous that a practically unlimited number of degrees of expression may be produced. The Tel-Electric players are operated by what is known as **autographic records**, made by a special process which permits the automatic recording of the note position and the power applied to the key, for each individual note, as played by the person who produces the record.

The third type is known as the "Telektra Symphonic Organ," is simply an adaptation of the Telelektra to the **pipe-organ transmitter**. The organ is specially designed for the purpose, and though many sizes of organs are constructed, standard music rolls are made that can be played in all the various sizes. The player system is laid out to cover an organ of three claviers and thirty-two note pedal, 100 stops, all couplers and accessories, and

* Eimer and Amend.

Digitized by Google

three independent swell boxes. As there is no limit to the number of notes or combinations that can be put into operation simultaneously, the automatic player can produce effects that are impossible to the organist. The Tel-Electric system may also be applied to existing organs, and, in every case, the organs may be operated by hand in the usual way without removing the player.

**274. Mechanism.** The principle upon which the translating mechanism operates is shown in Fig. 37. The brass record, which is perforated with longitudinal slots, is wound from the roll *A* to the roll *M* over the so-called tracker roll *C*. Above the tracker roll there are arranged a number of reading fingers *D*, mounted on a shaft *R* about which they are free to rotate, there being a finger for each magnet on the piano, as well as for the expression magnets. These reading fingers each carry a contact wire *G* embedded in a piece of ivory *E*. Normally the reading fingers rest upon the surface of the brass record and the circuit of the magnet is open at the point *P*. As soon as a perforation passes underneath, the reading finger drops down and closes the circuit through its magnet, and remains closed for a length of time that depends upon the length of the slot. The amount of current in the circuit, that is, the dynamic power of the magnet, depends upon the value of resistance included in the circuit and this is regulated by magnets which cause the comb wire *J* to move up and down over the resistor unit *H*. The magnets all operate on the rotating armature principle. Fig. 38 shows one of the magnets as attached to a key on the pianoforte. The armatures of these magnets are laminated to minimize the retarding effect of eddy currents.

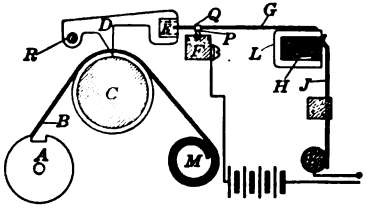

FIG. 37.—Skeleton diagram of the operating mechanism of a Tel-Electric piano player.

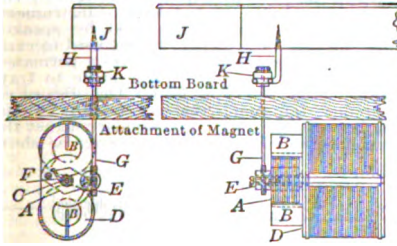

FIG. 38.—Showing attachment of magnets to key in a pianoforte.

**275. Combination organ and piano players.** Certain combinations are also made whereby the Tel-Electric transmitter operates a piano by means of a piano music roll. By turning over a coupler, the piano is cut out, and the same transmitter operates the organ by means of an organ music roll. With this type of combination, when the organ is coupled to the transmitter, the piano is played entirely automatically by means of the organ music sheet, so it is possible to play very closely organ and piano arrangements, the piano part being played nearly in full on the piano and the orchestral or organ accompaniment played in full on the organ. In this combination, the piano is used manually, similar to any stop in the organ, by means of one of the keyboards.

## THE TELEGRAPHONE

**BY OTIS ALLEN KENYON**

*Consulting Electrical Engineer, Assoc. Amer. Inst. Elec. Eng.*

**276. Theory.** The telegraphone, which was invented by Valdemar Poulsen, is based upon the peculiar magnetic properties of hard steel which

Digitized by Google

permit it to receive and retain magnetic impressions that are fixed in position. The principles of the invention may be explained with a simple model as shown in Fig. 39. Assume an endless steel wire to be passed over two revolving drums at a suitable speed. If an electromagnet (Fig. 40) is brought into close proximity to the traveling wire, the wire will be magnetized to a degree corresponding to the strength of the magnet. If the exciting circuit through the magnet is alternately opened and closed the steel wire will become magnetized only during the periods when the circuit is closed and because of the coercive strength of steel the magnetism will remain fixed in the positions where it is received and not equalize itself; that is, the steel wire

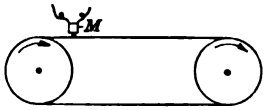

FIG. 39.—Principle of telegraphone.

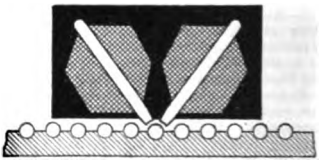

FIG. 40.—Electromagnet for wire recorder.

retains a permanent record of the magnetic fluctuations and if it were passed between the poles of a suitable electromagnet it would be capable of transforming the magnetic variations into electric variations by electromagnetic induction, the energy for which would be supplied entirely by the motor which drives the wire between the poles of the magnet.

**277. In the Poulsen telegraphone** these principles are utilised by connecting a system similar to that shown in Fig. 39 to telephone instruments. The electric currents produced by speaking into the transmitter (Fig. 41) are used to excite the recording magnet which leaves a permanent magnetic record in steel that is made to travel through the magnetic field. This record can reproduce the sounds that generated it by passing between the poles of a similar magnet that is connected to a telephone receiver as shown

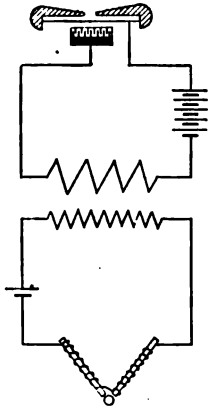

FIG. 41.—Transmitter.

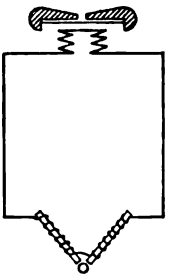

FIG. 42.—Receiver.

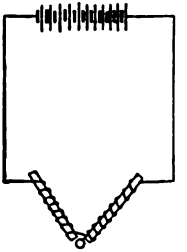

FIG. 43.—Eraser.

in Fig. 42. In order to make it possible to use the same steel over and over again a third magnet (Fig. 43) is provided which is excited with a relatively strong and constant current in the opposite direction to the transmitting magnet. This magnet obliterates all previous records and leaves the steel in condition to receive a new record.

Digitized by Google

**278. Recording and obliterating.** Most frequently the recording is effected by means of a polarised electromagnet. If, for instance, the electromagnet, by means of which the writing is to be performed is used to obliterate a prior magnetic record and also simultaneously magnetise the writing basis, then, during the inscription, the electromagnet is given a polarisation opposed to that which it possessed when obliterating. In this way a lively movement of the molecular magnets is obtained at the very moment of forming the writing. The susceptibility seems to increase very much in that magnetic *status nascendi*, and every shade of the writing becomes extremely perceptible. Ordinarily the polarisation of the writing magnet is only a very small fraction of that of the obliterating one. The nearer its polarization approaches the neutralisation of that of the writing basis, however, the feebler may be the polarization of the obliterating magnet. The coercive force determines the degree of polarization which exactly neutralises the magnetisation of the writing basis. It is found that the writing is somewhat weak when the polarization of the electromagnet during the process of inscription is just equal to that used in the preceding obliteration. In order to polarize the electromagnet, either a constant-current or a permanent magnet may be used.

**279. Recorders.** There are three distinct forms of recorders which are as follows: (a) the wire recorder; (b) the tape recorder; (c) the disc recorder.

The type of magnet used with the **wire recorder** is shown in Fig. 40, the wire being wound upon grooved drums first in one direction and then in the other. The disc and tape recorders use magnets with straight cores.

In the **tape recorder** the tape is wound up like a ribbon without any intervening substance. There is no perceptible effect from this method of procedure as experience has shown that the magnetism does not traverse the tape but is present only in the uppermost portions near the surface.

The **disc recorder** is constructed somewhat similar to the disc form of phonograph and the electromagnet is provided with a very sharp point.

**280. Adaptations.** There are many practical uses to which the telegraphone may be adapted and a number of commercial forms have been placed upon the market. These are described in Par. **281** to **286**.

**281. Amplification of weak voice currents.** In telephone work it sometimes happens that the current impulses received over the line are so weak that they do not furnish sufficient energy to produce records of proper magnetic intensity. However, in such cases the only effect is a diminution in the volume of sound. In an attempt to avoid this effect William A. Rosenbaum patented in 1903 a modified form of magnet for use with Poulsen's apparatus. In this improved construction a permanent magnet is used and a variation in intensity is obtained by varying the distance between the poles of the magnet and the steel record. Fig. 44 shows the principle of the construction. The permanent magnet is mounted upon an iron diaphragm which is vibrated by electric impulses received over the telephone line.

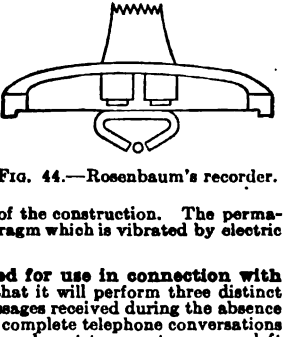

FIG. 44.—Rosenbaum's recorder.

**282. A type of telegraphone intended for use in connection with the ordinary telephone** is so arranged that it will perform three distinct services: (a) it may be set to record all messages received during the absence of the operator; (b) it may be set to record complete telephone conversations for the purpose of accurate record; (c) it may be set to repeat messages left by the operator. When the telegraphone is set for operation during the absence of the operator it is arranged to start automatically when a call is received and to run for a definite period of time, usually 2 min. It usually begins by sending a buzzing signal which apprises the speaker at the other end of the fact that the telegraphone is in operation, either to receive or transmit a message.

Digitized by Google

**283. The telegraphone may be used for the repetition of telephone messages,** receiving messages at one point on the steel, retransmitting them at a later point and then obliterating the record.

**284. The telegraphone is also built for phonographic uses** and in many ways it is superior to the best forms of wax record phonographs. Its reproduction of sound is more faithful than the phonograph, although if not shielded from external magnetic fields the records will be destroyed.

**285. As a dictating machine** the telegraphone has many advantages over the ordinary phonograph. For instance, it may be placed at any convenient point entirely independent of the location of the dictator and by means of a special electrical indicator the dictator is constantly informed of the operation of the machine and knows exactly the amount of unused record at his disposal. By pushing a switch he can retrace any portion of the record and have his dictation repeated to him. He also can make erasures by pushing a switch and can re-dictate in the erased portion of the record. The machines themselves are usually installed in the room with the typists, and as soon as the record is filled with dictation a bell rings and an attendant removes the record and inserts a new one. As soon as the dictation has been transcribed the record can be restored by passing it under an erasing magnet and it is then exactly as good as when new.

**286. The telegraphone has also been used as a wireless receiver** by installing it in connection with other regulation receiving devices.

## THE TELHARMONIUM

### BY OTIS ALLEN KENYON

*Consulting Electrical Engineer, Assoc. Amer. Inst. Elec. Eng.*

**287. General.** The telharmonium, invented by Dr. Thaddeus Cahill, produces a new form of music, by electrical means. This music offers unlimited possibilities to the composer, giving him power to produce effects which are impossible with other musical instruments. At one time there was installed in New York City a telharmonium plant of sufficient power to produce music in 10,000 places simultaneously. This plant was described by Dr. A. S. McAllister in the *Electrical World*, Vol. XLIX, 1907, p. 22. In this system the music is produced by mixing vibrations generated in a set of inductor alternators. In the New York plant there were 144 of these alternators, all geared together and driven by a constant-speed 185-h.p. motor. The frequencies of these alternators extended over a range of from 40 to 4,000 cycles per sec.

**288. Circuits.** The currents taken from the alternator are delivered to bus bars corresponding to the ground and partial tones. All currents composing the ground tones are superposed in one circuit, all the currents for the second partial in another and so on with other orders of harmonics. Each of these bus bars is closed through the primary of a closed iron-core transformer. The secondaries of these transformers are connected through impedance rheostats with a common circuit which in turn includes an impedance rheostat and is closed through the primary of an open iron-core transformer. The secondary of this transformer includes a number of impedance rheostats and is closed through the primary of an air-core transformer. The secondary of the air-core transformer contains a number of taps permitting the choice of secondary voltage for transmission to suit the impedance of the line. In this circuit is included a telephone receiver which translates the composite vibrations of the music.

**289. Theory of operation.** Thus it is seen that the vibrations supplied from the alternators are collected into composite ground tones and partial tones by a system of buses, and that these composite tones are regulated by the impedance rheostats, in the secondary of the iron-core transformers which are operated by stops. The rheostat in the primary circuit of the open iron-core transformer regulates the volume of the total composite vibrations, and is operated by the pedal. The impedance rheostats in the secondary of the open iron-core transformer, are used to give fine expression to the music and are manipulated constantly by the musician.

**290. Connections.** All the connections are made with solenoid switches, each key on the keyboard controlling a switch. The solenoids are bal-

Digitized by Google

anced to give a minimum of inertia. All are exactly alike so that the action is uniformly prompt and precisely the same for all notes. Every detail in this entire system is the result of careful study and long experimentation. The alternators, the transformers, the switches, the rheostats and plunger magnets have all been specially worked out to fulfil the difficult conditions here required.

**291. Mixed tones.** In the above brief description it was assumed that we were dealing with one keyboard only, with the switches and expression devices belonging to it. One of the most striking features of this electrical music is that a number of switchboards and keyboards can be connected to the same system of generators, and that these several keyboards may be made to give the same quality of tone or widely different qualities of tone, though fed from the same alternators. Thus, by mixing the harmonics of different tones in varying proportions, the musicians can give to one keyboard a wood-wind quality like that of the clarinet, to another the quality of brass, or if desired, a quality similar to that of the 'cello.

The telharmonium has beautiful qualities of tone never heard before, and resulting from the power which the performer has to mix the harmonics or overtones with the ground tones, in any desired proportions. Also, the attack and sostenuto of the instrument is surprising, in that at one instant it closely resembles wood-wind, at another brass, while at another one hears the bow on the string—according to the effect the performer wishes to produce. In its novel and singular power of controlling the timber, the attack and sostenuto, the electrical music differs from all the existing instruments of music and in a measure combines in itself the powers of the best instruments of the orchestra.

## TRAIN LIGHTING SYSTEMS

**BY JOHN C. BOGLE**

*Engineer, McMeen and Miller, Assoc. Am. Inst. Elec. Engineers*

**292. Systems classified.** In the **head-end system**, a small turbo-generator located on the locomotive or in the baggage car serves all cars through the medium of a train line which extends from the locomotive to the rear of the train. This system is adaptable to trains which make through runs without change in make-up. Where connections and disconnections must be made or where certain cars must be cut out at points along the run the incident difficulties have rendered this method of train lighting unsatisfactory. Another system, known as the **straight-storage system**, employs a battery of 32 cells, approximating 63 volts, which may be charged at some point in the run, usually in the yards at a division point of the railroad. The advantage of this system is its simplicity, but the disadvantages due to the necessity of "spotting" cars for charge, thereby losing time and space, together with interruptions of the yardmaster's schedule and the expense of installation and maintenance incident to a suitable charging system, have rendered this method probably the most expensive of all, everything considered. A third method of train lighting is known as the **axle-generator system.** Each car is a complete unit containing a charging generator belted to the axle of the car, a storage battery of 16 cells ("30-volt" system) feeding the lamp load, provision for maintaining proper conditions of charging, and also a device for disconnecting the generator from the battery when the rotative speed, and consequently the voltage, of the generator are inadequate for charging. See Sec. 20.

**293. Charging regulators for axle-generator systems.** One method which has been developed employs a charging generator which will supply constant potential independent of speed variation. An example of this type is the Rosenberg generator (Sec. 8). Charging systems employing constant generator potential apply a voltage to the battery which approximates 2.3 volts per cell. A tapering charge is thus realized, varying from relatively high currents at low battery voltages, to lesser currents as the battery voltage increases under charge. Naturally, the degree of taper depends upon the frequency with which charging recurs and the variation of battery voltage from the start until the end of the charging period.

The other well-recognized method of regulating the charge is to maintain

Digitized by Google

a constant charging current at all speeds. This is accomplished by a variation in the field strength of the charging generator. The degree of field strength is determined by the action, on a field rheostat, of a solenoid in series with one of the charging leads. Thus, the generator voltage is regulated by the current in the charging lead, and this current is thereby maintained at a satisfactory degree of constancy. Upon the termination of the charging period the generator is automatically allowed to suffer a slight diminution in voltage sufficient to float the battery and allow the generator to feed the lamps directly. Termination of the charging period may be secured by the action of a potential solenoid which operates when the voltage necessary to secure proper charging current, has reached a prescribed point. Another device, more in keeping with modern practice, provides an ampere-hour meter which terminates the charging period when a contact-making needle has travelled to a predetermined point. On discharge the meter moves in the opposite direction, and it is necessary that it be properly compensated for the error which otherwise would be interjected due to the imperfect efficiency of charge and discharge.

**294. Automatic cut-out.** The device employed for disconnecting the generator from the battery when the speed is below the prescribed point, is sometimes known as an automatic cut-out, which is nothing more or less than a reverse-current relay, Par. **80**. When the generator voltage has risen to the proper value, a solenoid actuates a plunger, thereby closing a set of relay contacts and connecting the generator to the battery. Should the charging current for any cause fall below the proper value, the action of the automatic cut-out will open the contacts and disconnect the generator from the battery.

**295. Polarity changer.** In the operation of cars provided with axle-generator lighting systems, some provision must be made for maintaining proper generator polarity, independent of the direction of travel of the car. There are several methods of accomplishing this end, the simplest being a device whereby the brushes are shifted on the commutator through approximately 180 electrical deg. when the direction of car motion reverses. In this arrangement, the brush holders are supported in a rotatable carrier which is free to move (between well-defined limits) in response to the rotation of the armature, the motion being communicated simply by brush friction.

**296. Lamp loads.** In ordinary coaches the lamp loads are approximately 750 to 800 watts. This figure corrresponds with modern practice to a reasonable extent, but is not conclusive, as little has been done by the railroads toward standardization of coach illumination. The Pullman Co., however, has endeavored to standardise all sleepers of an individual size, 1,600 watts for a 16-section sleeper being an example of their practice.

**297. Battery capacity.** Pullman sleepers carry batteries which are proportioned to the requirements of the type of run, varying from 300 to 350 amp-hr. at 30 volts. Naturally, the capacity for cars in trains making long runs with few stops may be relatively low. The 20-hr. trains plying between New York and Chicago have been subjected to exhaustive tests, and it has been found that in this run the batteries are required to supply the lamps for a total period of only about 1 hr. The cars of these trains carry, at present, 300 amp-hr. 30-volt batteries, but it is the consensus of opinion that, under the conditions stated, this value is considerably too high. For coaches with relatively smaller lamp load, the battery capacity ranges from 280 to 300 amp-hr., at 30 volts. Private cars meet the most severe requirements, as they are frequently compelled to stand for long intervals without charging. It is sometimes necessary to provide two sets of 350 amp-hr. batteries connected in parallel, but the use of storage batteries arranged in this manner is not considered good practice.

**298. Operation of a typical system.** Fig. 45 is a diagram showing the essential elements of a typical axle-generator train-lighting system. The automatic cut-out acts primarily in response to the pull of its potential winding when the generator speed and voltage have attained their proper values. This action, as will be seen, connects the battery with a source of charging current. At the same time, the charging current is maintained constant

Digitized by Google

by the pull due to the series winding of a solenoid, acting on a compression rheostat in series with the generator field. Meanwhile, the ampere-hour meter is running in the direction of "charge," and, when the contact-making needle has reached its point of contact, the resistance, *R*, is short-circuited.

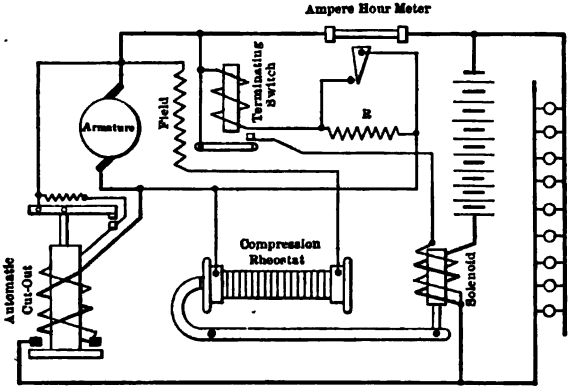

FIG. 45.—Simplified diagram of typical train-lighting system.

By this means, the solenoid of the terminating switch becomes sufficiently energized to close the contact points, thereby energizing the potential winding of the solenoid governing the field rheostat. This pull is added to the action of the series winding, and the effect is a sudden reduction in generator voltage by such percentage as the regulator has been adjusted for. The

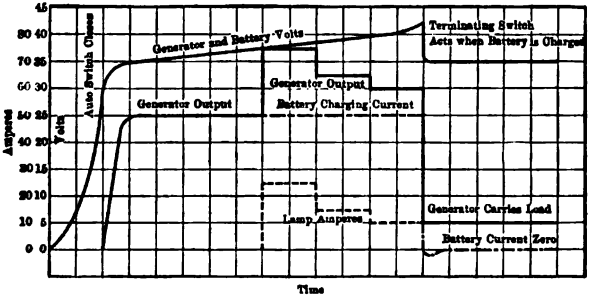

FIG. 46.—Curves illustrating performance of U-S-L-Axle equipment with type S-2 panel, starting from stand-still, with various lamp loads, and finally with battery fully charged.

battery is, by this process, floated on the supply circuit, the generator feeding the lamp load directly. See curves of Fig. 46. In this connection it is usual to employ what is known as a **lamp regulator**, in order that constant voltage may be applied to the lamps under all conditions of normal operation. Such a device consists of a potential solenoid controlling a series rheostat.

## STATISTICS OF THE ELECTRICAL INDUSTRY

**299. Census statistics of the electrical industry** are compiled periodically by the Dept. of Commerce, Bureau of the Census, at Washington, D. C. and persons desiring copies of the reports should address the department or the Supt. of Documents, Washington, D. C. The reports are subdivided under several principal headings, as follows:

**300. Central Electric Light and Power Stations**

| | Year | | |
|---|---|---|---|
| | 1902 | 1907 | 1912 |
| Number of stations: | | | |
| Commercial | 2,805 | 3,462 | 3,659 |
| Municipal | 815 | 1,252 | 1,562 |
| Total | 3,620 | 4,714 | 5,221 |
| Total income | $85,700,605 | $175,642,338 | $302,115,599 |
| Total expenses | $68,081,375 | $134,196,911 | $234,419,478 |
| Total persons employed | 30,326 | 47,632 | 79,335 |

The term "station" as here used may represent a single station or a number of stations under one ownership. Income excludes sales of energy to other public service corporations. See Bulletin 124, Dept. of Commerce, 1914.

**301. Street and Electric Railways**

| | Year | | |
|---|---|---|---|
| | 1902 | 1907 | 1912 |
| Number of companies: | | | |
| Operating | 817 | 945 | 975 |
| Lessor | 170 | 291 | 285 |
| Total | 987 | 1,236 | 1,260 |
| Miles of line | 16,645 | 25,547 | 30,438 |
| Miles of track | 22,577 | 34,382 | 41,065 |
| Miles of track electrically operated | 21,902 | 34,038 | 40,808 |
| Number of employees | 140,769 | 221,429 | 282,461 |
| Number of passenger cars | 60,290 | 70,016 | 76,162 |

See Bulletin No. 124, Dept. of Commerce, 1914.

**302. Telephones**

| | Year | | |
|---|---|---|---|
| | 1902 | 1907 | 1912 |
| Number of telephones | | | |
| Bell system | 1,317,178 | 3,132,063 | 5,087,027 |
| All other systems | 1,053,866 | 2,986,515 | 3,642,565 |
| Total United States | 2,371,044 | 6,118,578 | 8,729,592 |
| Miles of wire | 4,900,451 | 12,999,364 | 20,248,326 |
| Estimated number of messages | 5,070,000,000 | 10,400,000,000 | 13,736,100,000 |

Dept. of Commerce; Bulletin No. 123; 1912.

Digitized by Google

**303. Telegraphs**

| | Year | | |
|---|---|---|---|
| | 1902 | 1907 | 1912 |
| Number of companies or systems | 25 | 26 | 27 |
| Miles of pole line | 237,990 | 239,646 | 247,528 |
| Miles of single wire | 1,318,350 | 1,577,961 | 1,814,196 |
| Nautical miles of ocean cable | 16,677 | 46,301 | 67,676 |
| Number of messages | 91,655,287 | 103,794,076 | 109,377,698 |
| Number of telegraph offices | 27,377 | 28,110 | 30,864 |
| Total income | $40,930,038 | $51,583,868 | $64,762,843 |

**304. Electrical machinery, apparatus and supplies,** according to the 1910 Census, had a total value as follows:

| Year | Total value |
|---|---|
| 1899 | $218,238,277 |
| 1904 | 309,775,089 |
| 1909 | 405,600,727 |

See Thirteenth Census of the U. S., 1910; Bulletin on Manufactures.

## ENGINEERING SPECIFICATIONS AND CONTRACTS

**305. Contracts.** Since a contract which is good in law embraces for the most part questions which are wholly legal in character, it is beyond the function of an engineering handbook to go into the matter. The advice of competent legal counsel is always advisable in all matters connected with contracts, even though the engineer may have acquired an extensive knowledge of the law of contracts. Such knowledge should never be relied upon as a final guide, but is frequently useful in assisting the engineer to avoid serious mistakes and difficulties. The bibliography appended hereto is recommended as a course of reading for engineers who wish to equip themselves with a general knowledge of the subject.

**306. Specifications.** An engineering specification is almost always made part of a contract, either by direct embodiment in the contract or by reference. It is therefore essential that such a specification should be clear, direct, definite, conclusive, and legally sound. The art of drawing specifications is acquired necessarily by practice, founded upon a thorough technical knowledge of the subject matter in hand. General rules for guidance have been formulated by numerous authorities and references to a number of these will be found in the appended bibliography. These general rules will usually be found helpful as to the proper or desirable scope of the subject matter in a specification, but it is frequently more helpful to have before one a specification covering similar or identical subject matter which was drawn by a competent engineer. If no other source is available, the specifications used by the U. S. Government are sometimes obtainable through the Supt. of Documents, at Washington, D. C.

# SECTION 23

## MECHANICAL SECTION

### ELEMENTS OF SECTIONS

1. **Definitions.** The properties of structural sections commonly met in engineering practice may be reduced to certain mathematical forms which are used to simplify the calculations of design. These are defined as follows:

**A. Area of section,** expressed in sq. in.

**R. Radius of gyration.** The distance in in. from the axis of moments of the section to the point or line at which its area is considered concentrated; the radius of gyration is equal to the square root of the quotient obtained by dividing the moment of inertia of the section (taken about the same axis) by the area of the section.

**I. Moment of inertia.** The summation, expressed in inches to the fourth power, of the products of the elementary areas of a section by the squares of their distances from the centre of gravity or any other axis assumed for purposes of computation.

**S. Section modulus.** The moment of inertia divided by the distance, $n$, from the axis of moments to the extreme fibre. In an unsymmetrical section there are two-section moduli for each axis of moments, the least of which determines the safe unit stress.

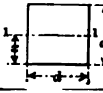
**Neutral axis.** Axis of moments through centre of area.

**x** and **y**, the distance or distances in an unsymmetrical section from the back or working line of the section to the centre of gravity of the section.

These mathematical expressions for the working values of a number of the more common sections, are given in Par. 2.

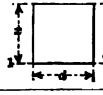
### 2. Mathematical Properties of Sections*

**Square**
Axis of moments through center



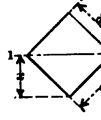
$$A = d^2$$
$$x = \frac{d}{2}$$
$$I_{1-1} = \frac{d^4}{12}$$
$$S_{1-1} = \frac{d^3}{6}$$
$$r_{1-1} = \frac{d}{\sqrt{12}} = 0.288675d$$

**Square**
Axis of moments on base



$$A = d^2$$
$$x = d$$
$$I_{1-1} = \frac{d^4}{3}$$
$$S_{1-1} = \frac{d^3}{3}$$
$$r_{1-1} = \frac{d}{\sqrt{3}} = 0.577350d$$

**Square**
Axis of moments on diagonal



$$A = d^2$$
$$x = \frac{d}{\sqrt{2}} = 0.707107d$$
$$I_{1-1} = \frac{d^4}{12}$$
$$S_{1-1} = \frac{d^3}{6\sqrt{2}} = 0.117851d^3$$
$$r_{1-1} = \frac{d}{\sqrt{12}} = 0.288675d$$

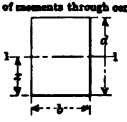
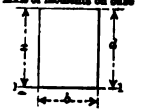
**Rectangle**
Axis of moments through center



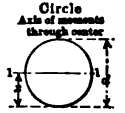
$$A = bd$$
$$x = \frac{d}{2}$$
$$I_{1-1} = \frac{bd^3}{12}$$
$$S_{1-1} = \frac{bd^2}{6}$$
$$r_{1-1} = \frac{d}{\sqrt{12}} = 0.288675d$$

**Rectangle**
Axis of moments on base



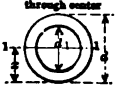
$$A = bd$$
$$x = d$$
$$I_{1-1} = \frac{bd^3}{3}$$
$$S_{1-1} = \frac{bd^2}{3}$$
$$r_{1-1} = \frac{d}{\sqrt{3}} = 0.577350d$$

**Circle**
Axis of moments through center



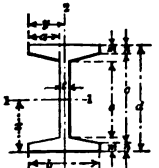
$$A = \frac{\pi d^2}{4} = 0.785398d^2$$
$$x = \frac{d}{2}$$
$$I_{1-1} = \frac{\pi d^4}{64} = 0.049087d^4$$
$$S_{1-1} = \frac{\pi d^3}{32} = 0.098175d^3$$
$$r_{1-1} = \frac{d}{4}$$

**Hollow Circle**
Axis of moments through center



$$A = \frac{\pi(d^2 - d_1^2)}{4} = 0.785398(d^2 - d_1^2)$$
$$x = \frac{d}{2}$$
$$I_{1-1} = \frac{\pi(d^4 - d_1^4)}{64} = 0.049087(d^4 - d_1^4)$$
$$S_{1-1} = \frac{\pi(d^4 - d_1^4)}{32d} = 0.098175\frac{(d^4 - d_1^4)}{d}$$
$$r_{1-1} = \frac{\sqrt{d^2 + d_1^2}}{4}$$

BEAM

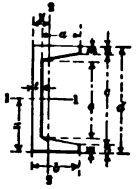


$$A = dt + 2a(m+n)$$
$$x = \frac{b}{2}$$
$$y = \frac{d}{2}$$
$$I_{1-1} = \frac{bd^3 - \frac{a}{4(m-n)}(c^4 - e^4)}{12}$$
$$I_{2-2} = \frac{2nb^3 + et^3 + \frac{m-n}{4a}(b^4 - t^4)}{12}$$

Digitized by Google

## 2. Mathematical Properties of Sections.—*Continued*

### CHANNEL



$$A = dt + a(m+n)$$

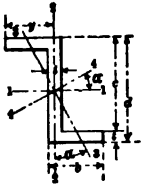
$$x = \frac{d}{2}$$

$$y = \frac{b^2 n + \frac{ct^2}{2} + \frac{a(m-n)}{3}(b+2t)}{A}$$

$$I_{1-1} = \frac{bd^3 - \frac{a}{8(m-n)}(c^4 - e^4)}{12}$$

$$I_{2-2} = \frac{2nb^3 + ct^3 + \frac{m-n}{2a}(b^4 - t^4)}{3} - Ay^2$$

### ZEE



$$A = t(d+2a)$$

$$x = \frac{d}{2}$$

$$y = \frac{2b-t}{2}$$

$$\text{Tan } 2\alpha = \frac{(dt-t^2)(b^2-bt)}{I_{1-1} - I_{2-2}}$$

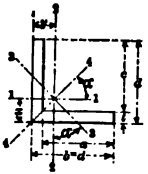
$$I_{1-1} = \frac{bd^3 - a(d-2t)^3}{12}$$

$$I_{2-2} = \frac{d(b+a)^3 - 2a^3c - 6ab^2c}{12}$$

$$I_{3-3} = \frac{I_{2-2}\cos^2\alpha - I_{1-1}\sin^2\alpha}{\cos 2\alpha}$$

$$I_{4-4} = \frac{I_{1-1}\cos^2\alpha - I_{2-2}\sin^2\alpha}{\cos 2\alpha}$$

### EQUAL ANGLE



$$A = t(b+c)$$

$$x = \frac{b^2+ct}{2(b+c)}$$

$$y = x$$

$$\alpha = 45°$$

$$I_{1-1} = \frac{t(b-x)^3 + bx^3 - a(x-t)^3}{3}$$

$$I_{2-2} = I_{1-1}$$

$$I_{3-3} = \frac{ct^3 + c^3t + 3ct(b-4x+2t)^2 + t^4 + 6t^2(2x-t)^2}{12}$$

$$I_{4-4} = \frac{ct^3 + c^3t - 3ctb^2 + t^4}{12}$$

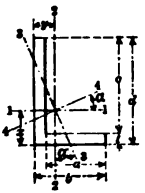
UNEQUAL ANGLE



$$A = t(b+c)$$

$$x = \frac{t(b+2c)+c^2}{2(b+c)}$$

$$y = \frac{t(2a+d)+a^2}{2(a+d)}$$

$$\text{Tan } 2\alpha = \frac{d[(2y-t)d(d-2x)+a(2x-t)(b+t-2y)]}{2(I_{1-1}-I_{2-2})}$$

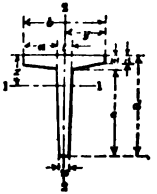
$$I_{1-1} = \frac{t(d-x)^3+bx^3-a(x-t)^3}{3}$$

$$I_{2-2} = \frac{t(b-y)^3+dy^3-c(y-t)^3}{3}$$

$$I_{3-3} = \frac{I_{2-2}\cos^2\alpha - I_{1-1}\sin^2\alpha}{\cos 2\alpha}$$

$$I_{4-4} = \frac{I_{1-1}\cos^2\alpha - I_{2-2}\sin^2\alpha}{\cos 2\alpha}$$

TEE



$$A = \frac{e(t+u)}{2} + mt + a(m+n)$$

$$x = \frac{6an^2+2a(m-n)(m+2n)+3td^2-e(t-u)(3d-e)}{6A}$$

$$y = \frac{b}{2}$$

$$I_{1-1} = \frac{e^3(3u+t)+4bm^3-2a(m-n)^3}{12} - A(x-m)^2$$

$$I_{2-2} = \frac{nb^3+(m-n)t^3+eu^3}{12} + \frac{a(m-n)[2a^2+(2a+3t)^2]}{36} + \frac{e(t-u)[(t-u)^2+2(t-2u)^2]}{144}$$

## BEAMS

**3. Moments.** The moment of a force with respect to any given point is equal to the product of the force and its perpendicular distance from the point. If the force is expressed in lb. and the distance in in., the moment will be expressed in in-lb.

**4. Reaction at supports.** In the case of a horizontal beam supported at two or more places, each support reacts against the beam, and the sum of all these reactions is equal to the combined weight of the beam and its loading.

**5. Shear.** The loads and the reactions of the supports are vertical forces tending to shear or cut the beam across, and the stresses they produce within the beam are, therefore, called shearing stresses. The shearing force at any section is the force with which the part of the beam on one side of the section tends to slide past the part on the opposite side. The shear at each support is equal to the reaction of the support; the shear at any point between the supports is equal to the reaction of the support less the total load between the support and the point; or if the upward reaction is considered

Digitized by Google

as positive and the downward loads are considered as negative, the shear at any point is the algebraic sum of the forces acting vertically on the beam between that point and either support.

**6. Bending moment.** The loads on the beam and the reactions of the supports constitute external forces which produce bending stresses in the beam. The summation of the moments of the external forces about the supports is called the bending moment and varies from point to point. It attains a maximum value at a point where the shear is zero.

**7. Calculation of maximum bending moment.** The general method for the computation of the maximum bending moment of a beam supported at the ends and loaded at various points is as follows:

First. Find the reaction at the left (or right) support by multiplying each load by its distance from the right (or left) support and dividing the sum of the products by the length of the span.

Second. Starting from the left (or right) end of the beam add the successive loads until a point is reached where the sum of the loads equals the reaction of the left (or right) support; at this point the bending moment will be a maximum.

Third. Multiply the reaction at the left (or right) support by its distance from the point of maximum bending moment and subtract the sum of the products of all loads to the left (or right) of this point by the corresponding distance from this point; the difference between these moments is then the maximum bending moment.

In Par. 8 are given expressions for the bending moments of beams for a variety of loadings, using the following notation:

| | |
|---|---|
| $A$ | = Area of section, in sq. in. |
| $n$ | = Distance from centre line of gravity to extreme fibre, in in. |
| $I$ | = Moment of inertia about centre line of gravity, in in.$^4$ |
| $M$ | = Static moment, in in.$^3$ |
| $S$ | = Section modulus $= I/n$, in in.$^3$ |
| $r$ | = Radius of gyration $= \sqrt{I/A}$, in in. |
| $f$ | = Bending stress in extreme fibre, in lb. per sq. in. |
| $f_s$ | = Resistance of web, in lb. per sq. in. |
| $E$ | = Modulus of elasticity, in lb. per sq. in. |
| $L$ | = Length of section, in ft. |
| $l$ | = Length of section, in in. |
| $d$ | = Depth of section, in in. |
| $b$ | = Width of section, in in. |
| $t$ | = Thickness of section, in in. |
| $W$, $W_1$, $W_2$ | = Superimposed loads supported by beam, in lb. |
| $w$ | = Superimposed load, in lb. per unit length or area. |
| $W$ *max* | = Maximum safe load at point given, in lb. |
| $R$, $R_1$ | = Reactions at points of support, in lb. |
| $V$ | = Vertical shear, in lb. |

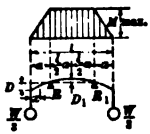
**8. Bending Moment, Deflection and Shear of Beams Under Various Loading Conditions.—*Continued***

**VI. BEAM CONTINUOUS OVER TWO SUPPORTS—Two exterior symmetrical loads**



$R$(max. shear) $= R_1 = \dfrac{W}{2}$

$M$, distance $x$ $= \dfrac{Wx}{2}$

$M$ max., from $R$ to $R_1$ $= \dfrac{Wa}{2}$

$W$ max. $= \dfrac{2fS}{a}$

$D$, distance $a$ $= \dfrac{Wa(3al-4a^2)}{12EI}$

$D_1$, distance $\dfrac{l}{2}-a$ $= \dfrac{Wa(l-2a)^2}{16EI}$

**VII. BEAM CONTINUOUS OVER TWO SUPPORTS—Uniformly distributed load**

$R$(max. shear) $= R_1 = \dfrac{W}{2}$

$M$, distance $x = \dfrac{W(x^2-lx+al)}{2l}$ 0, if $x = \dfrac{l}{2} \pm \sqrt{\dfrac{l(14-a)}{4}}$

$M_1$ at $R$ and $R_1 = \dfrac{Wa^2}{2l}$ max. if $a > l(\sqrt{\tfrac{1}{2}} - \tfrac{1}{4})$

$M_2$ at centre $= \dfrac{W(l-4a)}{8}$ max. if $a < l(\sqrt{\tfrac{1}{2}} - \tfrac{1}{4})$

$W_1$ max. $= \dfrac{2fS}{a^2}$ max. if $a > l(\sqrt{\tfrac{1}{2}} - \tfrac{1}{4})$

$W_2$ max. $= \dfrac{8fS}{l-4a}$ max. if $a < l(\sqrt{\tfrac{1}{2}} - \tfrac{1}{4})$

**9. Beam calculations.** The fundamental beam formula, for bending, is

$$M = \frac{fI}{y} \text{ or } f = \frac{My}{I} \qquad (1)$$

where $M$ is the maximum permissible bending moment in in-lb., $y$ is the distance in in. from the neutral axis to the extreme fibre, $I$ is the moment of inertia expressed in in. to the fourth power, and $f$ is the allowable working stress. If $M$ is the bending moment at the most strained section under the breaking load, $f$ is termed the **modulus of rupture.***

The bending moment $M$ may be calculated from one of the formulas given in Par. **8**; $I$ may be selected from the group of sections represented in Par. **2**. Safe working values of $f$ depend largely upon the class of service to which the member will be put. The allowable working stress is equal to the modulus of rupture divided by the factor of safety.

Eq. 1 may be presented in a more simplified form as

$$M = Sf \qquad (2)$$

where $S$ is the section modulus (see Par. **1**).

After a beam which meets the conditions of these equations has been selected, it should be checked to determine whether the transverse shear (Par. **1**) at any point is the deciding factor. Shear may be calculated from one

* Lanza, G. "Applied Mechanics;" John Wiley & Sons, New York; Chap. VI.

Digitized by Google

of the formulas given in Par. 8. Resistance to shear bears the following relation to the shearing stress:

$$V = f_s A \qquad (3)$$

where $V$ is the total shear in lb., $f_s$ is the unit stress (lb. per sq. in.) allowable for shear, and $A$ is the area of the section in sq. in.

**10. Safe unit stresses for steel beams.** Steel beams are usually I-beams; however they may be of almost any section demanded by structural conditions. See Par. 9. The allowable unit stresses for general structural work will not usually depart from the following values* expressed in lb. per sq. in.; care, however, should be exercised in the assumption of unit stresses for structures which will be called upon to meet unusual requirements.

| | |
|---|---|
| Tension, net section, rolled steel | 16,000 |
| Direct compression, rolled steel and steel castings | 16,000 |
| Bending, on extreme fibres of rolled shapes, built sections, girders, and steel castings | 16,000 |
| Bending on extreme fibres of pins | 24,000 |
| Shear on shop rivets and pins | 12,000 |
| Shear on bolts and field rivets | 10,000 |
| Shear—average—on webs of plate girders and rolled beams, gross section | 10,000 |
| Bearing pressure on shop rivets and pins | 24,000 |
| Bearing on bolts and field rivets | 20,000 |

**11. Safe unit stresses for wooden beams.** The maximum safe loads, as limited by the allowable shearing stresses along horizontal axes of the beams, or allowable longitudinal shear, should be calculated from the formula

$$\text{Maximum safe load} = \tfrac{2}{3} A f \qquad \text{(lb.)} \qquad (4)$$

where $A$ is the area of the section and $f$ is the allowable working stress in longitudinal shear. These limits should not be exceeded to avoid failure of the beam in the horizontal direction of the grain of the wood. The bending stress should be calculated as shown in Par. 9.

For a full discussion of the theory of longitudinal shear, see Chap. VI of Lanza's "Applied Mechanics." A table of allowable working stresses for structural timber is given in Sec. 4. The proper factor of safety is usually determined by the character or conditions of service.

**12. Concrete beams and floor slabs.** The arrangement of concrete beams follows the same principles as in structural-steel construction. On short spans, floor cross beams may be omitted, or used only at columns in order to secure lateral stiffness. Beams are usually designed as tee beams, and a part of the floor slab thus comprises part of the beam. The width of the slab considered to act as part of the beam should not exceed five times the slab thickness.

The reinforcement of floor slabs may be of small rods, wires or metal fabric, the latter especially on cross spans. Cross reinforcement of small rods or wires about 2 ft. apart laid parallel to the beam supporting the slab, should be used to prevent cracks, shrinkage, etc. If the length of the slab exceeds one and one-half times its width, the entire load should be carried by transverse reinforcement. The distribution of the load on a rectangular slab supported on four sides and reinforced in both directions may be approximately determined by the formula

$$R = \frac{l^4}{l^4 + b^4} \qquad (5)$$

where $R$ is the ratio of the load, $l$ the length and $b$ the width of the slab. An effective bond should be provided at the junction of the beam and the slab, and if the principal reinforcement of the slab is parallel to the beam, transverse reinforcement should be used extending over the beam and well into the slab.

In the calculation of shear or web reinforcement, concrete may be assumed to carry one-quarter to one-third of the total shear, the remainder being taken

* "Pocket Companion," Carnegie Steel Co., 1913; pp. 126 and 127.

Digitized by Google

by additional reinforcement arranged at intervals equal to the depth of the beam. The usual method of reinforcing beams against failure by diagonal tension or shear, is to use bent rods or stirrups in either a vertical or inclined position. The longitudinal spacing of such rods or stirrups should not exceed three-fourths of the depth of the beam.

**13. Formulas for rectangular concrete beams reinforced for tension only.***

$z$ = Depth to resultant of $C+C'$, in in.

**16. Shear and bond in reinforced concrete beams.***

| | | | | |
|---|---|---|---|---|
| Rectangular Beams | $f_v = \frac{V}{bjd}$ | (6) | $f_u = \frac{V}{jd\Sigma o}$ | (7) |
| T Beams | $f_v = \frac{V}{b'jd}$ | (8) | $f_u = \frac{V}{jd\Sigma o}$ | (9) |

$V$ = Total shear, in lb.; $f_v$ = Unit shearing stress in concrete, in lb. per sq. in.; $f_u$ = Unit bonding stress in concrete, in lb. per sq. in.: $\Sigma_o$ = Sum of the perimeters of the tension bars.

**17. Unit allowable stresses in reinforced-concrete beams.** The following working stresses are in current use for reinforcing bars of medium structural steel and good Portland cement and gravel concrete of a 1 : 2 : 4 or 1 : 2½ : 5 mixture:

| | |
|---|---|
| $f_c$ = unit compressive stress of concrete | 650 lb. per sq. in. |
| $f_v$ = unit shearing stress of concrete, | |
| straight reinforcement | 30 to 40 lb. per sq. in. |
| special shear reinforcement | 60 to 100 lb. per sq. in. |
| $f_u$ = unit bond stress of concrete, | |
| smooth rods | 60 to 80 lb. per sq. in. |
| deformed bars | 100 to 175 lb. per sq. in. |
| $f_s$ = unit tensile stress of steel | 16,000 lb. per sq. in. |
| $f_k$ = unit compressive stress of steel | 10,000 lb. per sq. in. |

$n = E_s \div E_c = 15$.

for notation, see Par. 13 to 16.

## COLUMNS

**18. Discussion of column formulas.** Due to the tendency to buckling, compression members are assumed to carry bending stresses. Failure of a column may, then, be due to direct compression, to bending or to a combination of both. No rigorous formula has ever been deduced for columns under all conditions of loading. However, several empirical formulas (Par. 21) have proven satisfactory when checked by tests made on full-sized members. All these formulas take into consideration the properties of the section (Par. 1), the allowable unit stress and the ratio of slenderness (Par. 20).

**19. Radius of gyration** is defined in Par. 1. For purposes of computation it is more convenient to employ the radius of gyration than either the moment of inertia or the section modulus.

* See footnote, Par. 13 and 14.

Digitized by Google

**20. Ratio of slenderness** is the unsupported length of the compression member divided by its radius of gyration (Par. 1). The term "unsupported" refers to the length of member which is free to deflect transversely, unhampered by bracing. The maximum allowable ratio of slenderness, in usual construction, is 120 for main members under steady stress. But this ratio, however temporary the loading, should in no case exceed 200.

**22. Combination of compression and bending stresses.** When a column, in addition to its axial load, carries an eccentric load, bending stresses

* "Pocket Companion," Carnegie Steel Co., 1913; p. 254.
† See Par. 20.

Digitized by Google

are produced. In Fig. 1 a column is pictured as carrying a beam supported on a bracket with a load $W_1$, and also a direct loading $W$. Selection of the proper column size may be accomplished by repeated trials, using the following formula:

$$f = \frac{w+w_1}{A} + \frac{Mn}{I} \qquad \text{(lb. per sq. in.)} \qquad (10)$$

where $W$ and $W_1$ are expressed in lb.; $A$ is the area of the column section in sq. in.; $M$ is the bending moment in in-lb., $(=w_1 x)$ due to eccentric loading; $n$ is the distance of the extreme fibre from the neutral axis, measured in the direction of bending; and $f$ is the allowable axial unit compression stress, in lb. per sq. in.

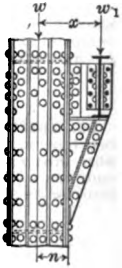

FIG. 1.—Column with eccentric superposed load.

**23. Wooden columns.*** The safe load tables of wooden columns which follow, based upon the working unit stresses adopted by the American Railway Engineering Association, give the allowable direct compressive loads for square and round columns.

The safe loads of rectangular columns may be found from the safe loads of square columns by direct proportion of areas, using the safe load unit stress of the square column whose side is equal to the least side of the rectangular section.

The following table gives the safe load in lb. per sq. in. of sectional area for ratios of

$$\frac{l}{d} = \frac{\text{effective length of column, in in.}}{\text{least side or diameter, in in.}} \qquad (11)$$

ranging between limits of 15 and 30.

* "Pocket Companion," Cambria Steel Co., 1913; p. 327.

Digitized by Google

$P$, given in the formula which follows, refers to longitudinal steel reinforcement only:

$$P = f_c(A_c + nA_s) \tag{12}$$

where $P$ = total load on column, in lb.; $A_c$ = area of concrete in sq. in.; $A_s$ = area of steel in sq. in.; $f_s$ = unit compressive stress in steel in lb. per sq. in.; $f_c$ = unit compressive strength of concrete; $n = f_s/f_c$. See Par. 17.

## SHAFTING

**25. Shaft design.** When shafting carries pulleys, the stresses due to belt tension tend to create a bending back and forth, which throws any given fibre into alternate tension and compression. These bending stresses also combine with the shearing stresses due to twisting. The following expression has been offered by Rankine, based on the theory of elasticity.*

$$f = \frac{r}{2I}[M_1 + \sqrt{M_1^2 + M_2^2}] \tag{13}$$

where $M_1$ = greatest bending moment; $M_2$ = greatest twisting moment; $r$ = external radius of shaft; $I$ = moment of inertia of the section about a diameter; $f$ = greatest allowable unit stress at outside of fibre.

It may be more convenient to use a table of horse-powers transmitted at various speeds by shafts of standard sizes. See Par. 27.

## GEARING AND CHAIN DRIVE

**28. Toothed gearing** is used for positive drive between shafts, that is, where the requirements will permit no slippage. There are two styles of teeth, the cycloidal and the involute. The former is used where the distance between centres of driving and driven member can be rigidly maintained. **Cycloidal gears** do not wear so rapidly as involute gears, and are used to transmit energy at rather high speeds. **Involute gears**, on the other hand, do not require so accurate a spacing of centres, although, after wearing for some time, this advantage becomes lessened, and such gearing is no longer insensible to badly adjusted bearings. Involute teeth are thicker at the root than cycloidal gears, and this added strength has considerable weight in the selection of gears for high-torque service. They operate at somewhat lower allowable speeds than cycloidal gears.

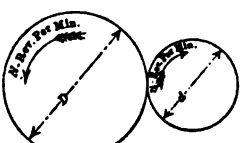

FIG. 2.—$D : d :: n : N$.

**29. Gear pitch.*** When, as in Fig. 2, two elemental circles may be said to roll one on the other with no slippage, their speeds in rev. per min. are inversely proportional to their diameters. In the case of gearing, the elemental circle just mentioned is known as the **pitch circle**, and the ratio of rotational speeds of a pair of meshed gears follows the relation above expressed. There are two common methods of describing the pitch of gear teeth. **Diametral pitch** is an expression derived by dividing the number of teeth on the gear by the diameter of the pitch circle in in. Thus, an eight-pitch gear has eight teeth per in. of pitch-circle diameter. **Circular**

* Schwamb & Merrill. "Elements of Mechanism," John Wiley & Sons.

Digitized by Google

pitch is the distance in in., measured along the pitch circle, from a point on one tooth to a corresponding point on the next tooth.

Selection of gears to accomplish a desired result, is determined by the rotational speed ratio which is sought for driver and driven member; the speed in ft. per min. at which the gear pitch circle is to rotate; and the stresses to which the gears will be subjected in service.

**30. Horse-power and working loads of cut steel gears.*** Under the heading "w.l." is given the working load or number of pounds of power-transmitting stress which can safely be brought on each inch width of tooth of a cut-steel gear or pinion of the size indicated at left of table, when it is running at the speed listed at top.

Under the heading "h.p." this is converted into horse-power transmitted at the speed named.

These figures should be multiplied by the width of working face in in., for the power of the gear in question.

The ft. per min. at pitch line equals pitch diameter in in. multiplied by rev. per min. and by 0.2618.

**31. Gear noise at various speeds.** Spur gears usually begin to make a noticeable noise at pitch-line speeds above 600 ft. per min. The allowable noise is dependent upon the attendant conditions at the installation. How-

* Data Book 125, Link-Belt Co., New York, 1914, p. 107.

Digitized by Google

ever with ordinary gears it would be exceptional to secure speeds, satisfactory from a standpoint of noise, which would range as high as 1,200 ft. per min. With herring-bone gears running in oil, pitch-line speeds as great as 5,000 ft. per min. have been reached. In the case of rawhide and cloth pinions, operation with a satisfactory minimum of noise can be attained at speeds ranging from 2,000 to 3,000 ft. per min.

### 32. Maximum Speed of Gearing

(A. Towler, *Engineering*, April 19, 1889, p. 388)

**34. Chain drive.** When the pitch-line speed does not exceed 600 ft. per min., it is possible to use **steel-roller chains** (Fig. 3) for positive transmission between two parallel shafts. These chains move on cut sprockets, the rollers engaging the surfaces of the teeth being free to turn. For higher speeds it is customary to use some form of **toothed (silent) chain** passing over toothed wheels (Fig. 4). The most economical speed at which a silent chain can be operated is from 1,000 to 1,300 ft. per min., though by no means are these limits impassable. The distance between centres should be not less than the sum of the diameters of driver and driven wheel. The proper tooth combination should be determined under the following considerations:

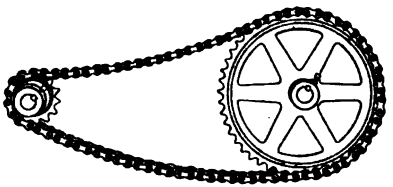

FIG. 3.—Steel-roller chain.

| Pitch of chain (nominal) | ⅜ | ½ | ⅝ | ¾ | 1 | 1¼ | 1½ | 2 | 2½ |
|---|---|---|---|---|---|---|---|---|---|
| Minimum number of teeth in driving wheel. | 15 | 17 | 17 | 17 | 17 | 17 | 17 | 19 | 19 |
| Minimum number of teeth in driven wheel. | 17 | 19 | 19 | 19 | 21 | 21 | 21 | 23 | 23 |
| Maximum number of teeth in driver. | 90 | 90 | 90 | 90 | 90 | 90 | 90 | 90 | 90 |
| Maximum number of teeth in driven wheel. | 120 | 130 | 130 | 130 | 130 | 130 | 130 | 130 | 130 |
| Maximum rev. per min. of minimum wheel. | 2260 | 1835 | 1460 | 1220 | 920 | 800 | 700 | 530 | 425 |
| Corresponding chain speed (ft. per sec.) | 1200 | 1300 | 1300 | 1300 | 1300 | 1400 | 1500 | 1500 | 1500 |

It is desirable to have an odd number of teeth in the pinions and an even number of links in the chain. Chains whose widths range from two times the pitch to six times the pitch, are preferable and are usually employed. Where it is possible, partiality is shown the chains of shorter pitch, as these have the advantage of greater durability and life than the narrower chains, of somewhat longer pitch, that would correspond in fulfilling the requirements.

The approximate strength (ultimate) of these chains can be obtained by multiplying the pitch in in. by the width in in., and multiplying the product by 5,500, the result being expressed in pounds.

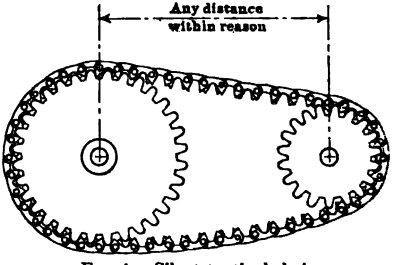

FIG. 4.—Silent-toothed chain.

## BELTS AND ROPE DRIVE

**35. Classification of belts.** Belts are made of leather, rubber or some cloth fabric. They are made single or double if of leather, and of several plys if their material is rubber or fabric. **Rubber belts** are adapted to installations where there is considerable moisture or high temperatures. **Fabric belts** may also be used in moist places if they are sure to receive proper attention, but for all-round service these belts are not nearly so good as leather or rubber belts. **Leather belts**, if they can be kept dry, are the most satisfactory in every way.

* Link-Belt Co., Data Book, No. 125, 1914.

*S* and *D* refer to thickness of leather belting; 4 ply, 6 ply, and 8 ply refer to thickness of cotton or rubber belting. 5,280 ft. per min. is the limiting speed for iron pulleys. A good belt speed is 3,500 ft. per min. If possible, use pulleys listed below sigzag line.

Digitized by Google

**37. Belt drive.** The driving force of a belt is the difference in belt tension on the tight and loose sides ($T_1 - T_2$). In ordinary practice it is usual to assume that $T_1 = 2T_2$, provided there is sufficient arc of contact on both pulleys, and that a **coefficient of friction** of about 0.22 can be realized. For leather belts on iron pulleys this coefficient may be 0.56 when dry, 0.36 when wet, 0.23 when greasy, and 0.15 when oily.*

Belts should always be run with the tight side undermost, and with the grain of the leather next the pulley surface. Where considerable power is to be transmitted, the pulley centres should be spaced about 20 or 25 ft. for best results. Shortening this distance usually necessitates additional belt tension in order to prevent an excess of slip. One form of drive which is coming into extended use is the employment of a spring or weighted idler operating on the slack side of the belt. The function of this idler, in the **short-belt drive**, is to increase the arc of contact on the pulley surface. The purpose of the whole arrangement is to economise space.

Belts which are operated at excessive tensions will occasion great annoyance and expense. Hot bearings, broken pulleys, stretched and broken belts are all attributable to this cause, and such damage not only entails the expense of its own replacement or repair but also should be held responsible for production time lost at the working machines.

**38. Determination of the proper belt thickness** is a much mooted question, there being excellent authority favoring directly opposing practices.†

In general it may be said that thin belts are better adapted to high speeds because of the decreased centrifugal forces secured through their use. In large belts it is usually the case that other conditions fix the choice of belt thickness.

**39. Belt splicing.** The best splice is the glued joint, made by bevelling the ends and cementing a lapped joint. However, there are many occasions where this is not justifiable. **Belt lacing** may be done with rawhide strips or with wire. Many configurations of holes have been advanced, but, whatever lacing method is adopted, care must be taken to insure proper and permanent alignment of the ends. Enough material should be left below the holes to prevent the lacing from being torn out. Where there is considerable work of this nature to be done, it is customary to install a belt-lacing machine; this furnishes a very satisfactory and cheap method of belt splicing.

**40. Length of belt.**‡ Unqualifiedly the best method of determining the proper length of belt to be used over pulleys of known diameter and spacing, is by direct measurement. Sometimes, however, this cannot be done. For **open belts** the following formula may be used:

$$\text{Length} = R(\pi + 0.0349\alpha) + r(\pi - 0.0349\alpha) + 2C\cos\alpha \qquad (14)$$

where $R$ is the radius of the larger pulley; $r$ the radius of the smaller pulley; $C$ the distance between centres; and $\alpha$ is the angle whose sine is $(R-r)/C$.

For **crossed belts**

$$\text{Length} = (R+r) \times (\pi + 0.0349\beta) + 2C\cos\beta \qquad (15)$$

where $\beta$ is the angle whose sine is $(R+r)/C$.

**41. Rope drive** is suited to those cases where mechanical energy must be transmitted comparatively long distances, and also where the transmission is to be made at an angle or in a vertical direction. The ropes may be of hemp, steel or cotton. Manila hemp is in widest use where a multiplicity of ropes is employed, and steel cable is used chiefly for long-distance single-rope drives.

The **multiple-rope (English)** system uses a number of ropes running side by side. By the use of couplings instead of splices, unequal tension may be compensated and repairs facilitated. In the **continuous-rope**

**(American) system,** one rope is used; this is wrapped around the sheaves the desired number of times, and then carried over from the last groove of one sheave to the first groove of the other by a guide pulley which, at the same time, maintains a constant tension in the rope. It is clearly seen that while the latter system is the more flexible and easily installed of the two, the results of a single breakage would be much more serious.

The angle of the groove should be about as shown in Figs. 5 and 6, which illustrate the grooves used for manila, hemp, or cotton ropes on the driving sheaves of both the English system and the American. For economical wear the pulleys should be not less than forty times the diameter of the rope.

The horse-power which can be transmitted by ropes at various speeds is the subject of much controversy, some engineers imposing loads greater by 35 or 40 per cent. than the recommendations of others. The data offered

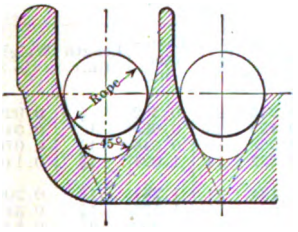

FIG. 5.—Standard groove of English system.

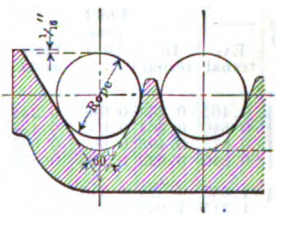

FIG. 6.—Standard groove of American system.

in Par. 42 represent conservative practice. Lanza* and the Link-Belt Co.† in their tables advocate values considerably higher, while J. J. Flather‡ is even more conservative than the accompanying authority.

**42. Horse-power of Transmission Rope at Various Speeds****

# SECTION 24

## STANDARDIZATION RULES OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

### DEFINITIONS

NOTE.—The following definitions are intended to be practically descriptive, rather than scientifically rigid.

#### CURRENT, E.M.F. and POWER

(The definitions of currents given below apply also, in most cases, to electromotive force, potential difference, magnetic flux, etc.)

1. **Direct current.** A unidirectional current. As ordinarily used, the term designates a practically non-pulsating current.

2. **Pulsating current.** A current which pulsates regularly in magnitude. As ordinarily employed, the term refers to unidirectional current.

3. **Continuous current.** A practically non-pulsating direct current.

4. **Alternating current.** A current which alternates regularly in direction. Unless distinctly otherwise specified, the term "alternating current" refers to a periodic current with successive half waves of the same shape and area.

5. **Oscillating current.** A periodic current whose frequency is determined by the constants of the circuit or circuits.

6. **Cycle.** One complete set of positive and negative values of an alternating current.

7. **Electrical degree.** The 360th part of a cycle.

8. **Period.** The time required for the current to pass through 1 cycle.

9. **Frequency.** The number of cycles or periods per second. The product of $2\pi$ by the frequency is called the *angular velocity* of the current.

10. **Root-mean-square** or **effective value.** The square root of the mean of the squares of the instantaneous values for one complete cycle. It is usually abbreviated r.m.s. Unless otherwise specified, the numerical value of an alternating current refers to its r.m.s. value. The r.m.s. value of sinusoidal wave is equal to its maximum, or crest value, divided by $\sqrt{2}$. The word "virtual" is sometimes used in place of r.m.s., particularly in Great Britain.

11. **Wave form** or **wave shape.** The shape of the curve obtained when the instantaneous values of an alternating current are plotted against time in rectangular coordinates. The distance along the time axis corresponding to one complete cycle of values is taken as $2\pi$ radians, or 360 deg. Two alternating quantities are said to have the same wave form when their ordinates of corresponding phase (see Par. 13) bear a constant ratio to each other. The wave shape, as thus understood, is therefore independent of the frequency of the current and of the scale to which the curve is represented.

12. **Simple alternating** or **sinusoidal current.** One whose wave-shape is sinusoidal.

Alternating-current calculations are commonly based upon the assumption of sinusoidal currents and voltages.

13. **Phase.** The distance, usually in angular measure, of the base of any ordinate of an alternating wave from any chosen point on the time axis, is called the phase of this ordinate with respect to this point. In the case of a sinusoidal alternating quantity, the phase at any instant may be represented by the corresponding position of a line or *vector* revolving about a point with such an angular velocity ($\omega = 2\pi f$), that its projection at each instant upon a convenient reference line is proportional to the value of the quantity at that instant.

Digitized by Google

**14. Non-sinusoidal quantities.** Quantities that cannot be represented by vectors of constant length in a plane. The following definitions of phase, active component, reactive component, etc., are not in general applicable thereto. Certain "equivalent" values, as defined below, may, however, be used in many instances, for the purpose of approximate representation and calculation.

**15. Crest-factor or peak-factor.** The ratio of the crest or maximum value to the r.m.s. value. The crest factor of a sine-wave is $\sqrt{2}$.

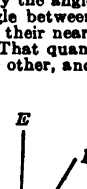
**16. Form factor.** The ratio of the r.m.s. to the algebraic mean ordinate taken over a half-cycle beginning with the zero value. If the wave passes through zero more than twice during a single cycle, that zero shall be taken which gives the largest algebraic mean for the succeeding half-cycle. The form factor of a sine wave is 1.11.

**17. The distortion factor of a wave.** The ratio of the r.m.s. value of the first derivative of the wave with respect to time, to the r.m.s. value of the first derivative of the equivalent sine-wave.

**18. Equivalent sine-wave.** A sine-wave which has the same frequency and the same r.m.s. value as the actual wave.

***19. Phase difference: lead and lag.** When corresponding cyclic values of two sinusoidal alternating quantities of the same frequency occur at different instants, the two quantities are said to differ in phase by the angle between their nearest corresponding values, *e.g.*, the phase angle between their nearest corresponding values; *e.g.*, the phase angle between their nearest ascending zeros or between their nearest positive maxima. That quantity whose maximum value occurs first in time is said to lead the other, and the latter is said to lag behind the former.

***20. Counter-clockwise convention.** It is recommended that in any vector diagram, the leading vector be drawn counter-clockwise with respect to the lagging vector,† as in the accompanying diagram, where *OI* represents the vector of a current in a simple alternating-current circuit, lagging behind the vector *OE* of impressed e.m.f.



***21. The active or in-phase component** of the current in a circuit is that component which is in phase with the voltage across the circuit; similarly the active component of the voltage across a circuit is that component which is in phase with the current. The use of the term *energy component* for this quantity is disapproved.

*** 22. Reactive or quadrature component of the current in a circuit.** That component which is in quadrature with the voltage across the circuit; similarly, the reactive component of the voltage across the circuit is that component which is in quadrature with the current. The use of the term *wattless component* for this quantity is disapproved.

***23. Reactive factor.** The sine of the angular phase difference between voltage and current; *i.e.*, the ratio of the reactive current or voltage to the total current or voltage.

***24. Reactive volt-amperes.** The product of the reactive component of the voltage by the total current, or of the reactive component of the current by the total voltage.

***25. Non-inductive load and inductive load.** A *non-inductive* load is a load in which the current is in phase with the voltage across the load. An *inductive* load is a load in which the current lags behind the voltage across the load. A *condensive* or *anti-inductive* load is one in which the current leads the voltage across the load.

**26. Power in an Alternating-current circuit.** The average value of the products of the coincident instantaneous values of the current and voltage for a complete cycle, as indicated by a wattmeter.

---

* NOTE.—Definitions 19, 20, 21, 22, 23, 24, 25 refer strictly only to cases where the voltage and current are both sinusoidal (see Par. **11** and **12**).

† See Publication 12 of the International Electrotechnical Commission (Report of Turin Meeting, Sept., 1911, p. 78).

Digitized by Google

**27. Volt-amperes or apparent power.** The product of the r.m.s. value of the voltage across a circuit by the r.m.s. value of the current in the circuit. This is ordinarily expressed in kilovolt-amperes.

**28. Power-factor.** The ratio of the power (cyclic average as defined in Par. **26**) to the volt-amperes. In the case of sinusoidal current and voltage, the power-factor is equal to the cosine of their difference in phase.

**29. Equivalent phase difference.** When the current and e.m.f. in a given circuit are non-sinusoidal, it is customary, for purposes of calculation, to take as the "equivalent" phase difference, the angle whose cosine is the power-factor (see Par. **28**) of the circuit. There are cases, however, where this equivalent phase difference is misleading, since the presence of harmonics in the voltage wave, current wave, or in both, may reduce the power-factor without producing a corresponding displacement of the two wave forms with respect to each other; *e.g.*, the case of an a-c. arc. In such cases, the components of the equivalent sine-waves, the equivalent reactive factor and the equivalent reactive volt-amperes may have no physical significance.

**30. Single-phase.** A term characterising a circuit energised by a single alternating e.m.f. Such a circuit is usually supplied through two wires. The currents in these two wires, counted positively outward from the source, differ in phase by 180 deg. or a half-cycle.

**31. Three-phase.** A term characterising the combination of three circuits energised by alternating e.m.fs. which differ in phase by one-third of a cycle, *i.e.*, 120 deg.

**32. Quarter-phase, also called two-phase.** A term characterising the combination of two circuits energised by alternating e.m.fs. which differ in phase by a quarter of a cycle; *i.e.*, 90 deg.

**33. Six-phase.** A term characterising the combination of six circuits energised by alternating e.m.fs. which differ in phase by one-sixth of a cycle; *i.e.*, 60 deg.

**34. Polyphase.** A general term applied to any system of more than a single phase. This term ordinarily applied to symmetrical systems.

**50. Per cent. drop.** In electrical machinery, the ratio of the **internal resistance drop** to the terminal voltage, expressed in per cent., is called the "*per cent. resistance drop.*"

**51.** Similarly the ratio of the **internal reactance drop** to the terminal voltage, expressed in per cent., is called the "*per cent. reactance drop.*"

**52.** Similarly the ratio of the **internal impedance drop** to the terminal voltage, expressed in per cent., is called the "*per cent. impedance drop.*"

Unless otherwise specified, these per cent. drops shall be referred to rated load and rated power-factor.

**53. In the case of transformers,** the per cent. drop will be the sum of the primary drop (reduced to secondary turns) and the secondary drop, in per cent. of secondary terminal voltage.

**54. In the case of induction motors,** it is advantageous to express the drops in per cent. of the internally induced e.m.f.

**55. The load factor of a machine, plant or system.** The ratio of the average power to the maximum power during a certain period of time. The average power is taken over a certain period of time, such as a day, a month, or a year, and the maximum is taken as the average over a short interval of the maximum load within that period.

In each case, the interval of maximum load and the period over which the average is taken should be definitely specified, such as a "half-hour monthly" load factor. The proper interval and period are usually dependent upon local conditions and upon the purpose for which the load factor is to be used.

**56. Plant factor.** The ratio of the average load to the rated capacity of the power plant, *i.e.*, to the aggregate ratings of the generators.

**57. The demand of an installation or system** is the load which is drawn from the source of supply at the receiving terminals averaged over a suitable and specified interval of time. Demand is expressed in kilowatts, kilovolt-amperes, amperes, or other suitable units.

**58. The maximum demand of an installation or system** is the great-

Digitized by Google

est of all the demands which have occurred during a given period. It is determined by measurement, according to specifications, over a prescribed time interval.

**59. Demand factor.** The ratio of the maximum demand of any system or part of a system, to the total connected load of the system, or of the part of system, under consideration.

**60. Diversity factor.** The ratio of the sum of the maximum power demands of the subdivisions of any system or parts of a system to the maximum demand of the whole system or of the part of the system under consideration, measured at the point of supply.

**61. Connected load.** The combined continuous rating of all the receiving apparatus on consumers' premises, connected to the system or part of the system under consideration.

**62. The saturation factor of a machine.** The ratio of a small percentage increase in field excitation to the corresponding percentage increase in voltage thereby produced. Unless otherwise specified, the saturation factor of a machine refers to the no-load excitation required at normal rated speed and voltage. It is determined from measurements of saturation made on open circuit at rated speed.

**63. The percentage saturation** of a machine at any excitation may be found from its saturation curve of generated voltage as ordinates, against excitation as abscissas, by drawing a tangent to the curve at the ordinate corresponding to the assigned excitation, and extending the tangent to intercept the axis of ordinates drawn through the origin. The ratio of the intercept on this axis to the ordinate at the assigned excitation, when expressed in percentage, is the percentage of saturation and is independent of the scales selected for excitation and voltage. This ratio, as a fraction, is equal to the reciprocal of the saturation factor at the same excitation, deducted from unity; or, if $f$ be the saturation factor and $p$ the percentage of saturation,

$$p = 100\left(1 - \frac{1}{f}\right)$$

**64. Magnetic degree.** The 360th part of the angle subtended, at the axis of a machine, by a pair of its field poles. One **mechanical degree** is thus equal to as many magnetic degrees as there are pairs of poles in the machine.

**65. The variation in prime movers** which do not give an absolutely uniform rate of rotation or speed, as in reciprocating steam engines, is the maximum angular displacement in position of the revolving member expressed in degrees, from the position it would occupy with uniform rotation, and with one revolution taken as 360 deg.

**66. The variation in alternators** or alternating-current circuits in general, is the maximum angular displacement, expressed in electrical degrees (1 cycle = 360 deg.) of corresponding ordinates of the voltage wave and of a wave of absolutely constant frequency equal to the average frequency of the alternator or circuit in question, and may be due to the variation of the prime mover.

**67. Relations of variations in prime mover and alternator.** If $p$ is the number of pairs of poles, the variation of an alternator is $p$ times the variation of its prime mover, if direct connected, and $pn$ times the variation of the prime mover if rigidly connected thereto in such a manner that the angular speed of the alternator is $n$ times that of the prime mover.

**68. The pulsation in prime movers, or in the alternator connected thereto.** The ratio of the difference between the maximum and minimum velocities in an engine-cycle to the average velocity.

**69. Capacity.** The two different senses in which this word is used sometimes lead to ambiguity. It is therefore recommended that whenever such ambiguity is likely to arise, the descriptive term *power capacity* or *current capacity* be used, when referring to the power or current which a device can safely carry, and that the term "*Capacitance*" be used when referring to the electrostatic capacity of a device.

**71. Resistor.** A device, heretofore commonly known as a resistance, used for the operation, protection, or control of a circuit or circuits. See Par. 740.

Digitized by Google

**82. Reactor.** A coil, winding or conductor, heretofore commonly known as a reactance coil or choke coil, possessing inductance, the reactance of which is used for the operation, protection or control of a circuit or circuits. See also Par. 214 and 736.

**83. Efficiency.** The efficiency of an electrical machine or apparatus is the ratio of its useful output to its total input.

**90. Table 1.—Symbols and Abbreviations**

| Name of quantity | Symbol for the quantity | Unit | Abbreviation for the unit |
|---|---|---|---|
| Electromotive force, abbreviated e.m.f. | $E$, $e$ | volt | |
| Potential difference, abbreviated p.d. | $V$, $v$ or $E$, $e$ | volt | |
| Voltage | $E$, $e$ or $V$, $v$ | volt | |
| Current | $I$, $i$ | ampere | |
| Quantity of electricity | $Q$, $q$ | coulomb or ampere-hour | |
| Power | $P$, $p$ | watt | |
| Electrostatic flux | $\psi$ | | |
| Electrostatic flux density | $D$ | | |
| Electrostatic field intensity | $F$ | | |
| Magnetic flux | $\Phi$, $\varphi$ | maxwell* | |
| Magnetic flux density | $B$, $\mathfrak{B}$ | gauss* | |
| Magnetic field intensity | $H$, $\mathfrak{H}$ | gilbert per centimeter or gauss† | gilbert per cm. |
| Magnetomotive force, abbreviated m.m.f. | $\mathfrak{F}$ | gilbert* | |
| Intensity of magnetization | $J$ | | |
| Susceptibility | $\kappa = J/H$ | | |
| Permeability | $\mu = B/H$ | | |
| Resistance | $R$, $r$ | ohm | |
| Reactance | $X$, $x$ | ohm | |
| Impedance | $Z$, $z$ | ohm | |
| Conductance | $g$ | mho | |
| Susceptance | $b$ | mho | |
| Admittance | $Y$, $y$ | mho | |
| Resistivity | $\rho$ | ‡ohm-centimeter | ohm-cm. |
| Conductivity | $\gamma$ | ‡mho per centimeter | mho per cm. |
| Dielectric constant | $\epsilon$ or $k$ | | |
| Reluctance | $\mathfrak{R}$ | | |
| Capacitance (electrostatic capacity) | $C$ | farad | |
| Inductance (or coefficient of self induction) | $L$ | henry | |
| Mutual inductance (or coefficient of mutual induction) | $M$ | henry | |

* An additional unit for m.m.f. is the "ampere-turn," for flux the "line," for magnetic flux density "maxwells per sq. in."

† The gauss is provisionally accepted for the present as the name of both the unit of field intensity and flux density, on the assumption that permeability is a simple numeric.

‡ NOTE.—The numerical values of these quantities are *ohms resistance* and *mhos conductance* between two opposite faces of a cm. cube of the material in question, but the correct names are as given, not ohms and mhos per cm. cube, as commonly stated.

Digitized by Google

**Table 1.—Symbols and Abbreviations.**—*Continued*

| Name of quantity | Symbol for the quantity | Unit | Abbreviation for the unit |
|---|---|---|---|
| Phase displacement | $\theta$, $\varphi$ | degree or radian | ° |
| Frequency | $f$ | cycle per second | — |
| Angular velocity | $\omega$ | radians per second | |
| Velocity of rotation | $n$ | revolutions per second | rev. per sec. |
| Number of conductors or turns | $N$ | convolutions or turns of wire | |
| Temperature | $T$, $t$, $\theta$ | degree centigrade | °C |
| Energy in general | $U$ or $W$ | joule, watt-hour | |
| Mechanical work | $W$ or $A$ | joule, watt-hour | |
| Efficiency | $\eta$ | per cent. | |
| Length | $l$ | centimeter | cm. |
| Mass | $m$ | gram | g. |
| Time | $t$ | second | sec. |
| Acceleration due to gravity | $g$ | centimeter per second per second | cm. per sec. per sec. |
| Standard acceleration due to gravity (at about 45 deg. latitude and sea level) equals 980.665* | $g_o$ | centimeter per second per second | cm. per sec. per sec. |

**91.** $E_m$, $I_m$ and $P_m$ should be used for maximum cyclic values, $e$, $i$ and $p$ for instantaneous values, $E$ and $I$ for r.m.s. values (see Par. 10) and $P$ for the average value of the power, or the active power. These distinctions are not necessary in dealing with continuous-current circuits. In print, vector quantities should be represented by bold-face capitals.

## CLASSIFICATION OF MACHINERY

**100.** The machinery under consideration in these rules may be classified in various ways, these various classifications overlapping or interlocking in considerable degree. Briefly, they are direct-current or alternating-current, rotating or stationary. Under rotating apparatus there are two principal classifications: *First*, according to the function of the machines; motors, generators, boosters, motor-generators, dynamotors, double-current generators, converters and phase advancers; *Second*, according to the type of construction or principle of operation; commutating, synchronous, induction, unipolar, rectifying. Obviously, some of these machines could be rationally included in either classification, *e.g.*, motor-generators and rectifying machines.

In the following, self-evident definitions have, for the most part, been omitted.

## ROTATING MACHINES

### FUNCTIONAL CLASSIFICATION OF ROTATING MACHINES

**101. Generator.** A machine which transforms mechanical power into electrical power.

**102. Motor.** A machine which transforms electrical power into mechanical power.

* This has been the accepted standard value for many years and was formerly considered to correspond accurately to 45 deg. latitude and sea level. Later researches, however, have shown that the most reliable value for 45 deg. and sea-level is slightly different; but this does not affect the standard value given above.

Digitized by Google

**103. Booster.** A generator inserted in series in a circuit to change its voltage. It may be driven by an electric motor (in which case it is termed a motor-booster) or otherwise.

**104. Motor-generator set.** A transforming device consisting of a motor mechanically coupled to one or more generators.

**105. Dynamotor.** A transforming device combining both motor and generator action in one magnetic field, either with two armatures, or with one armature having two separate windings and independent commutators.

**106. A direct-current compensator** or **balancer** comprises two or more similar direct-current machines (usually with shunt or compound excitation) directly coupled to each other and connected in series across the outer conductors of a multiple-wire system of distribution, for the purpose of maintaining the potentials of the intermediate wires of the system, which are connected to the junction points between the machines.

**107. A double-current generator** supplies both direct and alternating currents from the same armature-winding.

**108. A converter** is a machine employing mechanical rotation in changing electrical energy from one form into another. There are several types of converters as follow:

**109. A direct-current converter** converts from a direct current to a direct current, usually with a change of voltage. Such a machine may be either a motor-generator set or a dynamotor.

**110. A synchronous converter** (sometimes called a rotary converter) converts from an alternating to a direct current, or *vice versa*. It is a synchronous machine with a single closed-coil armature winding, a commutator and slip rings.

**111. A cascade converter, also called a motor converter,** is a combination of an induction motor with a synchronous converter, the secondary circuit of the former feeding directly into the armature of the latter; *i.e.*, it is a synchronous converter concatenated with an induction motor.

**112. A frequency converter** converts the power of an alternating-current system from one frequency to another, with or without a change in the number of phases, or in the voltage.

**113. A rotary phase-converter** converts from an alternating-current system of one or more phases to an alternating-current system of a different number of phases, but of the same frequency.

**114. A phase advancer** is a machine which supplies reactive volt-amperes to the system to which it is connected. Phase advancers may be either synchronous or asynchronous.

**115. A synchronous condenser** or **synchronous phase advancer** is a synchronous machine, running either idle or with load, the field excitation of which may be varied so as to modify the power-factor of the system, or through such modification to influence the load voltage. The function of a synchronous condenser is to supply reactive volt-amperes to the system with which it is connected.

## CONSTRUCTIONAL CLASSIFICATION OF ROTATING MACHINES

**130. Commutating machines. Direct-current commutating machines** comprise a magnetic field of constant polarity, an armature, and a commutator connected therewith. These include: direct-current generators; direct-current motors; direct-current boosters; direct-current motor-generator sets and dynamotors; direct-current compensators or balancers; and arc machines.

**131. Alternating-current commutating machines*** comprise a magnetic field of alternating polarity, an armature, and commutator connected therewith.

**132. Synchronous commutating machines** include synchronous converters, cascade-converters, and double-current generators.

**133. Synchronous machines** comprise a constant magnetic field and an armature receiving or delivering alternating-currents in synchronism with the

* A suggested classification of alternating current commutator motors is given in the July, 1916 *Proceedings* of the A. I. E. E.

Digitized by Google

motion of the machine; *i.e.*, having a frequency strictly proportional to the speed of the machine. They may be subdivided as follow:

**134. An alternator** is a synchronous alternating-current generator, either single-phase or polyphase.

**135. A polyphase alternator** is a polyphase synchronous alternating-current generator, as distinguished from **a single-phase alternator.**

**136. An inductor alternator is an alternator** in which both field and armature windings are stationary, and in which masses of iron or inductors, by moving past the coils, alter the magnetic flux through them. It may be either single-phase or polyphase.

**137. A synchronous motor** is a machine structurally identical with an alternator, but operated as a motor.

**138. Induction machines** include apparatus wherein primary and secondary windings rotate with respect to each other; *i.e.*, induction motors, induction generators, certain types of frequency converters and certain types of rotary phase-converters.

**139. An induction motor** is an alternating-current motor, either single-phase or polyphase, comprising independent primary and secondary windings, one of which, usually the secondary, is on the rotating member. The secondary winding receives power from the primary by electromagnetic induction.

**140. An induction generator** is a machine structurally identical with an induction motor, but driven above synchronous speed as an alternating-current generator.

**141. Unipolar or acyclic machines** are direct-current machines, in which the voltage generated in the active conductors maintains the same direction with respect to those conductors.

## SPEED CLASSIFICATION OF MOTORS

**150. Motors** may, for convenience, be classified with reference to their speed characteristics as follows:

**151. Constant-speed motors,** whose speed is either constant or does not materially vary; such as synchronous motors, induction motors with small slip, and ordinary direct-current shunt motors.

**152. Multispeed motors** (two-speed, three-speed, etc.), which can be operated at any one of several distinct speeds, these speeds being practically independent of the load; such as motors with two armature windings, or induction motors in which the number of poles is changed by external means.

**153. Adjustable-speed motors,** in which the speed can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load, such as shunt motors designed for a considerable range of speed variation.

**154. Varying-speed motors,** or motors in which the speed varies with the load, ordinarily decreasing when the load increases; such as series motors, compound-wound motors, and series-shunt motors. As a subclass of varying-speed motors, may be cited, **adjustable varying-speed motors,** or motors in which the speed can be varied over a considerable range at any given load, but when once adjusted, varies with the load; such as compound-wound motors arranged for adjustment of speed by varying the strength of the shunt field.

## CLASSIFICATION OF ROTATING MACHINES RELATIVE TO THE DEGREE OF ENCLOSURE OR PROTECTION

**160.** The following types are recognised:

| | |
|---|---|
| Open | Self-ventilated |
| Protected | Drip-proof |
| Semi-enclosed | Moisture-resisting |
| Enclosed | Submersible |
| Separately ventilated | Explosion-proof |
| Water-cooled | Explosion-proof slip-ring enclosure |

**161. An "open" machine** is of either the pedestal-bearing or end-bracket type where there is no restriction to ventilation, other than that necessitated by good mechanical construction.

**162. A "protected" machine** is one in which the armature, field coils,

Digitized by Google

and other live parts are protected mechanically from accidental or careless contact, while free ventilation is not materially obstructed.

**163. A "semi-enclosed" machine** is one in which the ventilating openings in the frame are protected with wire screen, expanded metal, or other suitable perforated covers, having apertures not exceeding ½ of a square inch (3.2 sq. cm.) in area.

**164. An "enclosed" machine** is so completely enclosed by integral or auxiliary covers as to prevent a circulation of air between the inside and outside of its case, but not sufficiently to be termed air-tight.

**165. A "separately ventilated" machine** has its ventilating air supplied by an independent fan or blower external to the machine.

**166. A "water-cooled" machine** is one which mainly depends on water circulation for the removal of its heat.

**167. A "self-ventilated" machine** differs from a separately ventilated machine only in having its ventilating air circulated by a fan, blower, or centrifugal device integral with the machine.

If the heated air expelled from the machine is conveyed away through a pipe attached to the machine, this should be so stated.

**168. A "drip-proof" machine** is one so protected as to exclude falling moisture or dirt. A "drip proof" machine may be either "open" or "semi-enclosed," if it is provided with suitable protection integral with the machine, or so enclosed as to exclude effectively falling solid or liquid material.

**169. A moisture-resisting machine** is one in which all parts are treated with moisture-resisting material. Such a machine shall be capable of operating continuously or intermittently in a very humid atmosphere, such as in mines, evaporating rooms, etc.

**170. A "submersible" machine** is a machine capable of withstanding complete submersion, in fresh water or sea water, as may be specified, for 4 hr. without injury.

**171. An "explosion-proof" machine** is a machine in which the enclosing case can withstand, without injury, any explosion of gas that may occur within it, and will not transmit the flame to any inflammable gas outside it.

**172.** An induction motor in which the slip rings and brushes alone are included within an explosion-proof case should not be described as an explosion-proof machine, but as a machine "with **explosion-proof slip-ring enclosure.**"

## STATIONARY INDUCTION APPARATUS

**200. Stationary induction apparatus** changes electric energy to electric energy, through the medium of magnetic energy, without mechanical motion. It comprises several forms, distinguished as follows:

**201. Transformers**, in which the primary and secondary windings are ordinarily insulated one from another.

**202.** The terms **"high-voltage"** and **"low-voltage"** are used to distinguish the winding having the greater from that having the lesser number of turns. The terms **"primary"** and **"secondary"** serve to distinguish the windings in regard to energy flow, the primary being that which receives the energy from the supply circuit, and the secondary that which receives the energy by induction from the primary.

**203.** The **rated current of a constant-potential transformer** is that secondary current which, multiplied by the rated-load secondary voltage, gives the kv-a. rated output. That is, a transformer of given kv-a. rating must be capable of delivering the rated output at rated secondary voltage, while the primary impressed voltage is increased to whatever value is necessary to give rated secondary voltage.

The **rated primary voltage** of a constant-potential transformer is the rated secondary voltage multiplied by the turn ratio.

**204.** The **ratio of a transformer**, unless otherwise specified, shall be the ratio of the number of turns in the high-voltage winding to that in the low-voltage winding; *i.e.*, the "turn-ratio."

**205.** The **voltage ratio** of a transformer is the ratio of the r.m.s. primary terminal voltage to the r.m.s. secondary terminal voltage, under specified conditions of load.

Digitized by Google

**206.** The **"current ratio"** of a current-transformer is the ratio of r.m.s. primary current to r.m.s. secondary current, under specified conditions of load.

**207.** The **"marked ratio"** of an instrument transformer is the ratio which the apparatus is designed to give under average conditions of use. When a precise ratio is required, it is necessary to specify the voltage, frequency, load and power-factor of the load.

**208. Volt-ampere ratio of transformers.** The volt-ampere ratio, which should not be confused with real efficiency, is the ratio of the volt-ampere output to the volt-ampere input of a transformer, at any given power-factor.

**209. Auto-transformers** have a part of their turns common to both primary and secondary circuits.

**210. Voltage regulators** have turns in shunt and turns in series with the circuit, so arranged that the voltage ratio of the transformation or the phase relation between the circuit-voltages is variable at will. They are of the following three classes:

**211. Contact voltage regulators,** in which the number of turns in one or both of the coils is adjustable.

**212. Induction voltage regulators,** in which the relative positions of the primary and secondary coils are adjustable.

**213. Magneto voltage regulators,** in which the direction of the magnetic flux with respect to the coils is adjustable.

**214. Reactors,** heretofore commonly called **reactance-coils,** also called **choke coils;** a form of stationary induction apparatus used to supply reactance or to produce phase displacement. See also Par. **82** and **736.**

## METERS AND INSTRUMENTS

**225.** Although the terms **instruments** and **meters** are frequently used synonymously in referring to electrical measuring devices, the meter departments of manufacturing and operating companies commonly use the word "meters" in the collective sense to designate only those devices which register the total energy or quantity of electricity consumed in or supplied to a circuit, and reserve the term "instruments," in the collective sense, for all other electrical measuring or indicating devices.

**226.** In general, the names of meters and instruments are self-defining, particularly when considered in connection with existing definitions. The following terms are preferred to other terms sometimes used for the same devices: **Reactive-factor meter, power-factor meter, watt-hour meter,** etc.

**227. Crest voltmeter.** A voltmeter depending for its indications upon the crest, that is the maximum value of the voltage of the system to which it is connected. The instruments are so calibrated that they indicate the r. m. s. value of the sinusoidal voltage having the same crest value.

**228. Synchronoscope** (also called a synchroscope or synchronism indicator). A device which in addition to indicating synchronism between two machines, shows whether the speed of the incoming machine is fast or slow.

**229. Reactive volt-ammeter** (also called a reactive-volt-ampere indicator). An instrument which indicates the reactive volt-amperes of the circuit to which it is connected.

**230. Line drop voltmeter compensator.** A device used in connection with a voltmeter which causes it to indicate the voltage at some distant point of the circuit.

**231. Recording ammeters, voltmeters, wattmeters, etc.,** are instruments which record graphically upon time-charts the values of the quantities they measure.

**232. A demand meter** is a device which indicates or records the demand or maximum demand (see Par. **57** and **58**). In practice two types are recognized:

**233. An integrated-demand meter** is one which indicates or records the maximum demand obtained through integration.

**234. A lagged-demand meter** is one in which the indication of maximum demand is subject to a characteristic time lag.

Digitized by Google

**235. Errors of indicating instruments.** In specifying the accuracy of an indicating instrument, the error at any point on the scale shall be expressed as a percentage of the full scale reading.

**236. Torque** of meters and instruments shall be expressed in millimetergrams.

## STANDARDS FOR ELECTRICAL MACHINERY

**250.** *The expressions "machinery" and "machines" are here employed in a general sense, in order to obviate the constant repetition of the words "machinery or induction apparatus."*

**251.** *All temperatures are to be understood as centigrade.*

**252.** *The expression "capacity" is to be understood as indicating "capability," except where specifically qualified as, for instance, in the case of allusions to electrostatic capacity, i.e., capacitance.*

**253.** *Wherever special rules are given for any particular type of machinery or apparatus (such as switches, railway motors, railway substation machinery, etc.) these special rules shall be followed, notwithstanding any apparent conflict with the provisions of the more general sections. In the absence of special rules on any particular point, the general rules on this point shall be followed.*

**260. Objects of standardization.** To ensure satisfactory results, electrical machinery should be specified to conform to the institute standardization rules, in order that it shall comply, in operation, with approved limitations in the following respects, so far as they are applicable.

Operating temperature
Mechanical strength
Commutation
Dielectric strength
Insulation resistance
Efficiency
Power-factor
Wave shape
Regulation

**261. Capacity or available output of an electrical machine.** So far as relates to the purposes of these standardization rules, the institute defines the capacity of an electrical machine as the load which it is capable of carrying for a specified time (or continuously), without exceeding in any respect the limitations herein set forth.

Except where otherwise specified, the capacity of an electrical machine shall be expressed in terms of its available *output*. For exceptions see Par. **277** and **802**.

**262. Rating of an electrical machine.** Capacity should be distinguished from rating. The rating of a machine is the output marked on the rating plate, and shall be based on, but shall not exceed, the maximum* load which can be taken from the machine under prescribed conditions of test. This is also called the rated output.

**263. The principle upon which machine ratings** are based, so far as relates to thermal characteristics, is that the rated load, applied continuously or for a stated period, shall produce a temperature rise which, superimposed upon a standard ambient temperature, will not exceed the maximum safe operating temperature of the insulation.

**264. A. I. E. E. and I. E. C. ratings.** When the prescribed conditions of test are those of the A. I. E. E. standardization rules, the rating of the machine is the institute rating. (See Par. **620**.) When the prescribed conditions of the test are those of the I. E. C.† rules, the rating of the machine is the I. E. C. rating. A machine so rated in either case may bear a distinctive sign upon its rating plate.

**265. Standard temperature and barometric pressure for institute rating.** The Institute rating (Par. **262**) of a machine shall be its capacity

* The term "maximum load" does not refer to loads applied solely for mechanical, commutation, or similar tests.

† I. E. C. stands for "International Electrochemical Commission." This rating has not yet been established.

Digitized by Google

when operating with a cooling medium of the ambient temperature of reference (40 deg. for air or 25 deg. for water, see Par. **205** and **209**) and with barometric conditions within the range given in Par. **208**. See Par. **205A**, **207**, **220** and **221**.

**266. The temperature rises specified in these rules** apply to all ambient temperatures up to and including, but not exceeding, 40 deg. cent., for air and 25 deg. cent. for water. (For definition of ambient temperature see Par. **203**.)

**267. Any machinery destined for use with higher ambient** temperatures of cooling mediums, and also any machinery for operation at altitudes for which no provision is made in Par. **208**, should be the subject of special guarantee by the manufacturer. The methods of test and performance set forth in these rules will, however, afford guidance in such cases.

## UNITS IN WHICH RATING SHALL BE EXPRESSED

**274.** The rating of **direct-current generators**, shall be expressed in kilowatts (kw.) available at the terminals.

**275.** The rating of **alternators** and **transformers**, shall be expressed in kilovolt-amperes (kv-a.) available at the output terminals, at a specified power factor.

**276.** It is strongly recommended that the **rating of motors** shall be expressed in kilowatts* (kw.) available at the shaft. (An exception to this rule is made in the case of Railway motors, which, for some purposes, are also rated by their *input*, see Par. **302**.)

**277. Auxiliary machinery**, such as regulators, resistors, reactors, balancer sets, stationary and synchronous condensers, etc.; shall have their ratings appropriately expressed. It is essential to specify also the voltage (and frequency, if a-c.), of the circuits on which the machinery may appropriately be used.

## KINDS OF RATING

There are various kinds of rating such as:

**281. Continuous rating.** A machine, rated for continuous service, shall be able to operate continuously at its rated output, without exceeding any of the limitations referred to in Par. **260**.

**282. Short-time rating.** A machine rated for short-time service; (*i.e.*, service including runs alternating with stoppages of sufficient duration to ensure substantial cooling), shall be able to operate at its rated output during a limited period, to be specified in each case, without exceeding any of the limitations referred to in Par. **260**. Such a rating is a **short-time rating.**

**283. Nominal ratings.** For railway motors and sometimes for railway substation machinery, certain nominal ratings are employed. See Par. **765** and **800**. Nominal ratings for automobile propulsion motors and generators are not recommended; see Par. **837**.

**284. Duty-cycle operation.** Many machines are operated on a cycle of duty which repeats itself with more or less regularity. For purposes of rating, either a continuous or a short-time equivalent load, may be selected, which shall simulate as nearly as possible the thermal conditions of the actual duty cycle.

---

* Since the input of machinery of this class is measured in electrical units and since the output has a definite relation to the input, it is logical and desirable to measure the delivered power in the same units as are employed for the received power. Therefore, the output of motors should be expressed in kilowatts instead of in horse power. However, on account of the hitherto prevailing practice of expressing mechanical output in horse power, it is recommended that for machinery of this class the rating should, for the present, be expressed both in kilowatts and in horse power; as follows:

kw.————approx. equiv. h.p.————

For the purposes of these rules the horse power shall be taken as 746.0 watts.

In order to lay stress upon the preferred future basis, it is desirable that on rating plates, the rating in kilowatts shall be shown in larger and more prominent characters than the rating in horse power.

Digitized by Google

**285. Standard durations of equivalent tests** shall be for machines operating under specified duty-cycles as follow (see also Par. 286):

5 min.
10 min.
15 min.
30 min.
60 min.
120 min.
and continuous.

Of these the first six are short-time ratings, selected as being thermally equivalent to the specified duty cycle.

When, for example, a short-time rating of 10 min. duration is adopted, and the thermally equivalent load is 25 kw. for that period, then such a machine shall be stated to have a 10-min. rating of 25 kw.

**286.** In every case the equivalent short-time test shall commence only when the windings and other parts of the machine are **within 5 deg. cent. of the ambient temperature** at the time of starting the test.

**287.** In the absence of any specification as to the kind of rating, the continuous rating shall be understood.*

**288.** Machines marked in accordance with Par. 264 shall be understood to have a continuous rating, unless otherwise marked in accordance with Par. 285.

## HEATING AND TEMPERATURE

**300. Temperature limitations of the capacity of electrical machinery.** The capacity, so far as relates to temperature, is usually limited by the maximum temperature at which the materials in the machine, especially those employed for insulation, may be operated for long periods without deterioration. When the safe limits are exceeded, deterioration is rapid. The insulating material becomes permanently damaged by excessive temperature, the damage increasing with the length of time that the excessive temperature is maintained, and with the amount of excess temperature, until finally the insulation breaks down.

**301.** The result of operating at temperatures in excess of the safe limit is to shorten the life of the insulating material. This shortening of life is, in certain special cases, warranted, when necessary for obtaining some other desirable result, as, for example, in some instances of railway and other motors for propelling vehicles, in providing greater power within a limited space. See Par. 304. Further instances may also be noted in the cases of contactors, controllers, induction-starters, arc-lamp-magnet windings, etc., designed and constructed for operation at relatively high temperatures.

**302.** There does not appear to be any advantage in operating at lower temperatures than the safe limits, so far as the life of the insulation is concerned. Insulation may break down from various causes, and when these breakdowns occur, it is not usually due to the temperature at which the insulation has been operated, provided the safe limits have not been exceeded.

**303. The ambient temperature** is the temperature of the air or water which, coming into contact with the heated parts of a machine, carries off its heat. See Par. 309, 310 and 314.

**304. The cooling fluid may** either be led to the machine through ducts, or through pipes, or merely surround the machine freely. In the former case the ambient temperature is to be measured at the intake of the machine itself. In the latter case see Par. 314.

**305. Ambient temperature of reference for air.** The standard ambient temperature of reference, when the cooling medium is air, shall be 40 deg. cent.

**305A. Whatever may be the ambient temperature** when the machine is in service, the limits of the maximum observable temperature and of temperature rise specified in the rules should not be exceeded in service; for, if the maximum temperature be exceeded, the insulation may be endangered, and if the rise be exceeded, the excess load may lead to injury, by exceeding

* An exception is made in the case of motors for railway service, where in the absence of any specification as to the kind of rating, the "**nominal rating**" as defined in Par. 319 and 415 shall be understood.

Digitized by Google

limits other than those of temperature; such as commutation, stalling load and mechanical strength. For similar reasons, load in excess of the rating should not be taken from a machine.

**306.** The permissible rises in temperature given in column 2 of Table III in Par. **376** have been calculated on the basis of the standard ambient temperature of reference, by subtracting 40 deg. from the highest temperatures permissible, which are given in column 1 of the same table.

**307.** A machine may be tested at any convenient ambient temperature, preferably not below 15 deg. cent., but *whatever be the value of this ambient temperature, the permissible rises of temperature must not exceed those given in column 2 of the table in Par.* **376.**

**308. Altitude.** Increased altitude has the effect of increasing the temperature rise of some types of machinery. In the absence of information in regard to the height above sea level at which the machine is intended to work in ordinary service, this height is assumed not to exceed 1,000 meters (3,300 ft.). For machinery operating at an altitude of 1,000 meters or less, a test at any altitude less than 1,000 meters is satisfactory, and no correction shall be applied to the observed temperatures. Machines intended for operation at higher altitudes shall be regarded as special. See Par. **267.** It is recommended that when a machine is intended for service at altitudes above 1,000 meters (3,300 ft.) the permissible temperature rise at sea level, until more nearly accurate information is available, shall be reduced by 1 per cent. for each 100 meters (330 ft.) by which the altitude exceeds 1,000 meters. Water-cooled oil transformers are exempt from this reduction.

**309. Ambient temperature of reference for water-cooled machinery.** For water-cooled machinery, the standard temperature of reference for incoming cooling water shall be 25 deg. cent., measured at the intake of the machine.

**310. In testing of water-cooled transformers,** it is not necessary to take into account the surrounding-air temperature, except where the cooling effect of the air is 15 per cent. or more of the total cooling effect, referred to the standard ambient temperature of reference of 25 deg. cent. for water and 40 deg. cent. for air. When the effect of the cooling air is 15 per cent. or more of the total, the temperature of the cooling water should be maintained within 5 deg. cent. of the surrounding air. Where this is impractical, the ambient temperature should be determined from the change in the resistance of the windings, using a disconnected transformer, supplied with the normal amount of cooling water, until the temperature of the windings has become constant.

**311. In the case of rotating machines,** cooled by forced draft, a conventional weighted mean shall be employed, a weight of four being given to the temperature of the circulating air supplied through ducts (see Par. **304**), and a weight of one to the surrounding room air. **In the case of air-cooled transformers,** see "exception" Par. **321.**

**312. Machines cooled by other means.** Machines cooled by means other than air or water shall receive special consideration.

**313. Outdoor machinery exposed to sun's rays.** Outdoor machinery not protected from the sun's rays at times of heavy load, must receive special consideration.

**314. Measurement of the ambient temperature during tests of machinery.** The ambient temperature is to be measured by means of several thermometers placed at different points around and half-way up the machine, at a distnce of 1 to 2 meters (3 to 6 ft.), and protected from drafts, and abnormal heat radiation, preferably as in Par. **316.**

**315.** The value to be adopted for the ambient temperature during a test, is the mean of the readings of the thermometers (placed as above), taken at equal intervals of time during the last quarter of the duration of the test.

**316.** In order to avoid **errors due to the time lag** between the temperature of large machines and the variations in the ambient air, all reasonable precautions must be taken to reduce these variations and the errors arising thereform. Thus, the thermometer for determining the ambient temperature shall be immersed in a suitable liquid, such as oil, in a suitable heavy metal cup. This can be made to respond to various rates of change, by pro-

Digitized by Google

portioning the amount of oil to the metal in the containing cup. A convenient form for such an oil-cup consists of a massive metal cylinder, with a hole drilled partly through it. This hole is filled with oil and the thermometer is placed therein with its bulb well immersed. The larger the machine under test, the larger should be the metal cylinder employed as an oil-cup in the determination of the ambient temperature. The smallest size of oil cup employed in any case shall consist of a metal cylinder 25 mm. in diameter and 50 mm. high (1 in. in diameter and 2 in. high).

**317. Thermometers used for taking temperatures of machinery** shall be covered by felt pads 3 mm. (⅛ in.) thick and 4 × 5 cm. wide (1½ in. × 2 in.), cemented on; oil putty may be used for stationary and small apparatus.

**318. In transformer testing,** and sometimes in testing other machines, it may be desirable to avoid errors due to time lag in temperature changes, by employing an idle unit of the same size and subjected to the same conditions of cooling as the unit under test, for obtaining the ambient temperature as described in Par. 310.

**319.** Where **machines are partly below the floor line** in pits, the temperature of the rotor shall be referred to a weighted mean of the pit and room temperatures, the weight of each being based on the relative proportions of the rotor in and above the pit. Parts of the stator constantly in the pit shall be referred to the ambient temperature in the pit.

**320. Correction for the deviation of the ambient temperature of the cooling medium, at the time of the heat test, from the standard ambient temperature of reference.** Numerous experiments have shown that deviation of the temperature of the cooling medium from that of the standard of reference, at the time of the heat run, has a negligible effect upon the temperature rise of the apparatus; therefore, no correction shall be applied for this deviation. It is, however, desirable that tests should be conducted at ambient temperatures not lower than 15 deg. cent.

**321. Exception. A correction shall be applied** to the observed temperature rise of the windings of *air-blast transformers*, due to difference in resistance, when the temperature of the ingoing cooling air differs from that of the standard of reference. This correction shall be the ratio of the inferred absolute ambient temperature of reference to the inferred absolute temperature of the ingoing cooling air, *i.e.*, the ratio $274.5/(234.5 + t)$; where $t$ is the ingoing cooling-air temperature.

Thus, a cooling-air room temperature of 30 deg. cent. would correspond to an inferred absolute temperature of 264.5 deg. on the scale of copper resistivity, and the correction to 40 deg. cent. (274.5 deg. inferred absolute temperature) would be $274.5/264.5 = 1.04$, making the correction factor 1.04; so that an observed temperature rise of say 50 deg. cent. at the testing ambient temperature of 30 deg. cent. would be corrected to $50 \times 1.04 = 52$ deg. cent. this being the temperature rise which would have occurred had the test been made with the standard ingoing cooling-air temperature of 40 deg. cent.

**322. Duration of temperature test of machine for continuous service.** The temperature test shall be continued until sufficient evidence is available to show that the maximum temperature and temperature rise would not exceed the requirements of the rules, if the test were prolonged until a steady final temperature was reached.

**323. Duration of temperature test of machine with a short-time rating.** The duration of the temperature test of a machine with a short-time rating shall be the time required by the rating. See Par. 285 and 286.

**324. Duration of temperature test for machine having more than one rating.** The duration of the temperature test for a machine with more than one rating shall be the time required by that rating which produces the greatest temperature rise. In cases where this cannot be determined beforehand, the machine shall be tested separately under each rating.

**325. Temperature measurements during heat run.** Temperature measurements, when possible, shall be taken during operation, as well as when the machine is stopped. The highest figures thus obtained shall be adopted. In order to abridge the long heating period, in the case of large machines, reasonable overloads of current, during the preliminary period are suggested for them.

## TEMPERATURE MEASUREMENTS

**340. The life of the insulation of a machine** depends in great measure upon the actual temperatures attained by the different parts, rather than on the rises of temperature in those parts.

**341. The temperature in the different parts of a machine** which it would be desirable to ascertain, are the maximum temperatures reached in those parts.

**342.** (Deleted in the last revision of the Standardization Rules.)

**343. As it is usually impossible to determine the maximum temperature** attained in insulated windings, it is convenient to apply a correction to the observable temperature, so as to approximate the difference between the actual maximum temperature and the observable temperature by the method used. This correction, or margin of security, is provided to cover the errors due to fallibility in the location of the measuring devices, as well as inherent inaccuracies in measurement and methods.

**344. In determining the temperature of different parts of a machine** three methods are provided. The appropriate method for any particular case is set forth below.

**345. Method No. 1. Thermometer method.** This method consists in the determination of the temperature, by mercury or alcohol thermometers, by resistance thermometers, or by thermo-couples, any of these instruments being applied to the hottest accessible part of the *completed* machine, as distinguished from the thermo-couples or resistance coils embedded in the machine as described under method No. 3.

**346. When method No. 1 is used,** the hottest-spot temperature for windings shall be estimated by adding a hottest-spot correction of 15 deg. cent. to the highest temperature observed, in order to allow for the practical impossibility of locating any of the thermometers at the hottest spot.

**347. Exception.** When the thermometers are applied directly to the surfaces of bare windings, such as an edgewise strip conductor, or a cast copper winding, a hottest-spot correction of 5 deg. cent., instead of 15 deg. cent., shall be made. For commutators, collector rings, bare metallic surfaces not forming part of a winding, or for oil in which apparatus is immersed, no correction is to be applied.

**348. Method No. 2. Resistance method.** This method consists in the measurement of the temperature of windings by their increase in resistance, corrected* to the instant of shut-down when necessary. In the application of this method, thermometer measurements shall also be made whenever practicable without disassembling the machine† in order to increase the probability of revealing the highest observable temperature. Whichever measurement yields the higher temperature, that temperature shall be taken as the "highest observable" temperature and a hottest-spot correction of 10 deg. cent. added thereto.

---

* Whenever a sufficient time has elapsed between the instant of shut-down and the time of the final temperature measurement to permit the temperature to fall, suitable corrections shall be applied, so as to obtain as nearly as practicable the temperature at the instant of shut-down. This can sometimes be approximately effected by plotting a curve, with temperature readings as ordinates and times as abscissas, and extrapolating back to the instant of shut-down. In other instances, acceptable correction factors can be applied. In transformers of 200 kv-a. and less the measured temperature shall be increased one degree for every minute between the instant of shut-down and the time of the final temperature measurement, provided this time does not exceed three minutes.

In cases where successive measurements show *increasing* temperatures after shut-down, the highest value shall be taken.

† As one of the few instances in which the thermometer check cannot be applied in Method No. 2, the rotor of a turbo-alternator may be cited.

Digitized by Google

**349. The temperature coefficient of copper** shall be deduced from the formula $1/(234.5+t)$. Thus, at an initial temperature $t=40$ deg. cent., the temperature coefficient of increase in resistance per degree centigrade rise, is $1/(274.5)=0.00364$. The foregoing table, deduced from the formula, is given for convenience of reference.

**Table II.—Temperature Coefficients of Copper Resistance**

| Temperature of the winding, in deg. cent. at which the initial resistance is measured | Increase in resistance of copper per deg. cent., per ohm of initial resistance | Temperature of the winding, in deg. cent. at which the initial resistance is measured | Increase in resistance of copper per deg. cent., per ohm of initial resistance |
|---|---|---|---|
| 0 | 0.00 427 | 25 | 0.00 385 |
| 5 | 0.00 418 | 30 | 0.00 378 |
| 10 | 0.00 409 | 35 | 0.00 371 |
| 15 | 0.00 401 | 40 | 0.00 364 |
| 20 | 0.00 393 | ..... | ..... |

**350. In circuits of low resistance**, other than transformer windings (see Par. **351**), where joints and connections form a considerable part of the total resistance, the measurement of temperature by the resistance method shall not be used.

**351. The temperature of the windings of transformers** is always to be ascertained by method 2. In the case of air-blast transformers, it is especially important to place thermometers on the coils near the air outlet. See Par. **348**.

**352. Method No. 3. Embedded temperature-detector method.** This method consists in the use of thermo-couples or resistance temperature detectors, located as nearly as possible at the estimated hottest spot. When method No. 3 is used, it shall, when required, be checked by method No. 2; the hottest spot shall then be taken to be the highest value by either method, the required correction factors (Par. **348** and **356**) being applied in each case.

**353. By building into the machine** suitably placed temperature detectors, a temperature not much less than that of the hottest spot will probably be disclosed. When these devices are adopted for such temperature determinations, a liberal number shall be employed, and all reasonable efforts, consistent with safety, shall be made to locate them at the various places where the highest temperatures are likely to occur.

**354. Temperature-detectors** should be placed in at least two sets of locations. One of these should be between a coil-side* and the core, and one between the top and bottom coil-sides where two coil-sides per slot are used. Where only one coil-side per slot is used, one set of detectors shall be placed between coil-side and core, and one set between coil-side and wedge.

**355.** Method No. 3 should be applied to all stators of machines with cores having a width of 50 cm. (20 in.) and over. It should also be applied to all machines of 5,000 volts and over, if of over 500 kv-a., regardless of core width. This method is not required for induction-regulators, which shall be tested as transformers.

**356. Correction factor for method No. 3.** In the case of two-layer windings, with detectors between coil-sides, and between coil-side and core, add 5 deg. cent. to the highest reading. In single-layer windings, with detectors between coil-side and core and between coil-side and wedge, add to the highest reading 10 deg. cent. +1 deg. cent. per 1,000 volts above 5,000 volts of terminal pressure.

## TEMPERATURE LIMITS

**375.** Table III gives the limits for the hottest-spot temperatures of insulations. The permissible limits are indicated in column 1 of the table. The limits of temperature rise permitted under rated-load conditions are given

* A coil-side is one of the two active sides of a coil.

Digitized by Google

in column 2, and are found by subtracting 40-deg. cent. from the figures in column 1. Whatever be the ambient temperature at the time of the test, the rise of temperature must never exceed the limits in column 2 of the table. The highest temperatures, and temperature rises, attained in any machine at the output for which it is rated, must not exceed the values indicated in the table and clauses following.

**376. Permissible temperatures and temperature rises for insulating materials.** Table III (following) gives the highest temperatures and temperature rises to which various classes of insulating materials may be subjected, based on a standard ambient temperature of reference of 40 deg. cent.

**377.** NOTE. The Institute recognizes the ability of manufacturers to ploy class B insulation successfully at maximum temperatures of 150 deg. cent. and even higher. However, a sufficient data covering experience over a period of years at such temperatures are at present unavailable, the institute adopts 125 deg. cent. as a conservative limit for this class of insulation, and any increase above this figure should be the subject of special guarantee by the manufacturer.

**Table III.—Permissible Temperatures and Temperature Rises for Insulating Materials**

| | | 1 | 2 |
|---|---|---|---|
| Class | Description of material | Maximum temperature to which the material may be subjected | Maximum temperature rise |
| A. | Cotton, silk, paper and similar materials, when so treated or impregnated as to increase the thermal limit, or when permanently immersed in oil; also enameled wire*..... | 105 deg. cent. | 65 deg. cent. |
| B. | Mica, asbestos and other materials capable of resisting high temperatures, in which any class A. material or binder is used for structural purposes only, and may be destroyed without impairing† the insulating or mechanical qualities of the insulation..... | 125 deg. cent. | 85 deg. cent. |
| C. | Fireproof and refractory materials, such as pure mica, porcelain, quarts, etc..... | No limits specified | |

**378.** When a lower-temperature class material is comprised in a completed product to such an extent, or in such ways, that its subjection to the temperature limits allowed for the higher-temperature class material, with which it is associated, would affect the integrity of the insulation either mechanically or electrically, the permissible temperature shall be fixed at such a value as shall afford ample assurance that no part of the lower-temperature class material shall be subjected to temperatures higher than those approved by the Institute and set forth above.

* For cotton, silk, paper and similar materials, when neither treated, impregnated nor immersed in oil, the highest temperatures and temperature rises shall be 10 deg. cent. below the limits fixed for class A, in Table III.

† The word impair is here used in the sense of causing any change which would disqualify the insulation for continuous service.

Digitized by Google

**379. Table IV.—Permissible Hottest Spot Temperatures and Limiting Observable Temperature Rises in Other than Water-cooled Machinery**

| | Class | | A* (deg.) | B (deg.) |
|---|---|---|---|---|
| | Permissible hottest spot temperature. | | 105 | 125 |
| Method I Thermometer only. See Par. 346–347 | Hottest spot correction | | 15 | 15 |
| | Limiting observable temperature | | 90 | 110 |
| | Limiting observable temperature rise | | 50 | 70 |
| Method II Resistance. See Par. 348 | Hottest spot correction | | 10 | 10 |
| | Limiting observable temperature | | 95 | 115 |
| | Limiting observable temperature rise | | 55 | 75 |
| Method III Embedded temperature detectors See Par. 352–356 | Double-layer windings. For all voltages | Hottest spot correction | 5 | 5 |
| | | Limiting observable temperature | 100 | 120 |
| | | Limiting observable temperature rise | 60 | 80 |
| | Single-layer windings. For 5,000 volts or less | Hottest spot correction | 10 | 10 |
| | | Limiting observable temperature | 95 | 115 |
| | | Limiting observable temperature rise | 55 | 75 |
| | Single-layer windings. For more than 5,000 volts | Hottest spot correction | 10+(*E*−5)† | 10+(*E*−5) |
| | | Limiting observable temperature | 95−(*E*−5) | 115−(*E*−5) |
| | | Limiting observable temperature rise | 55−(*E*−5) | 75−(*E*−5) |

## SPECIAL CASES OF TEMPERATURE LIMITS

**385. Temperature of oil.** The oil in which apparatus is permanently immersed shall in no part have a temperature, observable by thermometer, in excess of 90 deg. cent.

**386. Water-cooled transformers.** In these the hottest-spot temperature shall not exceed 90 deg. cent.

* For cotton, silk, paper and similar materials, when neither treated, impregnated nor immersed in oil, the highest temperatures and temperature rise shall be 10 deg. cent. below the limits fixed for class A.

† In these formulas, *E* represents the rated pressure between terminals in kilovolts. Thus for a three-phase machine with single-layer winding, and with 11 kilovolts between terminals, the hottest spot correction to be added to the maximum observable temperature will be 16 deg. cent.

Digitized by Google

**386A. Enclosed motors and generators.** In an enclosed machine (see Par. **164**) the limiting observable temperature and the limiting observable temperature rise shall be taken as 5 deg. cent. higher than in Table IV. This is not to be interpreted as an increase in the permissible hottest spot temperature, but is in recognition of the lesser difference between the hottest spot temperature and the observable temperature within an enclosed machine. This rule does not apply to those types of machines defined in Par. **163**, **165** and **167**.

**387. Railway motor temperature limits,** see Par. **804** and **805**.

**387A. Automobile propulsion motors and generators,** see Par. **838**.

**388. Squirrel-cage and amortisseur windings.** In many cases the insulation of such windings is largely for the purpose of making the conductors fit tightly in their slots, and the slightest effective insulation is ample. In other cases, there is practically no insulating material on the windings. Consequently, the temperature rise may be of any value such as will not occasion mechanical injury to the machine.

**389. Collector rings.** The temperature of collector rings shall not be permitted to exceed the "hottest spot" values set forth in Par. **376** and **379** for the insulations employed either in the collector rings themselves, or in adjacent insulations whose life would be affected by the heat from the collector rings.

**390. Commutators.** The observable temperature shall in no case be permitted to exceed the values given in Par. **376** and **379** for the insulation employed, either in the commutator or in any insulation whose life would be affected by the heat of the commutator. These temperature limits are intended only to protect the insulation of the commutator and of the adjacent parts, and are not intended as a criterion of successful commutation. See Par. **402**.

**391. Cores.** The temperature of those parts of the iron core in contact with insulating materials must not be such as to occasion in those insulating materials temperatures or temperature rises in excess of those set forth in Par. **376** and **379**.

**392. Other parts,** (such as brush-holders, brushes, bearings, pole-tips, cores, etc.) All parts of electrical machinery other than those whose temperature affects the temperature of the insulating material, may be operated at such temperatures as shall not be injurious in any respect.

## METHODS OF LOADING TRANSFORMERS FOR TEMPERATURE TESTS

**393.** Whenever practicable, transformers should be tested under conditions that will give losses approximating as nearly as possible to those obtained under normal or specified load conditions, maintained for the required time. See Par. **322–324**. The maximum temperature rises measured during this test should be considered as the observable temperature rises for the given load.

An approved method of making these tests is the **"loading-back"** method. The principal variations of this method are:

**394. With duplicate single-phase transformers.** Duplicate single-phase transformers may be tested in banks of two, with both primary and secondary windings connected in parallel. Normal magnetizing voltage should then be applied and the required current circulated from an auxiliary source. One transformer can be held under normal voltage and current conditions, while the other may be operating under slightly abnormal conditions.

**395. With one 3-phase transformer.** One 3-phase transformer may be tested in a manner similar to (a), provided the primary and secondary windings are each connected in delta for the test. Normal 3-phase magnetizing voltage should be applied and the required current circulated from an auxiliary single-phase source.

**396. With three single-phase transformers.** Duplicate single-phase transformers may be tested in banks of three, in a manner similar to (b) by connecting both primary and secondary windings in delta, and applying normal 3-phase magnetizing voltage and circulating the required current from an auxiliary single-phase source.

Digitized by Google

**397.** NOTE.—Among other methods that have a limited application and can be used only under special conditions may be mentioned:
(1) Applying dead load by means of some form of rheostat.
(2) Running alternately for certain short intervals of time on open circuit and then on short circuit, alternating in this way until the transformer reaches steady temperature. In this test, the voltage for the open-circuit interval and the current for the short-circuit interval shall be such as to give the same integrated core loss, and the same integrated copper loss, as in normal operation.

## ADDITIONAL REQUIREMENTS

**398. Short-circuit stresses.** The institute recognises the self-destructibility, both mechanical and thermal, of certain sizes and types of machines, when subjected to severe short-circuits, and recommends that ample protection be provided in such cases, external to the machine if necessary.

**399. Overspeeds. All types of rotating machines** shall be so constructed that they will safely withstand an overspeed of 25 per cent., except in the case of steam turbines, which, when equipped with emergency governors, shall be constructed to withstand 20 per cent. overspeed.

**400. In the case of series motors,** it is impracticable to specify percentage values for the guaranteed overspeed, on account of the varying service conditions.

**401. Water-wheel generators** shall be constructed for the maximum runaway speed which can be attained by the combined unit.

**402. Momentary loads. Continuously rated machines** shall be required to carry momentary loads of 150 per cent. of the amperes corresponding to the continuous rating, keeping the rheostat set for rated load excitation, (see Par. **281, 764** and **803**) and commutating machinery shall commutate successfully under this condition. Successful commutation is such that neither brushes nor commutator are injured by the test. In the case of direct-connected generators, this clause is not to be interpreted as requiring the prime mover to drive the generator at this overload.

**403. Machines for duty-cycle operation** shall be rated according to their equivalent load, either on the short-time or continuous basis, but if intended for operation with widely fluctuating loads, shall commutate successfully under their specified operating conditions. See Par. **284** and **285.**

**404. Stalling torque of motors.** Motors for continuous service shall, except when otherwise specified, be required to develop a running torque at least 175 per cent. of that corresponding to the running torque at their rated load, without stalling.
Obviously, duty-cycle machines must carry their peak loads without stalling.

## WAVE FORM

**405.** The **sine-wave** shall be considered as standard, except where deviation therefrom is inherent in the operation of the system of which the machine forms a part.

**406. The deviation of wave form** from the sinusoidal is determined by superposing upon the actual wave (as determined by oscillograph), the equivalent sine wave of equal length, in such a manner as to give the least difference between ordinates, and then dividing the maximum difference between corresponding ordinates by the maximum value of the equivalent sine wave. A maximum deviation of the terminal voltage wave on open circuit from sinusoidal shape not exceeding 10 per cent. is permissible, except when otherwise specified.

## EFFICIENCY AND LOSSES

**420. Machine efficiency** is the ratio of the power delivered by the machine to the power received by it.

**421. Plant or system efficiency** is the ratio of the energy delivered from the plant or system to the energy received by it in a specified period of time.*

* An exception should be noted in the case of the efficiency of **storage** batteries.

Digitized by Google

In calculating plant or system efficiency it may be desirable to calculate the losses in each individual machine or part of the system at the actual temperature of that machine or part during the specified interval. These losses may be appreciably different from the losses at 75 deg. cent., which latter shall be the standard temperature of reference for all efficiency guarantees. See Par. 422.

**422. In the case of machinery two efficiencies are recognized,** conventional efficiency (see Par. 423) and directly measured efficiency. Unless otherwise specified, the conventional efficiency is to be employed. When the efficiency of a machine is stated without specific reference to the load conditions, rated load is always to be understood whether the efficiency be the conventional or directly measured efficiency.

**423. Conventional efficiency** of machinery is the ratio of the output to the sum of the output and the losses; or of the input minus the losses to the input; when, in either case, conventional values are assigned to one or more of these losses. The need for assigning conventional values to certain losses, arises from the fact that some of the losses in electrical machinery are practicably indeterminable, and must, in many cases, either be approximated by an approved method of test, or else values recommended by the Institute and designated "conventional" values shall be employed for them in arriving at the "conventional efficiency."

**424.** (Deleted in last revision of Standardization Rules.)

**425. Directly measured efficiency.** Input and output determinations of efficiency may be made directly, measuring the output by brake, or equivalent, where applicable. Within the limits of practical application, the circulating-power method, sometimes described as the Hopkinson or "loading-back" method, may be used.

**426. Values of the indeterminate losses** may also be obtained by brake or other direct test, and used in estimating actual efficiencies of similar machines, by the separate-loss method.

**427. Normal conditions.** The efficiency shall correspond to, or be corrected to, the normal conditions herein set forth, which shall be regarded as standard. These conditions include voltage, current, power-factor, frequency, wave shape, speed, temperature, or such of them as may apply in each particular case.

**428. Measurement of efficiency.** Electric power shall be measured at the terminals of the apparatus. In polyphase machines, sufficient measurements shall be made on all phases to avoid errors of unbalance.

**429. Point at which mechanical power shall be measured.** Mechanical power delivered by machines, shall be measured at the pulley, gearing, or coupling, on the rotor shaft, thus excluding the loss of power in the belt or gear friction. See, however, an exception in Par. 800.

**430. The efficiency specified for alternators and transformers** shall be of the ratio of the kilowatt output to the kilowatt input at the rated kv-a. and power factor.

**431. Efficiency of alternating-current machinery in regard to wave shape.** In determining the efficiency of alternating-current machinery, the sine-wave is to be considered as standard, unless a different wave form is inherent in the operation of the system. See Par. 405.

**432. Temperature of reference for machine efficiency.** The efficiency, at all loads, of all apparatus, shall be corrected to a reference temperature of 75 deg. cent., but tests may be made at any convenient ambient temperature, preferably not less than 15 deg. cent. See Par. 348 and 445.

**433. The losses in constant-potential machinery,** either of the stationary type, or of the constant-speed rotary type, are of two classes, namely, those which remain substantially constant at all loads, and those which vary with the load. The former include iron losses, windage and friction, also $I^2R$ losses in any shunt windings. The latter include $I^2R$ losses in series windings. The constant losses may be determined by measuring the power required to operate the machine at no-load, deducting any series $I^2R$ losses. The variable loss at any load may be computed from the measured resistance of the series windings and the given load current.

Digitized by Google

**434. Stray load-losses.** The above simple method of determining the losses and hence the efficiency is only approximate, since the losses which are assumed to be constant do actually vary to some extent with the load, and also because the actual loss in the copper windings is sometimes appreciably greater than the calculated $I^2R$ loss. The difference between the approximate losses, as above determined, and the actual losses, is termed the "stray load-losses."* These latter are due to distortions in electric or magnetic fluxes from their no-load distributions or values, brought about by the load current. They are usually only approximately measurable, or may be indeterminable.

**435. Table V.—Classification of Losses in Machinery**

Losses in machinery may be classified as follows:

| *Accurately measurable or determinable* | *Approximately measurable or determinable* | *Indeterminable* |
|---|---|---|
| *a.* No-load core losses including eddy-current losses in conductors at no-load. | *c.* Brush friction loss. | *h.* Iron loss due to flux distortion. |
| *b.* Load $I^2R$ losses in windings. No-load $I^2R$ losses in windings. | *d.* Brush-contact loss. | *i.* Eddy-current losses in conductors due to transverse fluxes occasioned by the load currents. |
| | *e.* Losses due to windage and to bearing friction. | *k.* Eddy-current losses in conductors due to tooth saturation resulting from distortion of the main flux. |
| | *f.* Extra copper loss in transformer windings, due to stray fluxes caused by load currents. | *l.* Tooth-frequency losses due to flux distortion under load. |
| | *g.* Dielectric losses. | *m.* Short-circuit loss of commutation. |

**436. Evaluation of losses.** The larger individual losses are either accurately or approximately determinable, but certain of the indeterminable losses reach values in various kinds of machinery which require that they should be taken into account.

## LOSSES TO BE TAKEN INTO ACCOUNT IN VARIOUS TYPES OF MACHINES

**440. Direct-current commutating motors and generators.**

Core losses. See Par. **452.**

$I^2R$ loss in all windings.

Brush contact $I^2R$ loss. Unless otherwise specified, use the Institute standard of 1 volt for contact drop per brush; *i.e.*, 2 volts for total brush drop, either carbon or graphite brushes. (See Par. **454** and **819**). In the case of low voltage automobile propulsion motors and generators this loss should be determined experimentally; see Par. **839.**

Friction of bearings and windage.

Rheostat losses, when present.

Brush friction.

All indeterminable load losses (including stray-load iron losses) which may be important, which vary with the design, and for which no satisfactory

* In Table V, the stray load-losses include *f*, *h*, *i*, *k*, *l* and *m*; but do not include increased core losses due to increased excitation for compensating internal drop under load.

Digitized by Google

thod of determination has been found, shall be included as zero per cent. estimating conventional efficiency.

**441. Synchronous motors and generators.**

Core losses. See Par. **452.**

$I^2R$ loss in all windings, based upon rated k-va. and power factor.

Stray load-losses. In approximating these losses, the method described Par. **455** shall be employed.

Friction of bearings and windage.

Brush friction and brush-contact loss is negligible, except in the case revolving armature machines.

Rheostat losses, when present. corresponding to rated kv-a. and power tor.

**442. Induction machines.**

Core losses. See Par. **452.**

$I^2R$ losses in all windings.

Stray load-losses. In approximating these losses, the method described Par. **455** shall be employed.

Brush friction when collector rings are present.

Brush-contact loss. Unless otherwise specified, use the Institute standard 1 volt for contact drop per brush, for either carbon or graphite brushes. Par. **454.**

Friction of bearings and windage.

**443. Communicating a-c. machines.**

Core losses. See Par. **452.**

$I^2R$ losses in all windings.

Brush friction.

Brush-contact loss. Unless otherwise specified, use the Institute standard 1 volt for contact drop per brush, for either carbon or graphite brushes. Par. **454** and **819.**

Friction of bearings and windage.

Short-circuit loss of commutation.
Iron loss due to flux distortion.
Eddy-current losses due to fluxes rying with load and saturation.

The Institute is not at this time prepared to make recommendations for approximating these losses.

**444. Synchronous converters.**

Core losses. See Par. **452.**

$I^2R$ losses in all windings, based on rated kw. and unity power factor.

e $I^2R$ losses in the armature winding shall be derived from those corresponding to its use as a direct-current generator, by using suitable factors.

Brush friction.

Rheostat losses when present, corresponding to rated kw. and unity wer factor.

Brush-contact loss. Unless otherwise specified, use the Institute standard 1 volt for contact drop per brush, for either carbon or graphite brushes. Par. **454.**

Short-circuit loss of commutation.
Iron loss due to flux distortion en present.
Eddy-current losses due to fluxes rying with load and saturation.

These losses, while usually of low magnitude, are erratic, and the institute is not at this time prepared to make recommendations for approximating them.

Friction of bearings and windage.

For the booster type of synchronous converter, where the booster forms an egral part of the unit, its losses shall be included in the total converter ses in estimating the efficiency.

**445. Transformers.**

No-load losses. These include the core loss, and the $I^2R$ loss due to the iting current, also the dielectric loss in the insulation. See Par. **470.**

Load losses. These include $I^2R$ losses, and stray load-losses due to dy currents caused by fluxes varying with load. See Par. **471.**

## DETERMINATION OR APPROXIMATION OF LOSSES IN ROTATING MACHINERY

**450. Bearing friction and windage** may be determined as follows. ive the machine from an independent motor, the output of which shall suitably determined. The machine under test shall have its brushes

Digitized by Google

removed and shall not be excited. This output represents the bearing friction and windage of the machine under test.

The bearing friction and windage of induction motors may be measured by running motors free at the lowest voltage at which they will rotate continuously at approximately rated speed; the watts input, minus $I^2R$ loss, under these conditions being taken as the friction and windage.

In the case of engine-type generators, the windage and bearing friction loss is ordinarily very small, amounting to a fraction of 1 per cent. of the output. In these rules this loss is neglected owing to its small value and the difficulty of measuring it.

**451. Brush friction of commutator and collector rings.** Follow the test of Par. **450**, taking an additional reading with the brushes in contact with the commutator or collector rings. The difference between the output obtained in the test in Par. **450** and this output shall be taken as the brush friction. NOTE.—The surfaces of the commutator and brushes should already be smooth and glazed from running when this test is made.

**452. Core loss.** Follow the test of Par. **451** with an additional reading taken in a similar manner, except that the machine is to be excited so as to produce at the terminals a voltage corresponding to the calculated internal voltage for the load under consideration. The difference between the output obtained by this test and that obtained by test under Par. **451** shall be taken as the core loss.

**For synchronous machines**, the internal voltage shall be determined by correcting the terminal voltage for the resistance drop only.

**The core loss of induction motors** may be determined by measuring the watts input to the motor when running free at rated voltage and frequency and subtracting therefrom the no-load copper loss, bearing friction and windage.

**453.** (Deleted in the last revision of the Standardisation Rules.)

**454. The brush-contact $I^2R$ loss** depends largely upon the material of which the brush is composed. As indicating the range of variation the following table will be of interest:

**Table VI.—Brush-contact Drop**

| Grade of brush | Volts drop across one brush-contact. (Average of positive and negative brushes) |
|---|---|
| Hard carbon | 1.1 |
| Soft carbon | 0.9 |
| Graphite | 0.5 to 0.8 |
| Metal-graphite types | 0.15 to 0.5 (The former for largest proportion of metal.) |

One volt drop per brush shall be considered as the Institute standard drop corresponding to the $I^2R$ brush-contact loss, for carbon and graphite brushes. Metal-graphite brushes shall be considered as special. See Par. **319**.

**455. Field-rheostat losses** shall be included in the generator losses where there is a field rheostat in series with the field magnets of the generator, even when the machine is separately excited.

**456. Ventilating blower.** When a blower is supplied as part of a machine set, the power required to drive it shall be charged against the complete unit; but not against the machine alone.

**457. Losses in other auxiliary apparatus.** Auxiliary apparatus, such as a separate exciter for a generator or motor, shall have its losses charged against the plant of which the generator and exciter are a part, and not against the generator. An exception should be noted in the case of turbo-generator sets with direct-connected exciters, in which case the losses in the exciter shall be charged against the generator. The actual energy of excitation and the field-rheostat losses, if any (see Par. **455**) shall be charged against the generator.

**458. Stray load-losses in synchronous generators and motors** These include iron losses, and eddy-current losses in the copper, due to fluxes varying with load and also to saturation.

Digitized by Google

Stray load-losses are to be determined by operating the machine on short circuit and at rated-load current. This, after deducting the windage and friction and $I^2R$ loss, gives the stray load-loss for polyphase generators and motors. These losses in single-phase machines are large; but the institute is not yet prepared to specify a method for measuring them.

**459. Stray load-losses in induction machines.** These include eddy-current losses in the stator copper, and other eddy-current losses due to fluxes varying with the load. In windings consisting of relatively small conductors, these eddy-current losses are usually negligible.

With rotor removed, measure the power input to the stator with different values of current at the rated frequency. The curve plotted with these values gives the combined $I^2R$ and stray load-losses due to eddy currents in the stator copper. Deduct the $I^2R$ loss determined from the resistance, and the difference will represent the stray load-losses corresponding to the various currents. While this method is not accurate for some types of motors it usually represents a sufficiently good approximation.

**460. Polyphase induction-motor rotor $I^2R$ loss.** This should be determined from the slip, whenever the latter is accurately determinable, using the following equation:

$$\text{Rotor } I^2R \text{ loss} = \frac{\text{output} \times \text{slip}}{1 - \text{slip}}$$

In large slip-ring motors, in which the slip cannot be directly measured by loading, the rotor $I^2R$ loss shall be determined by direct resistance measurement; the rotor full-load current to be calculated by the following equation:

$$\text{Current per ring} = \frac{\text{watts output}}{\text{rotor voltage at stand-still} \times \sqrt{3} \times K}$$

This equation applies to 3-phase rotors. For rotors wound for 2 phase, use 2 instead of the $\sqrt{3}$. $K$ may be taken as 0.95 for motors of 150 kw. or larger. The factor $K$ usually decreases as the size of motor is reduced, but no specific value can be stated for smaller sizes.

### DETERMINATION OR APPROXIMATION OF LOSSES IN TRANSFORMERS

**470. No-load losses.** These shall be measured with open secondary circuit at the rated frequency, and with an applied primary voltage giving the rated secondary voltage plus the $IR$ drop which occurs in the secondary under rated load conditions.

**471. Load losses.** These include $I^2R$ and stray load-losses. They shall be measured by applying a primary voltage, preferably at rated frequency, sufficient to produce rated load current in the windings, with the secondary windings short circuited.

## TESTS OF DIELECTRIC STRENGTH OF MACHINERY

**480. Basis for determining test voltages.** The test voltage which shall be applied to determine the suitability of insulation for commercial operation is dependent upon the kind and size of the machinery, and its normal operating voltage, upon the nature of the service in which it is to be used, and upon the severity of the mechanical and electrical stresses to which it may be subjected. The voltages and other conditions of test which are recommended, have been determined as reasonable and proper for the great majority of cases, and are proposed for general adoption, except when specific reasons make a modification desirable.

**481. Condition of machinery to be tested.** Commercial tests shall, in general, be made with the completely assembled machinery and not with individual parts. The machinery shall be in good condition, and high-voltage tests, unless otherwise specified, shall be applied before the machine is put into commercial service, and shall not be applied when the insulation resistance is low owing to dirt or moisture. High-voltage tests shall be made at the temperature assumed under normal operation or at the temperature attained under the conditions of commercial testing. High-voltage tests to determine whether specifications are fulfilled, are admissible on new machines only. Unless otherwise agreed upon, high-voltage tests of a machine shall be understood as being made at the factory.

**482. Points of application of voltage.** The test voltage shall be suc-

Digitized by Google

cessively applied between each electric circuit and all other electric circuits and metal parts grounded.

**483. Interconnected polyphase windings** are considered as one circuit. All windings of a machine except that under test, shall be connected to ground.

**484. Frequency, wave form and test voltage.** The frequency of the testing circuit shall not be less than the rated frequency of the apparatus tested. A sine-wave form is recommended. See Par. **405.** The test shall be made with alternating voltage having a crest value equal to $\sqrt{2}$ times the specified test voltage. In d-c. machines, and in the general commercial application of a-c. machines, the testing frequency of 60 cycles per second is recommended.

**485. Duration of application of test voltage.** The testing voltage for all classes of apparatus shall be applied continuously for a period of 60 sec.

**485A. For all standard devices produced in large quantities** and with a standard test pressure of 2,500 volts or less, a test pressure applied for 1 sec. 20 per cent. higher than the 1-min. test pressure will be satisfactory.

**486. Apparatus for use on single-phase, 2-phase-delta or 3-phase-star circuits.** Apparatus, such as transformers, which may be used in star connection on three-phase circuits, shall have the delta voltage of the circuits on which they may be used indicated on the rating plate and the test shall be based on such delta voltage.

## VALUES OF A-C. TEST VOLTAGES

**500. The standard test for all classes of apparatus, except as otherwise specified, shall be twice the normal voltage of the circuit to which the apparatus is connected, plus 1,000 volts.**

**501. Exception—alternating-current apparatus connected to permanently grounded single-phase systems, for use on permanently grounded circuits of more than 300 volts,** shall be tested with 2.73 times the voltage of the circuit to ground + 1,000 volts. This does not refer to three-phase apparatus with grounded star neutral.

**502. Exception—distributing transformers.** Transformers for primary pressure from 550 to 5,000 volts, the secondaries of which are directly connected to consumers' circuits and commonly known as distributing transformers, shall be tested with 10,000 volts from primary to core and secondary combined. The secondary windings shall be tested with twice their normal voltage plus 1,000 volts.

**503. Exception—auto-transformers** used for starting purposes, shall be tested with the same voltage as the test voltage of the apparatus to which they are connected.

**504. Exception—household devices.** Apparatus taking not over 660 watts* and intended solely for operation on supply circuits not exceeding 250 volts, shall be tested with 900 volts, except in the case of heating devices which shall be tested with 500 volts at operating temperature.

**505. Exception—apparatus for use on circuits of 25 volts or lower,** such as bell-ringing apparatus,† electrical apparatus used in automobiles, apparatus used on low-voltage battery circuits, etc., shall be tested with 500 volts.

**506. Exception—field windings of alternating-current generators** shall be tested with 10 times the exciter voltage, but in no case with less than 1,500 volts nor more than 3,500 volts.

**507. Exception**—Field windings‡ of synchronous machines, including motors and converters which are to be started from alternating-current circuits, shall be tested as follows:

(*a*) When machines are started with fields short-circuited they shall be tested as specified in Par. **506.**

(*b*) When machines are started with fields open-circuited and sectionalised while starting, they shall be tested with 5,000 volts.

---

* The present *National Electric Code* power limit for a single outlet.

† This rule does not include bell-ringing transformers of ratio 125 to 6 volts. See *National Electric Code.*

‡ Series field coils should be regarded as part of the armature circuit and tested as such.

Digitized by Google

(c) When machines are started with fields open-circuited and connected all series while starting, they shall be tested with 5,000 volts for less than 275-volt excitation and 8,000 volts for excitation of 275 volts to 750 volts.

**508. Exception—phase-wound rotors of induction motors.** The secondary windings of wound rotors of induction motors shall be tested with twice their normal induced voltage, plus 1,000 volts. By normal induced voltage is here meant the voltage between slip rings on open circuit at standstill with normal voltage impressed on the primary.

When induction motors with phase-wound rotors are reversed, while running at approximately normal speed, by reversing the primary connections, the test shall be four times the normal induced voltage, plus 1,000 volts.

**509. Exception—switches and circuit control apparatus** above 600 volts, shall be tested with two and one-fourth times rated voltage, plus 2,000 volts. See Par. **720** to **741.**

**510. Exception—assembled apparatus.** Where a number of pieces of apparatus are assembled together and tested as an electrical unit, they shall be tested with 15 per cent. lower voltage than the lowest required on any of the individual pieces of apparatus.

**510A. Exception—meters and instruments.** The Institute is not at present in a position to make a recommendation in regard to the dielectric tests of meters and instruments.

**511. Testing transformers by induced voltage.** Under certain conditions it is permissible to test transformers by inducing the required voltage in their windings, in place of using a separate testing transformer. By "required voltage," is meant a voltage such that the line end of the windings shall receive a test to ground equal to that required by the general rules.

**512. Transformers with graded insulation** shall be so marked. They shall be tested by including the required test-voltage in the transformer and connecting the successive line leads to ground.

Transformer windings permanently grounded within the transformer shall be tested by inducing the required test voltage in such windings. (See Par **500.**)

## MEASUREMENT OF VOLTAGE IN DIELECTRIC TESTS OF MACHINERY

**530. Use of voltmeters and spark-gaps in insulation tests.** When making insulation tests on electrical machinery, every precaution must be taken against the occurrence of any spark-gap discharges in the circuits from which the machinery is being tested. A non-inductive resistance of about 1 ohm per volt shall be inserted in series with one terminal of the spark gap. If the test is made with one electrode grounded, this resistance shall be inserted directly in series with the non-grounded electrode. If neither terminal is grounded, one-half shall be inserted directly in series with each electrode. In any case this resistance shall be as near the measuring gap as possible and not in series with the tested apparatus. The resistance will damp high-frequency oscillations at the time of breakdown and limit the current which will flow. A water-tube is the most reliable form of resistor. Carbon resistors should not be used because their resistance may become very low at high voltages.

**531. For machinery of low capacitance.** When the machinery under test does not require sufficient charging current to distort the high-voltage wave shape, or change the ratio of transformation, the spark-gap should be set for the required test voltage and the testing apparatus adjusted to give a voltage at which this spark-gap just breaks down. This adjustment should be made with the apparatus under test disconnected. The apparatus should then be connected, and with the spark gap about 20 per cent. longer, the testing apparatus is again adjusted to give the voltage of the former breakdown, which is the assumed voltage of test. This voltage is to be maintained for the required interval.

**532. For machinery of high capacitance.** When the charging current of the machinery under test may appreciably distort the voltage wave or change the effective ratio of the testing transformer, the first adjustment of voltage with the gap set for the test voltage should be made with the apparatus under test connected to the circuit and in parallel with the spark-gap.

When making arc-over tests of large insulators, leads, etc., partial arc-

Digitized by Google

over of the tested apparatus may produce oscillations which will cause the measuring gap to discharge prematurely. The measured voltage will then appear too high. In such tests the "equivalent ratio" of the testing transformer should be measured by gap to within 20 per cent. of the arc-over voltage of the tested apparatus with the tested apparatus in circuit. The measuring gap should then be greatly lengthened out and the voltage increased until the tested apparatus arcs over. This arc-over voltage should then be determined by multiplying the voltmeter reading by the equivalent ratio found above. Direct measurement of the spark-over voltage over one gap by another gap should always be avoided.

**533. Measurements with voltmeter.** In measuring the voltage with a voltmeter, the instrument should preferably derive its voltage from the high-tension circuit, either directly, or by means of a voltmeter coil placed in the testing transformer, or through an auxiliary *ratio-transformer*. It is permissible to measure the voltage at other places, such as the transformer primary provided corrections can be made for the variations in ratio caused by the charging current of the machinery under text, or provided there is no material variation of this ratio. In any case, when the capacitance of the apparatus to be tested is such as to cause wave distortion, the testing voltage must be checked by a spark-gap as set forth in Par. **536**, or by a crest voltage meter. If the crest-voltage meter is calibrated in crest volts, its readings must be reduced to the corresponding r.m.s. sinusoidal value by dividing with $\sqrt{2}$.

**534. Measurements with spark-gaps.** If proper precautions are observed, spark-gaps may be used to advantage in checking the calibration of voltmeters when set up for the purposes of high-voltage tests of the insulation of machinery.

**535. Ranges of voltages.** For the calibrating purposes set forth in Par. **534** the sphere-gap shall be used for voltages above 50 kv., and is to be preferred down to 30 kv. The needle spark-gap may, however, be used for voltages from 10 to 50 kv.

**536. The needle spark gap.** The needle spark gap shall consist of new sewing needles, supported axially at the ends of linear conductors which are at least twice the length of the gap. There must be a clear space around the gap for a radius of at least twice the gap length.

**537.** The sparking distances in air between No. 00 sewing needle points for various root-mean-square sinusoidal voltages are as follows:

**Table VII.—Needle-gap Spark-over Voltages**
(At 25 deg. cent. and 760 mm. barometer)

| R. M. S. kilovolts | Millimeters | R. M. S. kilovolts | Millimeters |
|---|---|---|---|
| 10 | 11.9 | 35 | 51 |
| 15 | 18.4 | 40 | 62 |
| 20 | 25.4 | 45 | 75 |
| 25 | 33.0 | 50 | 90 |
| 30 | 41.0 | ..... | ..... |

The above values refer to a relative humidity of 80 per cent. Variations from this humidity may involve appreciable variations in the sparking distance.

**538. The sphere spark-gap.** The standard sphere spark-gap shall consist of two suitably mounted metal spheres. When used as specified below, the accuracy obtainable should be approximately 2 per cent.

No extraneous body, or external part of the circuit, shall be nearer the gap than twice the diameter of the spheres. By the "gap" is meant the shortest path between the two spheres.

The shanks should not be greater in diameter than one-fifth the sphere diameter. Metal collars, etc., through which the shanks extend, should be as small as practicable and should not, during any measurement, come closer to the sphere than the maximum gap length used in that measurement.

The sphere diameter should not vary more than 0.1 per cent. and the curvature, measured by a spherometer, should not vary more than 1 per cent. from that of a true sphere of the required diameter.

Digitized by Google

**539. In using the spherometer** to measure the curvature, the distance between the points of contact of the spherometer feet should be within the following limits:

**Table VIII.—Spherometer Specifications**

| Diameter of sphere in mm. | Distance between contact points in mm. | |
|---|---|---|
| | Maximum | Minimum |
| 62.5 | 35 | 25 |
| 125.0 | 45 | 35 |
| 250.0 | 65 | 45 |
| 500.0 | 100 | 65 |

**539A. In using sphere gaps** constructed as above, it is assumed that the apparatus will be set up for use in a space comparatively free from external dielectric fields. Care should be taken that conducting bodies forming part of the circuit, or at circuit potential, are not so located with reference to the gap that their dielectric fields are superposed on the gap; *e.g.*, the protecting resistance should not be arranged so as to present large masses or surfaces near the gap, even at a distance of two sphere diameters.

In case the sphere is grounded, the spark point of the grounded sphere should be approximately five diameters above the floor or ground.

**540. The sparking distances between different spheres** for various r.m.s. sinusoidal voltages shall be assumed to be as follows:

**Table IX.—Sphere-gap Spark-over Voltages**
(At 25 deg. cent. and 760 mm. barometric pressure)

| Kilovolts | Sparking distance in millimeters | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 62.5 mm. spheres | | 125 mm. spheres | | 250 mm. spheres | | 500 mm. spheres | |
| | One sphere grounded | Both spheres insulated | One sphere grounded | Both spheres insulated | One sphere grounded | Both spheres insulated | One sphere grounded | Both spheres insulated |
| 10 | 4.2 | 4.2 | ..... | ..... | ..... | ..... | ..... | ..... |
| 20 | 8.6 | 8.6 | ..... | ..... | ..... | ..... | ..... | ..... |
| 30 | 14.1 | 14.1 | 14.1 | 14.1 | ..... | ..... | ..... | ..... |
| 40 | 19.2 | 19.2 | 19.1 | 19.1 | ..... | ..... | ..... | ..... |

Digitized by Google

The sphere gap is more sensitive than the needle gap to momentary rises of voltage and the voltage required to spark over the gap should be obtained by slowly closing the gap under constant voltage, or by slowly raising the voltage with a fixed setting of the gap. Open arcs should not be permitted in proximity to the gap during its operation, as they may affect its calibration.

**541. Air-density correction-factors for sphere gaps. The spark-over voltage,** for a given gap, decreases with decreasing barometric pressure and increasing temperature. This correction may be considerable at high altitudes.

The spacing at which it is necessary to set a gap to spark over at some required voltage, is found as follows: Divide the required voltage by the correction factor given below in Table X. A new voltage is thus obtained. The spacing on the standard curves obtained from Table IX, corresponding to this new voltage, is the required spacing.

The voltage at which a given gap sparks over is found by taking the voltage corresponding to the spacing from the standard curves of Table IX, and multiplying by the correction factor.

When the variation from sea level is not great, the relative air density may be used as the correction factor; when the variation is great, or greater accuracy is desired, the correction factor corresponding to the relative air density should be taken from Table X below, in which

$$\text{Relative air density} = \frac{0.392b}{273+t}$$

$b$ = barometric pressure in mm.

$t$ = temperature in deg. cent.

Corrected curves may be plotted for any given altitude, if desired.

Values of relative air density and corresponding values of the correction factor are tabulated below. It will be seen that for values above 0.9, the correction factor does not differ greatly from the relative air density.

**Table X.—Air-density Correction Factors for Sphere Gaps**

| Relative air density | Diameter of standard spheres in mm. | | | |
|---|---|---|---|---|
| | 62.5 | 125 | 250 | 500 |
| 0.50 | 0.547 | 0.535 | 0.527 | 0.519 |

## INSULATION RESISTANCE OF MACHINERY

**550. The insulation resistance of a machine** at its operating temperature shall be not less than that given by the following formula:

$$\text{Insulation resistance in megohms} = \frac{\text{voltage at terminals}}{\text{rated capacity in kv-a.} + 1000}$$

The formula only applies to dry apparatus. Such high values are not attainable in oil-immersed apparatus.

Insulation resistance tests shall, if possible, be made at a d-c. pressure of 500 volts. Since the insulation varies with the pressure, it is necessary that, if a pressure other than 500 volts is to be employed in any case, this other pressure shall be clearly specified.

Digitized by Google

The order of magnitude of the values obtained by this rule is shown in the following table:

**Table XI.—Insulation Resistance of Machinery**

| Rated voltage of machine | Megohms | | |
|---|---|---|---|
| | 100 kv-a. | 1,000 kv-a. | 10,000 kv-a. |
| 100 | 0.091 | 0.05 | ..... |
| 1,000 | 0.91 | 0.50 | 0.091 |
| 10,000 | 9.1 | 5.0 | 0.91 |
| 100,000 | ..... | 50.0 | 9.1 |

**551.** It should be noted that the insulation resistance of machinery is of doubtful significance by comparison with the dielectric strength. The insulation resistance is subject to wide variation with temperature humidity and cleanliness of the parts. When the insulation resistance falls below that corresponding to the above rule, it can, in most cases of good design and where no defect exists, be brought up to the required standard by cleaning and drying out the machine. The insulation-resistance test may therefore afford a useful indication as to whether the machine is in suitable condition for the application of the dielectric test.

## REGULATION

### DEFINITIONS

**560. Regulation.** The regulation of a machine in regard to some characteristic quantity (such as terminal voltage or speed) is the change in that quantity occurring between any two loads. Unless otherwise specified, the two loads considered shall be zero load and rated load, and at the temperature attained under normal operation. The regulation may be expressed by stating the numerical values of the quantity at the two loads, or it may be expressed by the "percentage regulation," which is the percentage ratio of the change in the quantity occurring between the two loads, to the value of the quantity at either one or the other load, taken as the normal value. It is assumed that all parts of the machine affecting the regulation maintain constant temperature between the two loads, and where the influence of temperature is of consequence, a reference temperature of 75 deg. cent. shall be considered as standard. If change of temperature should occur during the tests, the results shall be corrected to the reference temperature of 75 deg. cent.

The normal value may be either the no-load value, as the no-load speed of induction motors; or it may be the rated-load value, as in the voltage of a-c. generators.

It is usual to state the regulation of d-c. generators by giving the numerical values of the voltage at no-load and rated load, and in some cases it is advisable to state regulation at intermediate loads.

**561.** The **regulation of d-c. generator** refers to changes in voltage corresponding to gradual changes in load and does not relate to the comparatively large momentary fluctuations in voltage that frequently accompany instantaneous changes in load.

In determining the regulation of a compound-wound d-c. generator, two tests shall be made, one bringing the load down and the other bringing the load up, between no-load and rated load. These may differ somewhat, owing to residual magnetism. The mean of the two results shall be used.

**562.** In **constant-potential a-c. generators**, the regulation is the rise in voltage (when the specified load at specified power factor is reduced to zero) expressed in per cent. of normal rated-load voltage.

**563.** In **constant-current machines**, the regulation is the ratio of the maximum difference of current from the rated-load value (occurring in the range from rated-load to short-circuit, or minimum limit of operation), to the rated-load current.

**564.** In **constant-speed d-c. motors**, and induction motors, the regulation is the ratio of the difference between full-load and no-load speeds to the no-load speed.

Digitized by Google

**565.** In **constant-potential transformers**, the regulation is the difference between the no-load and rated-load values of the secondary terminal voltage at the specified power-factor (with constant primary impressed terminal voltage) expressed in per cent. of the rated-load secondary voltage, the primary voltage being adjusted to such a value that the apparatus delivers rated output at rated secondary voltage.

**566.** In **converters, dynamotors, motor-generators and frequency converters**, the regulation is the change in the terminal voltage of the output side between the two specified loads. This may be expressed by giving the numerical values, or as the percentage of the terminal voltage at rated load.

**567.** In **transmission lines, feeders, etc.**, the regulation is the change in the voltage at the receiving end between rated non-inductive load and no-load, with constant impressed voltage upon the sending end. The percentage regulation is the percentage change in voltage to the normal rated voltage at the receiving end.

**568.** In **steam engines, steam turbines and internal combustion engines**, the percentage speed regulation is usually expressed as the percentage ratio of the maximum variation of speed, to the rated-load speed in passing slowly from rated load to no-load (with constant conditions at the supply).

**569.** If the test is made by passing suddenly from rated load to no-load, the immediate percentage speed regulation so derived shall be termed the **fluctuation.**

**570.** In a **hydraulic turbine**, or other water motor, the percentage speed regulation is expressed as the percentage ratio of the maximum variation in speed in passing slowly from rated load to no-load (at constant head of water), to the rated-load speed.

**571.** In a **generator unit**, consisting of a generator combined with a prime mover, the speed or voltage regulation should be determined at constant conditions of the prime mover; *i.e.*, constant steam-pressure, head, etc. It includes the inherent speed variations of the prime mover. For this reason, the regulation of a generator unit is to be distinguished from the regulation of either the prime mover, or of the generator combined with it, when taken separately.

## CONDITIONS FOR TESTS OF REGULATION

**580. Speed and frequency.** The regulation of generators is to be determined at constant speed, and of alternating-current apparatus at constant frequency.

**581. Power-factor.** In apparatus generating, transforming or transmitting alternating currents, the power-factor of the load to which the regulation refers should be specified. Unless otherwise specified, it shall be understood as referring to non-inductive load, that is to a load in which the current is in phase with the *e.m.f.* at the output side of the apparatus.

**582. Wave form.** In the regulation of alternating-current machinery receiving electric power, a sine-wave of voltage is assumed, except where expressly specified otherwise. See Par. 405.

**583. Excitation.** In commutating machines, rectifying machines, and synchronous machines, such as direct-current generators and motors, as well as in alternating-current generators, the regulation is to be determined under such conditions as to maintain the field adjustment constant at that which gives rated-load voltage at rated-load current, as follows:

(1) In the case of separately excited field magnets—constant excitation.

(2) In the case of shunt machines, constant resistance in the shunt-field circuit.

(3) In the case of series or compound machines, constant resistance shunting the series-field windings.

**584. Tests and computation of regulation of a-c. generators.** Any one of the following three methods may be used. They are given in the order of preference.

**Method a.** The regulation can be measured directly, by loading the generator at the specified load and power-factor, then reducing the load to zero, and measuring the terminal voltage, with speed and excitation adjusted to the same values as before the change. This method is not generally applicable for shop tests, particularly on large generators, and it becomes

Digitized by Google

necessary to determine the regulation from such other tests as can be readily made.

**585. Method b.** This consists in computing the regulation from experimental data of the open-circuit saturation curve and the zero power-factor saturation curve. The latter curve, or one approximating very closely to it, can be obtained by running the generator with overexcitation on a load of idle-running underexcited synchronous motors. The power-factor under these conditions is very low and the load saturation curve approximates very closely the zero power-factor saturation curve. From this curve and the open circuit curve, points for the load saturation curve, for any power-factor, can be obtained by means of vector diagrams.

To apply Method b, it is necessary to obtain from test, the open-circuit saturation curve *OA*, Fig. 1, and the saturation curve *BC* at zero power-factor and rated-load current. At any given excitation *Oc*, the voltage that would be induced on open circuit is *ac*, the terminal voltage at zero power-factor is *bc*, and the apparent internal drop is *ab*. The terminal voltage *dc* at any other power-factor can then be found by drawing an e.m.f. diagram* as in Fig. 2, where $\phi$ is an angle such that cos $\phi$ is the power-factor of the load, *be* the resistance drop (*IR*) in the stator winding, *ba* the total internal drop, and *ac* the total induced voltage; *ba* and *ac* being laid off to correspond with the values obtained from Fig. 1. The terminal voltage at power-factor cos $\phi$, is then *eb* of Fig. 2, which, laid off in Fig. 1, gives point *d*. By finding a number of such points, the curve *Bdd'* for power-factor cos $\phi$ is obtained and the regulation at this power-factor (expressed in per cent.) is $\frac{100 \times a'd'}{d'c'}$, since *a'd'* is the rise in voltage when the load at power-factor cos $\phi$ is thrown off at normal voltage *c'd'*.

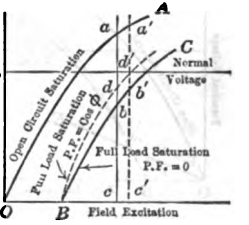

FIG. 1.

Generally, the ohmic drop can be neglected, as it has very little influence on the regulation, except in very low-speed machines where the armature resistance is relatively high, or in some cases where regulation at unity power-factor is being estimated. For low power-factors, its effect is negligible in practically all cases. If resistance is neglected, the simpler e.m.f. diagram, Fig. 3, may be used to obtain points on the load saturation curve for the power-factor under consideration.

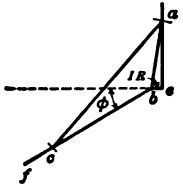

FIG. 2.

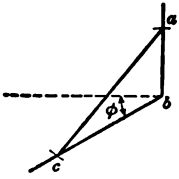

FIG. 3.

**586. Method c.** Where it is not possible to obtain by test a zero power-factor saturation curve as in Method b, this curve can be estimated closely from open-circuit and short-circuit curves, by reference to tests at zero power-factor on other machines of similar magnetic circuit. Having obtained the estimated zero power-factor curve, the load saturation for any other power-factor is obtained as in Method b.

* Method b, for deducing the load saturation curve, at any assigned power-factor, from no-load and zero power-factor saturation curves obtained by test, must be regarded as empirical. Its value depends upon the fact that experience has demonstrated the reasonable correctness of the results obtained by it.

Digitized by Google

Thus Method c is the same as Method b; except that the zero power-factor curve must be estimated. This may be done as follows: In Fig. 4, *OA* is the open-circuit saturation curve and *OE* the short-circuit line as shown by test. The zero power-factor curve corresponding to any given current *BF* will start from point *B*, and for machines designed with low saturation and low reactance, will follow parallel to *OA* as shown by the dotted curve *BD*, which is *OA* shifted horizontally parallel to itself by the distance *OB*. In high-speed machines, or in others having low reactance and a low degree of saturation in the magnetic circuit the zero power-factor curve will lie quite close to *BD*, particularly in those parts that are used for determining the regulation. This is the case with many turbo-generators and high-speed water-wheel generators. In many cases, however, the zero power-factor curve will deviate from *BD*, as shown by *BC*, and the deviation will be most pronounced in machines of high reactance, high saturation, and large magnetic leakage. The position of the actual curve *BC* with relation to *BD*, can be approximated with sufficient exactness by investigating the corresponding relation as obtained by test at zero power-factor on machines of similar characteristics and magnetic circuit. Or curve *BC* can be calculated by methods based on the results of tests at zero power-factor. After *BC* has been obtained, the saturation curve and regulation for any other power-factor can be derived as in Method b.

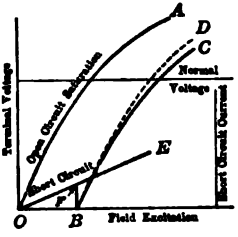

FIG. 4.

**587. Tests and computation of regulation for constant-potential transformers.** The regulation can be determined by loading the transformer and measuring the change in voltage with change in load, at the specified power-factor. This method is not generally applicable for shop tests, particularly on large transformers.

The regulation for any specified load and power-factor can be computed from the measured impedance watts and impedance volts, as follows:

Let

$P$ = impedance watts, as measured in the short-circuit test and corrected to 75 deg. cent.; $E_s$ = impedance volts, as measured in the short-circuit test; $IX$ = reactance drop in volts; $I$ = rated primary current; $E$ = rated primary voltage; $q_r$ = per cent. drop in phase with current; $q_x$ = per cent. drop in quadrature with current.

$$IX = \sqrt{E_s^2 - \left(\frac{P}{I}\right)^2}$$

$$q_r = 100\,\frac{P}{EI}$$

$$q_x = 100\,\frac{IX}{E}$$

**588. Then—**

1. For **unity power-factor**, we have approximately:

$$\text{Per cent. regulation} = q_r + \frac{q_x^2}{200}$$

**589.** 2. For **inductive loads** of power-factor $m$ and reactive-factor $n$,

$$\text{Per cent. regulation} = mq_r + nq_x + \frac{(mq_x - nq_r)^2}{200}$$

## TRANSFORMER CONNECTIONS*

*(These rules do not apply to auto-transformers.)*

**600. Diagrammatic sketch of connections.** The manufacturer shall furnish with each transformer a complete diagrammatic sketch of the internal

* Sections **601** to **611**, relative to a specific scheme of marking the leads, are tentative only, subject to the adoption of a comprehensive scheme of marking the terminals of all classes of apparatus.

Digitized by Google

connections, and all terminals and taps of the transformer shall be marked to correspond with letters and numbers in the sketch. This sketch should preferably be on a metal plate on the transformer case.

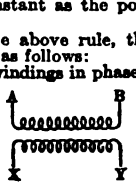
## SINGLE-PHASE TRANSFORMERS

**601. Marking of leads.** The leads of single-phase transformers shall be distinguished from each other by marking the high-voltage leads with the letters *A* and *B*, and the low-voltage leads with the letters *X* and *Y*.

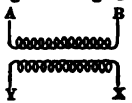
The terminals (by terminals is meant the ends of the windings) shall be so marked that the potential difference in all windings at any instant shall have the same sign, that is, the potential difference between *A* and *B* shall have the same sign at any instant as the potential difference between *X* and *Y*.*

**602.** In accordance with the above rule, the terminals of single-phase transformers shall be marked as follows:

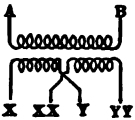
(1) High- and low-voltage windings in phase:



**603.** (2) High- and low-voltage windings 180 deg. apart in phase:

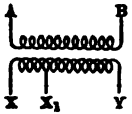


**604. Single-phase transformers with more than two windings.** Transformers with three or more windings (each provided with separate outgoing leads) shall have the leads of two of their windings lettered in accordance with the preceding paragraph. The remaining leads shall be designated *AA*, *BB*, etc. in the case of high-voltage leads and *XX*, *YY*, etc. in the case of low-voltage leads. For example, transformers having four secondary leads from two distinct, similar windings shall be lettered as follows:



This indicates that the low-voltage winding consists of two disconnected parts, one part having terminals *X*, *Y* and the other part having terminals *XX*, *YY*. For multiple connection, *X* and *XX* are to be connected and *Y* and *YY* are to be connected. For series operation, *Y* is to be connected to *XX*.

**605. Tap connections.** All tap connections which are not brought outside the transformer case shall be marked serially with numerals only. Where tap leads are brought out of the transformer case they shall be given the letter designation together with a subscript indicating the relative position of the tap, as in the following diagram.



* To test the correctness of single-phase markings, connect *A* to *X* and apply voltage to the high voltage winding *A-B*. Voltage *B-Y* must be numerically less than voltage *A-B*.

Digitized by Google

**606. Neutral lead.** Where a neutral lead is brought outside the transformer case, it shall be lettered *N*.

**607. Parallel operation.** Transformers marked as above may be operated in paralell, by connecting similarly marked terminals provided their ratios, voltages, resistances and reactances are such as to permit parallel operation.

## THREE-PHASE TRANSFORMERS

**608. Marking of leads.** Three-phase transformers ordinarily have three or four leads for high-voltage and three or four leads for low-voltage windings. To distinguish the various leads from each other, and also to distinguish between the various phase relations obtainable, the three high-voltage leads should be lettered *A*, *B* and *C* and the three low-voltage leads *X*, *Y* and *Z*.

For transformers having six-phase secondaries the primary leads should be lettered *A*, *B* and *C* as above, and the secondary leads *U*, *V*, *W*, *X*, *Y* and *Z*.

The letters shall be so applied to the transformer terminals that if the phase sequence of voltage on the high-voltage side is in the order of *A* to *B* to *C*, it is in the order of *X* to *Y* to *Z*, etc., on the low-voltage side. This arrangement is represented by the diagrams below, which show the various common angular displacements between high- and low-voltage windings of standard transformers. In addition it should be distinctly stated, preferably on the rating plate, in which of the groups given in the following diagrams the transformer belongs.

| | THREE-PHASE TRANSFORMERS | |
|---|---|---|
| GROUP-1 Angular Displacement 0° |   |   |
| GROUP-2 Angular Displacement 180° |   |   |
| GROUP-3 Angular Displacement 30° |   |   |

| | SIX-PHASE TRANSFORMERS | |
|---|---|---|
| GROUP-4 Angular Displacement 0° |   |   |
| GROUP-5 Angular Displacement 30° |   |   |

**609.** The rules given above for single-phase transformers in regard to the neutral tap (see Par. **606**), and also in regard to internal connections (see Par. **601** to **605**), are applicable to three-phase transformers and six-phase transformers.

Digitized by Google

**610. Angular displacement.** The angular displacement between high- and low-voltage windings, is the angle in the diagram in Par. **608** between the lines passing from the neutral point through *A* and *X* respectively for three-phase transformers and through *A* and *U* for six-phase transformers. Thus, in group 1, the angular displacement is zero degrees; in group 2, the angular displacement is 180°, and in group 3, the angular displacement is 30°.

**611. Parallel operation.** Three-phase and six-phase transformers marked as above may be operated in parallel, by connecting similarly marked terminals together, provided their ratios, voltages, resistances, reactances and angular displacements are such as to permit parallel operation.

## INFORMATION ON THE RATING PLATE OF A MACHINE

**620.** It is recommended that the rating plate of machines which comply with the Institute rules shall carry a distinctive special sign, such as "A. I. E. E. 1916 Rating" or "A 16" Rating.

**621.** The absence of any statement to the contrary on the rating plate of a machine implies that it is intended for continuous service and for the standard altitude and ambient temperature of reference. See Par. **237, 305, 308,** and **309.**

**622.** The rating plate of a machine intended to work under various kinds of rating must carry the necessary information in regard to those kinds of ratings.

**623–630.** (Deleted in the last revision of the Standardization Rules.)

## STANDARDS FOR WIRES AND CABLES

### TERMINOLOGY*

**635. Wire.** A slender rod or filament of drawn metal.

The definition restricts the term to what would ordinarily be understood by the term "solid wire." In the definition, the word "slender" is used in the sense that the length is great in comparison with the diameter. If a wire is covered with insulation, it is properly called an insulated wire; while primarily the term "wire" refers to the metal, nevertheless when the context shows that the wire is insulated, the term "wire" will be understood to include the insulation.

**636. Conductor.** A wire or combination of wires not insulated from one another, suitable for carrying a single electric current.

The term "conductor" is not to include a combination of conductors insulated from one another, which would be suitable for carrying several different electric currents.

Rolled conductors (such as bus bars) are, of course, conductors, but are not considered under the terminology here given.

**637. Stranded conductor.** A conductor composed of a group of wires, or of any combination of groups of wires.

The wires in a stranded conductor are usually twisted or braided together.

**638. Cable.** (1) A stranded conductor (single-conductor cable); or (2) a combination of conductors insulated from one another (multiple-conductor cable).

The component conductors of the second kind of cable may be either solid or stranded, and this kind of cable may or may not have a common insulating covering. The first kind of cable is a single conductor, while the second kind is a group of several conductors. The term "cable" is applied by some manufacturers to a solid wire heavily insulated and lead-covered; this usage arises from the manner of the insulation, but such a conductor is not included under this definition of "cable." The term "cable" is a general one and, in practice, it is usually applied only to the larger sizes. A small cable is called a "stranded wire" or a "cord," both of which are defined below. Cables may be bare or insulated, and the latter may be armored with lead or with steel wires or bands.

**639. Strand.** One of the wires, or groups of wires, of any stranded conductor.

**640. Stranded wire.** A group of small wires, used as a single wire.

A wire has been defined as a slender rod or filament of drawn metal. If such a filament is subdivided into several smaller filaments or strands, and is

* From Circular No. 37 of the Bureau of Standards.

Digitized by Google

used as a single wire, it is called a "stranded wire." There is no sharp dividing line of size between a "stranded wire" and a "cable." If used as a wire, for example in winding inductance coils or magnets, it is called a stranded wire and not a cable. If it is substantially insulated, it is called a "cord," defined below.

**641. Cord.** A small and very flexible cable, substantially insulated to withstand wear.

There is no sharp dividing line in respect to size between a "cord" and a "cable," and likewise no sharp dividing line in respect to the character of insulation between a "cord" and a "stranded wire." Rubber is used as the insulating material for many classes of cords.

**642. Concentric strand.** A strand composed of a central core surrounded by one or more layers of helically-laid wires or groups of wires.

**643. Concentric-lay cable.** A single-conductor cable composed of a central core surrounded by one or more layers of helically-laid wires.

**644. Rope-lay cable.** A single-conductor cable composed of a central core surrounded by one or more layers of helically-laid groups of wires.

This kind of cable differs from the preceding in that the main strands are themselves stranded.

**645. N-conductor cable.** A combination of N conductors insulated from one another.

It is not intended that the name as here given be actually used. One would instead speak of a "3-conductor cable," a "12-conductor cable," etc. In referring to the general case, one may speak of a "multiple-conductor cable" (as in definition Par. 638 above).

**646. N-conductor concentric cable.** A cable composed of an insulated central conducting core with (N − 1) tubular stranded conductors laid over it concentrically and separated by layers of insulation.

This kind of cable usually has only two or three conductors. Such cables are used for carrying alternating currents. The remark on the expression "N-conductor" given for the preceding definition applies here also.

**647. Duplex cable.** Two insulated single-conductor cables twisted together.

They may or may not have a common insulating covering.

**648. Twin cable.** Two insulated single-conductor cables laid parallel, having a common covering.

**649. Triplex cable.** Three insulated single-conductor cables, twisted together.

They may or may not have a common insulating covering.

**650. Twisted pair.** Two small insulated conductors, twisted together, without a common covering.

The two conductors of a "twisted pair" are usually substantially insulated, so that the combination is a special case of a "cord."

**651. Twin wire.** Two small insulated conductors laid parallel, having a common covering.

## SPECIFICATION OF SIZES OF CONDUCTORS

**652. The sizes of solid wires** shall be stated by their diameter in mils, the American Wire Gage (Brown and Sharpe) sizes being taken as standard. The sizes of stranded conductors shall be stated by their cross-sectional area in circular mils. For brevity, in cases where the most careful specification is not required, the sizes of solid wires may be stated by the gage number in the American Wire Gage, and the sizes of stranded conductors smaller than 250,000 cir. mils (*i.e.*, No. 0000 A.W.G. or smaller) may likewise be stated by means of the gage number in the American Wire Gage of a solid wire having the same cross-sectional area. Furthermore, an exception is made in the case of "Flexible Stranded Conductors," for which see Par. 656 below. In **stating large cross-sections**, it is sometimes convenient to use a circular inch (507 sq. mm.) instead of 1,000,000 cir. mils.

## STRANDING

**653.** Cables not requiring special flexibility shall be stranded in accordance with the following table (Table XII).

Digitized by Google

**Table XII.—Standard Stranding of Concentric-lay Cables**

| Size (see note 1) | Number of wires (see note 2) | |
|---|---|---|
| | A Bare, insulated or weather-proof cables for aerial use | B Insulated cables for other than aerial use |
| 2.0 cir. in. | 91 | 127 |
| 1.5 cir. in. | 61 | 91 |
| 1.0 cir. in. | 61 | 61 |
| 0.6 cir. in. | 37 | 61 |
| 0.5 cir. in. | 37 | 37 |
| 0.4 cir. in. | 19 | 37 |
| 0000 A.W.G. | 19 or 7 (See note 3) | 19 |
| 00 A.W.G. | 7 | 19 |
| 2 A.W.G. | 7 | 7 |
| 7 and smaller | .. | 7 |

NOTE 1. For intermediate sizes, use stranding for next larger size.

NOTE 2. Conductors of 0000 A.W. G. and smaller are often made solid and this table of stranding should not be interpreted as excluding this practice.

NOTE 3. Class A cable, sizes 0000 and 000 A.W. G., is usually made of 7 strands when bare and 19 strands when insulated or weatherproof.

**Table XIII.—Proposed Standard Stranding of Flexible Cables**

| Nearest A.W.G. size (see note 1) | Circular mils (see note 3) | Diameter of cable, mils | Number of wires | Size of each wire A.W.G. | Diameter, mils | Make-up (see note 2) |
|---|---|---|---|---|---|---|
| ..... | 2,039,000 | 1,836. | 703 | 15.5 | 53.9 | 37×19 |
| ..... | 1,816,000 | 1,778. | 703 | 16.0 | 50.8 | 37×19 |
| ..... | 1,617,000 | 1,680. | 703 | 16.5 | 48.0 | 37×19 |
| ..... | 1,440,000 | 1,586. | 703 | 17.0 | 45.3 | 37×19 |
| ..... | 1,282,000 | 1,495. | 703 | 17.5 | 42.7 | 37×19 |
| ..... | 1,103,000 | 1,372. | 427 | 16.0 | 50.8 | 61×7 |
| ..... | 874,500 | 1,223. | 427 | 17.0 | 45.3 | 61×7 |
| ..... | 693,400 | 1,088. | 427 | 18.0 | 40.3 | 61×7 |
| ..... | 550,000 | 969. | 427 | 19.0 | 35.9 | 61×7 |
| ..... | 436,400 | 864. | 427 | 20.0 | 32.0 | 61×7 |
| ..... | 345,900 | 770. | 427 | 21.0 | 28.5 | 61×7 |
| ..... | 274,300 | 686. | 427 | 22.0 | 25.4 | 61×7 |
| ..... | 264,700 | 672. | 259 | 20.0 | 32.0 | 37×7 |

| 000 | 171,300 | 539. | 133 | 19.0 | 35.9 | 19×7 |
| 00 | 135,900 | 480. | 133 | 20.0 | 32.0 | 19×7 |
| 0 | 107,700 | 428. | 133 | 21.0 | 28.5 | 19×7 |
| 1 | 82,780 | 332. | 91 | 20.5 | 30.2 | Concentric |
| 2 | 65,660 | 296. | 91 | 21.5 | 26.9 | Concentric |
| 3 | 58,460 | 279. | 91 | 22.0 | 25.4 | Concentric |
| 4 | 39,190 | 229. | 61 | 22.0 | 25.4 | Concentric |
| 5 | 31,080 | 203. | 61 | 23.0 | 22.6 | Concentric |
| 6 | 24,650 | 181. | 61 | 24.0 | 20.1 | Concentric |
| 8 | 17,400 | 152. | 61 | 25.5 | 16.9 | Concentric |
| 10 | 10,560 | 118. | 37 | 25.5 | 16.9 | Concentric |
| 12 | 6,442 | 94. | 37 | 27.5 | 13.4 | Concentric |
| 14 | 4,177 | 74. | 37 | 29.5 | 10.6 | Concentric |
| Smaller | ..... | ..... | To equal required size | 30.0 | .... | Bunched |

NOTE 1. The A.W.G. sizes except for 61 strands are approximated within 2 per cent. In the case of 61-strand cables the approximation is 6 per cent.

NOTE 2. "61 × 7" signifies a rope-lay cable composed of 61 strands of wires each.

NOTE 3. Circular mils are based on theoretical diameters of A.W.G. sizes which vary above or below values given in table by less than 0.1 mil.

Digitized by Google

**654. Sectional area of cables.** The cross-sectional area of a cable shall be considered to be the sum of the cross-sectional areas of its component wires, when measured perpendicular to their axes.

**655. Flexible stranding.** Conductors of special flexibility should ordinarily be made with wires of regular A.W.G. sizes,* the number of wires and size being given. The approximate gage number or approximate circular mils of such flexible stranded conductors may be stated. The stranding of standard flexible cables is given in Table XIII and a tentative stranding for apparatus cable in Table XIII-A.

**Table XIII-A.—Proposed Standard Stranding of Apparatus Cables**
(This table is offered for consideration but will not be recommended for final adoption until ratified by other societies interested.)

| Nearest A.W.G. size (see note 1) | Circular mils (see note 3) | Diameter of cable, mils | Number of wires | Size of each wire, A.W.G. | Diameter, mils | Make-up |
|---|---|---|---|---|---|---|
| ..... | 2,053,000 | 1,903. | 2,257 | 20.5 | 30.2 | 61×37 |
| ..... | 1,829,000 | 1,796. | 2,257 | 21.0 | 28.5 | 61×37 |
| ..... | 1,629,000 | 1,695. | 2,257 | 21.5 | 26.9 | 61×37 |
| ..... | 1,450,000 | 1,600. | 2,257 | 22.0 | 25.4 | 61×37 |
| ..... | 1,291,000 | 1,506. | 2,257 | 22.5 | 23.9 | 61×37 |
| ..... | 1,150,000 | 1,424. | 2,257 | 23.0 | 22.6 | 61×37 |
| ..... | 1,054,000 | 1,359. | 1,159 | 20.5 | 30.2 | 61×19 |
| ..... | 938,900 | 1,283. | 1,159 | 21.0 | 28.5 | 61×19 |
| ..... | 836,200 | 1,211. | 1,159 | 21.5 | 26.9 | 61×19 |
| ..... | 744,500 | 1,143. | 1,159 | 22.0 | 25.4 | 61×19 |
| ..... | 663,000 | 1,076. | 1,159 | 22.5 | 23.9 | 61×19 |
| ..... | 590,500 | 1,017. | 1,159 | 23.0 | 22.6 | 61×19 |
| ..... | 525,800 | 958. | 1,159 | 23.5 | 21.3 | 61×19 |
| ..... | 451,600 | 889. | 703 | 22.0 | 25.4 | 37×19 |
| ..... | 402,200 | 836. | 703 | 22.5 | 23.9 | 37×19 |
| ..... | 358,200 | 791. | 703 | 23.0 | 22.6 | 37×19 |
| ..... | 319,000 | 745. | 703 | 23.5 | 21.3 | 37×19 |
| ..... | 284,000 | 703. | 703 | 24.0 | 20.1 | 37×19 |
| ..... | 253,000 | 665. | 703 | 24.5 | 19.0 | 37×19 |
| 0000 | 217,600 | 610. | 427 | 23.0 | 22.6 | 61×7 |
| 000 | 172,500 | 543. | 427 | 24.0 | 20.1 | 61×7 |
| 00 | 136,800 | 483. | 427 | 25.0 | 17.9 | 61×7 |
| 0 | 104,600 | 422. | 259 | 24.0 | 20.1 | 37×7 |
| 1 | 82,980 | 376. | 259 | 25.0 | 17.9 | 37×7 |
| 2 | 65,810 | 334. | 259 | 26.0 | 15.9 | 37×7 |
| 3 | 52,190 | 298. | 259 | 27.0 | 14.2 | 37×7 |
| 4 | 42,610 | 268. | 133 | 25.0 | 17.9 | 19×7 |
| 5 | 33,800 | 238. | 133 | 26.0 | 15.9 | 19×7 |
| 6 | 26,800 | 213. | 133 | 27.0 | 14.2 | 19×7 |
| see note 2 | | | | | | |

NOTE 1. The A.W.G. sizes are approximated within 3 per cent.
NOTE 2. For sizes smaller than No. 6 see table XIII.
NOTE 3. Circular mils are based on theoretical diameters of A.W.G. sizes, which vary above or below values given in table by less than 0.1 mil.

**656. Correction for lay.** The resistance and mass of a stranded conductor are greater than in a solid conductor of the same cross-sectional area, depending on the lay (*i.e.*, the pitch of the twist of the wires). Two per cent. shall be taken as the standard increment of resistance and of mass. In cases where the lay is definitely known, the increment should be calculated and not assumed.

The direction of lay is the lateral direction in which the strands of a cable run over the top of the cable as they recede from an observer looking along the axis of the cable.

* Where necessary to closely approximate a regular size cable, the strands may be made of half-size wires from No. 15 to No. 30 A.W.G.

Digitized by Google

**657.** The lay of any layer of wires of a cable or strand shall not exceed 15 times the pitch diameter of that layer. The lay of any layer of strands of rope-lay cables shall not exceed 12 times the pitch diameter of the layer.

## CONDUCTIVITY OF COPPER

**675.** The following I. E. C. rules are adopted:*

The following shall be taken as normal values for standard annealed copper:

(1) At a temperature of 20 deg. cent., the resistance of a wire of standard annealed copper 1 m. in length and of a uniform section of 1 sq. mm. is $\frac{1}{58}$ ohm = 0.017241 . . . ohm.

(2) At a temperature of 20 deg. cent., the density of standard annealed copper is 8.89 g. per cu. cm.

(3) At a temperature of 20 deg. cent., the "constant mass" temperature coefficient of resistance of standard annealed copper, measured between two potential points rigidly fixed to the wire, is $0.00393 = \frac{1}{254\frac{1}{2}}$ . . . per deg. cent.

(4) As a consequence, it follows from (1) and (2) that, at a temperature of 20 deg. cent., the resistance of a wire of standard annealed copper of uniform section, 1 m. in length and weighing 1 g., is $(\frac{1}{58}) \times 8.89 = 0.15328$ . . . ohm.†‡

**676. Copper-wire tables.** The copper-wire tables published by the Bureau of Standards in Circular No. 31 are adopted. These tables are based upon the I. E. C. rules stated in Par. **675.**

## HEATING AND TEMPERATURE OF CABLES

**677. Maximum safe limiting temperatures.** The maximum safe limiting temperature in deg. cent. at the surface of the conductor in a cable shall be:

For impregnated paper insulation $(85—E)$
For varnished cambric $(75—E)$
For rubber insulation $(60—0.25E)$

where $E$ represents the r.m.s. operating e.m.f. in kilovolts between conductors.

Thus, at a working pressure of 3.3 kv., the maximum safe limiting temperature at the surface of the conductor, or conductors, in a cable would be:

For impregnated paper 81.7 deg. cent.
For varnished cambric 71.7 deg. cent.
For rubber insulation 59.2 deg. cent.

## ELECTRICAL TESTS

**678. Lengths tested.** Electrical tests of insulation on wires and cables shall be made on the entire lengths to be shipped.

**679. Immersion in water.** Electrical tests of insulated conductors not enclosed in a lead sheath, shall be made while immersed in water after an immersion of twelve (12) consecutive hours, if insulated with rubber compound, or if insulated with varnished cambric. It is not necessary to immerse in water insulated conductors enclosed in a lead sheath.

In multiple-conductor cables, without waterproof overall jacket of insulation, no immersion test should be made on finished cables, but only on the individual conductors before assembling.

**680. Dielectric-strength tests. Object of tests.** Dielectric tests are intended to detect weak spots in the insulation and to determine whether the dielectric strength of the insulation is sufficient for enabling it to withstand the voltage to which it is likely to be subjected in service, with a suitable factor of assurance.

---

* See I. E. C. Publication No. 28 "International Standard of Resistance for Copper" March, 1914.

† Paragraphs (1) and (4) of Par. **675** define what are sometimes called "volume resistivity," and "mass resistivity" respectively. This may be expressed in other units as follows: volume resistivity = 1.7241 microhm-cm. (or microhms in a cm. cube) at 20 deg. cent. = 0.67879 microhm-in. at 20 deg. cent., and mass resistivity = 875.20 ohms (mile, pound) at 20 deg. cent.

‡ For detailed specifications of commercial copper, see the "Standard Specifications" of the American Society for Testing Materials.

Digitized by Google

The initially-applied voltage must not be greater than the working voltage, and the rate of increase shall not be over 100 per cent. in 10 sec.

**681. Factor of assurance.** The factor of assurance of wire or cable insulation shall be the ratio of the voltage at which it is tested to that at which it is used.

**682. Test voltage.** The dielectric strength of wire and cable insulation shall be tested at the factory, by applying an alternating test voltage between the conductor and sheath or water.

**683. The magnitude and duration of the test voltage** should depend upon the dielectric strength and thickness of the insulation, the length and diameter of the wire or cable, and the assurance factor required, the latter in turn depending upon the importance of the service in which the wire or cable is employed.

**684. The following test voltages** shall apply unless a departure is considered necessary, in view of the above circumstances. Rubber covered wires or cable for voltages up to 7 kv. shall be tested in accordance with the National Electric Code. Standardization for higher voltages for rubber insulated cables is not considered possible at the present time.

Varnished cambric and impregnated paper insulated wires or cables shall be tested at the place of manufacture for five (5) minutes in accordance with the Table XIV below.

**Table XIV.—Recommended Test Kilovolts Corresponding to Operating Kilovolts**

| Operating kv. | Test kv. | Operating kv. | Test kv. |
|---|---|---|---|
| Below 0.5 | 2.5* | 5 | 14 |
| 0.5 | 3.0 | 10 | 25 |
| 1.0 | 4.0 | 15 | 35 |
| 2.0 | 6.5 | 20 | 44 |
| 3.0 | 9.0 | 25 | 53 |
| 4.0 | 11.5 | ..... | ..... |

Different engineers specify different thickness of insulation for the same working voltages. Therefore, at the present time the test kv. corresponding to working kv. given in Table XIV are based on the **minimum** thickness of insulation specified by engineers and operating companies.†

**685. The frequency of the test voltage** shall not exceed 100 cycles per second, and should approximate as closely as possible to a sine wave. The source of energy should be of ample capacity.

**686. Where ultimate break-down tests** are required, these shall be made on samples not more than 6 meters (20 ft.) long. The maximum allowable temperature at which the test is made for the particular type of insulation and the particular working pressure, shall not be greater than the temperature limits given in Par. **677**.

**687. Multiple-conductor cables.** Each conductor of a multiple-conductor cable shall be tested against the other conductors connected together with the sheath or water.

## INSULATION RESISTANCE

**688. Definition.** The insulation resistance of an insulated conductor is the electrical resistance offered by its insulation, to an impressed voltage tending to produce a leakage of current through the same.

**689. Insulation resistance** shall be expressed in megohms for a specified length (as a kilometer, or a mile, or 1,000 ft.), and shall be corrected to a temperature of 15.5 deg. cent. using a temperature coefficient determined experimentally for the insulation under consideration.

---

* The minimum thickness of insulation shall be $\frac{1}{16}$ in. (1.6 mm.).

† The Standards Committee does not commit itself to the principle of basing test voltages on working voltages, but it is not yet in possession of sufficient data to base them upon the dimensions and physical properties of the insulation.

Digitized by Google

**690. Linear insulation resistance,** or the insulation resistance of unit length, shall be expressed in terms of the megohm-kilometer, or the megohm-mile, or the megohm-thousand-feet.

**691. Megohms constant.** The megohms constant of an insulated conductor shall be the factor "$K$" in the equation

$$R = K \log_{10} \frac{D}{d}$$

where $R$ = The insulation resistance, in megohms, for a specified unit length.
$D$ = Outside diameter of insulation.
$d$ = Diameter of conductor.

Unless otherwise stated, $K$ will be assumed to correspond to the mile unit of length.

**692. Test.** The apparent insulation resistance should be measured after the dielectric-strength test, measuring the leakage current after a 1-min. electrification, with a continuous e.m.f. of from 100 to 500 volts, the conductor being maintained negative to the sheath or water.

**693. Multiple-conductor cables.** The insulation resistance of each conductor of a multiple-conductor cable shall be the insulation resistance measured from such conductor to all the other conductors in multiple with the sheath or water.

## CAPACITANCE OR ELECTROSTATIC CAPACITY

**694. Capacitance** is ordinarily expressed in microfarads. Linear capacitance, or capacitance per unit length, shall be expressed in microfarads per unit length (kilometer, or mile, or 1,000 ft.) and shall be corrected to a temperature of 15.5 deg. cent.

**695. Microfarads constant.** The microfarads constant of an insulated conductor shall be the factor "$K$" in the equation

$$C = \frac{K}{\log_{10} \frac{D}{d}}$$

where $C$ = the capacitance in microfarads per unit length.
$D$ = the outside diameter of insulation.
$d$ = the diameter of conductor.

Unless otherwise stated, $K$ will be assumed to refer to the mile unit of length.

**696. Measurement of capacitance.** The capacitance of low-voltage cable, shall be measured by comparison with a standard condenser. For long lengths of high-voltage cables, where it is necessary to know the true capacitance, the measurement should be made at a frequency approximating the frequency of operation.

**697. Paired cables.** The capacitance shall be measured between the two conductors of any pair, the other wires being connected to the sheath or ground.

**698. Electric light and power cables.** The capacitance of low-voltage cables is generally of but little importance. The capacitance of high-voltage cables should be measured between the conductors, and also between each conductor and the other conductors connected to the lead sheath or ground.

**699. Multiple-conductor cables** (not paired). The capacitance of each conductor of a multiple-conductor cable shall be the capacitance measured from such conductor to all of the other conductors in multiple with the sheath or the ground.

# STANDARDS FOR SWITCHES AND OTHER CIRCUIT-CONTROL APPARATUS*

## SWITCHES

**720. The following rules apply to switches** of above 600 volts. (For 600 volts and below, see *National Electric Code.*†)

* These rules do not apply to magnetically-operated or air-operated switches used for motor control.

† By the term "Code" is meant "National Electrical Code" as recommended by the National Fire Protection Association.

Digitized by Google

**721. Definition.** A switch is a device for making, breaking, or changing connections in an electric circuit.

**722. Rating.** (*a*) By amperes to be carried with not more than 30 deg. cent. rise on contacts and current-carrying parts. (*b*) By normal voltage of circuit on which it may be used.

**723. Performance and tests.** (*a*) **Heating test** with rated current applied continuously until temperature is constant; ambient temperature 40 deg. cent. (*b*) **Dielectric test** at two and one-fourth times rated voltage plus 2,000. See Par. **509.**

## CIRCUIT BREAKERS

**724. Definition.** A device designed to open a current-carrying circuit without injury to itself. A circuit breaker* may be: (*a*) An automatic circuit breaker, which is designed to trip automatically under any predetermined condition of the circuit, such as an underload or overload of current or voltage. (*b*) A manually tripped circuit breaker, which is designed to be tripped by hand. Both types of operation may be combined in one and the same device.

**725. Rating.** (*a*) By normal current-carrying capacity. (*b*) By normal voltage. (*c*) By amperes which it can interrupt at normal voltage of the circuit.

**726. Performance and tests.** The heating test shall be made with normal current. In oil circuit breakers the same oil must be used for heating tests as for rupturing tests. The rise of temperature at the contacts shall not exceed 30 deg. cent. The rise on tripping solenoids and accessory parts not to exceed 50 deg. cent. Ambient temperature of reference, 40 deg. cent.

**727. Dielectric test.** Same as Par. **723.**

**728. Rupturing test** must be made with the current specified under Par. **725** (*c*), and at normal voltage.

NOTE.—Although circuit breakers should be considered as devices alone, no account being taken, in the rating, of the system on which they are to be used: yet in applying circuit breakers to any given service, it may be necessary to take into account the system on which they are to be used, with all its characteristics.

Allowances must be made for the reactance, resistance, etc., of the circuit to be controlled, as these have a direct bearing on the maximum current flow.

In some systems it has been found that the pressure rises so high during switching, that higher insulation tests than that specified in Par. **723** should be given.

## FUSES

(For circuits up to and including 600 volts, see *National Electric Code.*)

**729. Definition.** A fuse is an element designed to melt or dissipate at a predetermined current value, and intended to protect against abnormal conditions of current.

NOTE.—(The terminals, tubes, etc., which go with the fuse proper are included in the definition.)

**730. Rating.** Fuses shall be rated at the maximum current which they are required to carry continuously, and at the normal voltage of the circuit on which they are designed to be used.

Fuses may be divided into two classes: (1) Those designed to protect the circuit and apparatus both against short circuit and against definite amounts of overload (*e.g.*, fuses of the *National Electric Code* which open on 25 per cent. overload). (2) Those designed to protect the system only against short circuits; (*e.g.*, expulsion fuses, which blow at several times the current which they are designed to carry continuously). The line separating these two classes is not definitely fixed.

**731. Temperature.** Coils or windings (such as accompany fuses of the magnetic blow-out type) should not exceed the limits set for machine coils having the same character of insulation. (See Par. **376** to **379.**) The

* These rules refer only to circuit breakers of above 550 volts. For 550 volts and below, see the *National Electric Code.*

Digitized by Google

highest temperature for the fuse proper should not exceed the safe limit for the material employed (*e.g.*, the temperature of the fibre tube of an enclosed fuse should not exceed the safe limit for this material, but an open-link metal fuse may be run at any temperature which will not injure the fuse material; except that no application of the above rule shall contravene the *National Electric Code*).

**732. Test.** For fuses intended for use on circuits of small capacity, or in protected positions on systems of large capacity, see *National Electric Code*. For large power fuses intended for service similar to that required of circuit breakers, see Par. **724** to **728**, or the *National Electric Code*, as far as the latter applies.

NOTE.—Complete standardization of these fuses above 600 volts, according to the method of the *National Electric Code*, is not advisable at this time, but is expected to be accomplished by an eventual extension of the *National Electric Code*. Until such extension is made, the following definitions and ratings may be followed.

## LIGHTNING ARRESTERS

**733. Definition.** A lightning arrester is a device for protecting circuits and apparatus against lightning or other abnormal potential rises of short duration.

**734. Rating.** Arresters shall be rated by the voltage of the circuit on which they are to be used.

Lightning arresters may be divided into two classes: (*a*) Those intended to discharge for a very short time. (*b*) Those intended to discharge for a period of several minutes.

**735. Performance and tests.** Dielectric test same as Par. **723**.

The resistance of the arrester at double potential and also at normal potential, shall be determined by observing the discharge currents through the arrester.

(*c*) In the case of any arrester using a gap, a test shall be made of the spark potential on either direct-current or 60-cycle a-c. excitation. (*d*) The equivalent sphere gap under disruptive discharge shall also be measured, using a considerable quantity of electricity. (*e*) The endurance of the arrester to continuous surges shall be tested.

## PROTECTIVE REACTORS

**736. Definition.** A reactor (see Par. **82** and **214**) is a device for protecting circuits by limiting the current flow and localising the disturbance under short-circuit conditions.

**737. Rating.** (*a*) In kilovolt-amperes absorbed by normal current. (*b*) By the normal current, frequency and line (delta) voltage for which the reactor is designed. (*c*) By the current which the device is required to stand under short-circuit conditions.

**738. Performance and tests.** **The heat test** shall be made with normal current and frequency applied until the temperature is constant. The temperature should not exceed the safe limits for the materials employed. See Par. **276** to **279**.

**739. Dielectric test.** Two and one-fourth times line voltage plus 2,000, for 1 min., from conductor to ground.

NOTE.—The reactor shall be so designed as to be capable of withstanding, without mechanical injury, rated current at normal frequency, suddenly applied.

## RESISTOR OR RHEOSTAT

**740. Definition.** Any device heretofore commonly known as a resistance, used for operation or control. (Par. **81**.) See *National Electric Code*.

## INSTRUMENT TRANSFORMERS

**741. Definition.** An instrument transformer is a transformer for use with measuring instruments, in which the conditions in the primary circuit as to current and voltage are represented with high numerical accuracy in the secondary circuit.

Under this heading and for more general use: (*a*) A current transformer is a transformer designed for series connection in its primary circuit with the ratio of transformation appearing as a ratio of currents. (*b*) A

Digitized by Google

potential (voltage) transformer is a transformer designed for shunt or parallel connection in its primary circuit, with the ratio of transformation appearing as a ratio of potential differences (voltages). For further definitions relative to instrument transformers, see Par. **205** to **207**. For the dielectric test of potential transformers, see Par. **500**, and for the dielectric test of current transformers, see Par. **509**. Further standards concerning instrument transformers are still under discussion.

## STANDARDS FOR ELECTRIC RAILWAYS

### DEFINITIONS

**760. Transmission system.** When the current generated for an electric railway is changed in kind or voltage, between the generator and the cars or locomotives, that portion of the conductor system carrying current of a kind or voltage substantially different from that received by the cars or locomotives, constitutes the *transmission system.**

**761. Distribution system.** That portion of the conductor system of an electric railway which carries current of the kind and voltage received by the cars or locomotives, constitutes the *distribution system.**

**762. Substation.** A substation is a group of apparatus or machinery which receives current from a transmission system, changes its kind or voltage, and delivers it to a distribution system.

### RATING OF RAILWAY SUBSTATION MACHINERY

**763. Continuous rating.** The rating of a substation machine shall be the kv-a. output at a stated power factor input, which it will deliver continuously with temperatures or temperature rises not exceeding the limiting values given in Par. **276** and **279** and also fulfilling the other requirements set forth in these rules and summarized in Par. **260**.

**764. Momentary loads.** These machines should be capable of carrying a load of twice their rating for 1 min., after a continuous run at rated load, without disqualifying them for continuous service.

**765. Nominal rating.** Where the continuous rating is inconvenient, the following nominal rating may be used. The nominal rating of a substation machine shall be the kv-a. output at a stated power-factor input, which, having produced a constant temperature in the machine may be increased 50 per cent. for 2 hr., without producing temperatures or temperature rises exceeding by more than 5 deg. cent. the limiting values given in Par. **276** and **279**. These machines should be capable of carrying a load of twice their nominal rating for a period of 1 min., without disqualifying them for continuous service. The name plate should be marked "nominal rating."

### CONDUCTOR AND RAIL SYSTEMS

**766. Contact conductors.** That part of the distribution system other than the traffic rails, which is in immediate electrical contact with the circuits of the cars or locomotives, constitutes the contact conductors.

**767. Contact rail.** A rigid contact conductor.

**768. Overhead contact rail.** A contact rail above the elevation of the maximum equipment line.†

**769. Third rail.** A contact conductor placed at either side of the track, the contact surface of which is a few inches above the level of the top of the track rails.

**770. Centre contact rail.** A contact conductor placed between the track rails, having its contact surface above the ground level.

**771. Underground contact rail.** A contact conductor placed beneath the ground level.

---

* These definitions are identical in sense, although not in words, with those of the Interstate Commerce Commission, as given in their classification of accounts for electric railways.

† The contour which embraces cross-sections of all rolling stock under all normal operating conditions.

Digitized by Google

**772. Gage of third rail.** The distance, measured parallel to the plane of running rails, between the gage line of the nearer track rail and the inside gage line of the *contact surface* of the third rail.

**773. Elevation of third rail.** The elevation of the contact-surface of the third rail, with respect to the plane of the tops of running rails.

**774. Standard gage or third rails.** The gage of third rails shall be not less than 26 in. (66 cm.) and not more than 27 in. (68.6 cm.).

**775. Standard elevation of third rails.** The elevation of third rails shall be not less than 2¾ in. (70 mm.), and not more than 3½ in. (89 mm.).

**776. Third rail protection.** A guard for the purpose of preventing accidental contact with the third rail.

**777. Trolley wire.** A flexible contact conductor, customarily supported above the cars.

**778. Messenger wire or cable.** A wire or cable running along with and supporting other wires, cables or contact conductors.

A primary messenger is directly attached to the supporting system. A secondary messenger is intermediate between a primary messenger and the wires, cables or contact conductors.

**779. Classes of construction.** Overhead trolley construction will be classed as *direct suspension* and *messenger or catenary suspension*.

**780. Direct suspension.** All forms of overhead trolley construction in which the trolley wires are attached, by insulating devices, directly to the main supporting system.

**781. Messenger or catenary suspension.** All forms of overhead trolley construction in which the trolley wires are attached, by suitable devices, to one or more messenger cables, which in turn may be carried either in *simple catenary*, *i.e.*, by primary messengers, or in *compound catenary*, *i.e.*, by secondary messengers.

**782. Supporting systems** shall be classed as follows:

**783. Simple cross-span systems.** Those systems having at each support a single flexible span across the track or tracks.

**784. Messenger cross-span systems.** Those systems having at each support two or more flexible spans across the track or tracks, the upper span carrying part or all of the vertical load of the lower span.

**785. Bracket systems.** Those systems having at each support an arm or similar rigid member, supported at only one side of the track or tracks.

**786. Bridge systems.** Those systems having at each support a rigid member, supported at both sides of the track or tracks.

**787. Standard height of trolley wire on street and interurban railways.** It is recommended that supporting structures shall be of such height that the lowest point of the trolley wire shall be at a height of 18 ft. (5.5 m.) above the top of rail under conditions of maximum sag, unless local conditions prevent. On trackage operating electric and steam road equipment and at crossings over steam roads, it is recommended that the trolley wire shall be not less than 21 ft. (6.4 m.) above the top of rail, under conditions of maximum sag.

## RAILWAY MOTORS

### RATING

**800. Nominal rating.** The nominal rating of a railway motor shall be the mechanical output at the car or locomotive axle, measured in kilowatts, which causes a rise of temperature above the surrounding air, by thermometer, not exceeding 90 deg. cent. at the commutator, and 75 deg. cent. at any other normally accessible part after 1 hr.'s continuous run at its rated voltage (and frequency in the case of an alternating-current motor) on a stand with the motor covers arranged to secure maximum ventilation without external blower. The rise in temperature as measured by resistance, shall not exceed 100 deg. cent.*

* This definition differs from that in the 1911 edition of the Rules, principally by the substitution of a kilowatt rating for the horse-power rating

(*Cont. on next page.*)

Digitized by Google

**801.** The statement of the nominal rating shall also include the corresponding voltage and armature speed.

**802. Continuous rating.** The continuous ratings of a railway motor shall be the *inputs* in amperes at which it may be operated continuously at ¼, ½ and full voltage respectively, without exceeding the specified temperature rises (see Par. **805**), when operated on stand test with motor covers and cooling system, if any, arranged as in service. Inasmuch as the same motor may be operated under different conditions as regards ventilation, it will be necessary in each case to define the system of ventilation which is used. In case motors are cooled by external blowers, the flow of air on which the rating is based shall be given.

**803. Maximum input.** The subject of momentary loads for railway motors is under investigation.

## TEMPERATURE LIMITATIONS

**804. The allowable temperature** in any part of a motor in service will be governed by the kind of material with which that part is insulated. In view of space limitations, and the cost of carrying dead weight on cars, it is considered good practice to operate railway motors for short periods at higher temperatures than would be advisable in stationary motors. The following temperatures are permissible:

**Table XV.—Operating Temperatures of Railway Motors**

| Class of material, (see Par. **376** to **379**) | Maximum observable temperature of windings when in continuous service | |
|---|---|---|
| | By thermometer See Par. **345** | By resistance |
| A..... | 85 | 110 |
| B..... | 100 | 130 |

For infrequent occasions, due to extreme ambient temperatures, it is permissible to operate at 15 deg. higher temperature.

**805.** With a view to not exceeding the above temperature limitations, the continuous ratings shall be based upon the **temperature rises** tabulated below:

**Table XVI.—Stand-test Temperature Rises of Railway Motors***

| Class of material (see Par. **376** to **379**) | Temperature rises of windings | |
|---|---|---|
| | By thermometer (see Par. **345**) | By resistance |
| A..... | 65 | 85 |
| B..... | 80 | 105 |

and the omission of a reference to a room temperature of 25 deg. cent. For the purpose of these Rules the horsepower shall be taken as 746.0 watts. On account of the hitherto prevailing practise of expressing mechanical output in horse-power, it is recommended that, for the present, the capacity be expressed both in kilowatts and in horse power, a double rating, namely,

kw.————approx. equiv. h.p.————

In order to lay stress upon the preferred future basis, it is desirable that on rating plates, the rating in kilowatts shall be shown in larger and more prominent characters than the capacity in horse power.

* The temperature rise in service may be very different from that on stand test. See Par. **1104** for relation between stand test and service temperatures, as affected by ventilation.

Digitized by Google

**806. Field-control motors.** The nominal and continuous ratings of field-control motors shall relate to their performance with the operating field which gives the maximum motor rating. Each section of the field windings shall be adequate to perform the service required of it, without exceeding the specified temperature rises.

## CHARACTERISTIC CURVES

**810. The characteristic curves** of railway motors shall be plotted with the current as abscissas and the tractive effort, speed and efficiency as ordinates. In the case of a-c. motors, the power factor shall also be plotted as ordinates.

**811. Characteristic curves of direct-current motors** shall be based upon full voltage, which shall be taken as 600 volts, or a multiple thereof.

**812. In the case of field-control motors,** characteristic curves shall be given for all operating field connections.

## EFFICIENCY AND LOSSES

**815. The efficiency** of railway motors shall be deduced from a determination of the losses enumerated in Par. **816** to **820.** (See also Par. **1100** and **1101.**)

**816. The copper loss** shall be determined from resistance measurements corrected to 75 deg. cent.

**817. The no-load core loss, brush friction, armature-bearing friction and windage** shall be determined as a total under the following conditions:

In making the test, the motor shall be run without gears. The kind of brushes and the brush pressure shall be the same as in commercial service. With the field separately excited, such a voltage shall be applied to the armature terminals as will give the same speed for any given field current as is obtained with that field current when operating at normal voltage under load. The sum of the losses above-mentioned, is equal to the product of the counter-electromotive force and the armature current.

**818.** The **core loss** in direct-current motors shall be separated from the friction and windage losses above described by measuring the power required to drive the motor at any given speed without gears, by running it as a series motor on low voltage and deducting this loss from the sum of the no-load losses at corresponding speed. (See Par. **1101** for alternative method.)

The friction and windage losses under load shall be assumed to be the same as without load, at the same speed.

The core loss under load shall be assumed as follows:

**Table XVII.—Core Loss in D-C. Railway Motors at Various Loads**

| Per cent. of input at nominal rating | Loss as per cent. of no-load core loss | Per cent. of input at nominal rating | Loss as per cent. of no-load core loss |
|---|---|---|---|
| 200 | 165 | 75 | 125 |
| 150 | 145 | 50 | 123 |
| 100 | 130 | 25 and under | 122 |

NOTE.—With motors designed for field control the core losses shall be assumed as the same for both full and permanent field. It shall be the mean between the no-load losses at full and permanent field, increased by the percentages given in the above table.

**819. The brush-contact resistance loss** to be used in determining the efficiency, may be obtained by assuming that the sum of the drops at the contact surfaces of the positive and negative brushes is 3 volts.

**820.** The losses in gearing and axle bearings for single-reduction single-geared motors, varies with type, mechanical finish, age and lubrication. The following values, based on accumulated tests, shall be used in the comparison of single-reduction single-geared motors.

Digitized by Google

**Table XVIII.—Losses in Axle Bearings and Single-reduction Gearing of Railway Motors**

| Per cent. of input at nominal rating | Losses as per cent. of input | Per cent. of input at nominal rating | Losses as per cent. of input |
|---|---|---|---|
| 200 | 3.5 | 60 | 2.7 |
| 150 | 3.0 | 50 | 3.2 |
| 125 | 2.7 | 40 | 4.4 |
| 100 | 2.5 | 30 | 6.7 |
| 75 | 2.5 | 25 | 8.5 |

NOTE.—Further investigation may indicate the desirability of giving separate values of the losses for full and tapped fields, or low- and high-speed motors.

## ELECTRIC LOCOMOTIVES

**830. Rating.** Locomotives shall be rated in terms of the weight on drivers, nominal 1-hr. tractive effort, continuous tractive effort and corresponding speeds.

**831. Weight on drivers.** The weight on drivers, expressed in pounds, shall be the sum of the weights carried by the drivers and of the drivers themselves.

**832. Nominal tractive effort.** The nominal tractive effort, expressed in pounds, shall be that exerted at the rims of the drivers, when the motors are operating at their nominal (1-hr.) rating.

**833. Continuous tractive effort.** The continuous tractive effort, expressed in pounds, shall be that exerted at the rims of the drivers when the motors are operating at their full-voltage continuous rating, as indicated in Par. **802.**

In the case of locomotives operating on intermittent service, the continuous tractive effort may be given for one-half or three-fourths voltage, but in such cases the voltage shall be clearly specified.

**834. Speed.** The rated speed, expressed in miles per hour, shall be that at which the continuous tractive effort is exerted.

See also Appendix II on Additional Standards for Railway Motors.

## RATING OF AUTOMOBILE PROPULSION MOTORS AND GENERATORS

### (ROAD VEHICLES)

**835. Continuous rating.** Automobile propulsion motors and generators shall be given a continuous rating, expressed in kilowatts output available at the shaft at specified speed. The machines shall be able to operate continuously at their rated outputs without exceeding any of the limitations referred to in Par. **260.**

**836. Short-time rating.** Owing to the variety of services which road vehicles are called upon to perform, no single standard period for short-time ratings is recommended.

**837. Nominal rating.** No special nominal rating is required for automobile propulsion motors or generators.

**838. Temperature rises.** Owing to space limitations and the cost of carrying dead weight on automobiles, it is considered good practice to operate the propulsion machinery at higher temperatures than would be advisable in stationary machines. The rating of automobile motors and generators shall be based upon temperature rise, on a stand test and with motor covers arranged as in service, fifteen degrees by thermometer or twenty-five degrees by resistance, above those of Par. **279.**

**839. Efficiency and losses.** Unless otherwise specified the efficiency of automobile propulsion machines shall be based upon the output at the shaft, using conventional losses as tabulated in Par. **440.** When such machines are of low voltage, the great influence of brush-contact losses on the efficiency requires that these losses be determined experimentally for the type of brush used.

## ILLUMINATION AND PHOTOMETRY

**The following paragraphs, 850 to 895, are the rules of the Nomenclature and Standards Committee of the Illuminating Engineering Society. They are here included by permission.**

**850. Luminous flux** is radiant power evaluated according to its capacity to produce the sensation of light.

**851. The stimulus coefficient** $K\lambda$ for radiation of a particular wave-length, is the ratio of the luminous flux to the radiant power producing it.

**852. The mean value of the stimulus coefficient,** $K_m$, over any range of wave-lengths, or for the whole visible spectrum of any source, is the ratio of the total luminous flux (in lumens) to the total radiant power (in ergs per second, but more commonly in watts).

**853. The luminous intensity** of a point source of light is the solid angular density of the luminous flux emitted by the source in the direction considered; or it is the flux per unit solid angle from that source.

Defining equation:

Let $I$ be the intensity, $F$ the flux and $\omega$ the solid angle.

Then if the intensity is uniform,

$$I = \frac{F}{\omega},$$

**854. Illumination,** on a surface, is the luminous flux-density over that surface, or the flux per unit of intercepting area.

Defining equation:

Let $E$ be the illumination and $S$ the area of the intercepting surface.

Then when uniform,

$$E = \frac{F}{S},$$

**855. Candle,** the unit of luminous intensity maintained by the National Laboratories of France, Great Britain, and the United States.*

**856. Candle-power,** luminous intensity expressed in candles.

**857. Lumen,** the unit of luminous flux, equal to the flux emitted in a unit solid angle (steradian) by a point source of 1 candle-power.†

**858. Lux,** a unit of illumination equal to one lumen per sq. m. The C.G.S. unit of illumination is one lumen per sq. cm. For this unit Blondel has proposed the name "Phot." One millilumen per sq. cm. (milliphot) is a practical derivative of the C.G.S. system. One foot-candle is one lumen per sq. ft., and is equal to 1.0764 milliphots.

**859.** (Deleted in the last revision of the Standardisation Rules.)

**860. Specific luminous radiation,** the luminous flux-density emitted by a surface, or the flux emitted per unit of emissive area. It is expressed in lumens per sq. cm.

Defining equation:

Let $E'$ be the specific luminous radiation.

Then, for surfaces obeying Lambert's cosine law of emission,

$$E' = \pi b_0$$

**861.**
**862.** } (Deleted in the last revision of the Standardisation Rules.)

**863. The lambert, the C.G.S. unit of brightness,** the brightness of a perfectly diffusing surface radiating or reflecting one lumen per sq. cm. This is equivalent to the brightness of a perfectly diffusing surface having a coefficient of reflection equal to unity and illuminated by one phot.

**864. For most purposes, the millilambert** (0.001 lambert) is the preferable practical unit. A perfectly diffusing surface emitting one lumen per sq. ft. will have a brightness of 1.076 millilamberts.

---

* This unit, which is used also by many other countries, is frequently referred to as the international candle.

† A uniform source of one candle emits $4\pi$ lumens.

Digitized by Google

**865. Brightness expressed in candles per sq. cm.** may be reduced to lamberts by multiplying by $\pi$.

Brightness expressed in candles per sq. in. may be reduced to ft.-candle brightness, by multiplying by the factor $144\pi = 452$.

Brightness expressed in candles per sq. in. may be reduced to lamberts by multiplying by $\pi/6.45 = 0.4868$.

In practice, no surface obeys exactly Lambert's cosine law of emission; hence the brightness of a surface in lamberts is, in general not numerically equal to its specific luminous radiation in lumens per sq. cm.

Defining equations:

**866. Coefficient of reflection,** the ratio of the total luminous flux reflected by a surface to the total luminous flux incident upon it. It is a simple numeric. The reflection from a surface may be regular, diffuse or mixed. In perfect regular reflection, all of the flux is reflected from the surface at an angle of reflection equal to the angle of incidence. In perfect diffuse reflection, the flux is reflected from the surface in all directions, in accordance with Lambert's cosine law. In most practical cases, there is a superposition of regular and diffuse reflection.

**867. Coefficient of regular reflection** is the ratio of the luminous flux reflected regularly to the total incident flux.

**868. Coefficient of diffuse reflection** is the ratio of the luminous flux reflected diffusely to the total incident flux.

Defining equation:

Let $m$ be the coefficient of reflection (regular or diffuse).

Then, for any given portion of the surface,

$$m = \frac{E'}{E}$$

**869. Lamp,** a generic term for an artificial source of light.

**870. Primary luminous standard,** a recognised standard luminous source reproducible from specifications.

**871. Representative luminous standard,** a standard of luminous intensity adopted as the authoritative custodian of the accepted value of the unit.

**872. Reference standard,** a standard calibrated in terms of the unit from either a primary or representative standard and used for the calibration of working standards.

**873. Working standard,** any standardized luminous source for daily use in photometry.

**874. Comparison lamp,** a lamp of constant but not necessarily known candle-power, against which a working standard and test lamps are successively compared in a photometer.

**875. Test lamp,** in a photometer—a lamp to be tested.

**876. Performance curve,** a curve representing the behavior of a lamp in any particular (candle-power, consumption, etc.) at different periods during its life.

**877. Characteristic curve,** a curve expressing a relation between two variable properties of a luminous source, as candle-power and volts, candle-power and rate of fuel consumption, etc.

**878. Horizontal distribution curve.** A polar curve representing the luminous intensity of a lamp, or lighting unit, in a plane perpendicular to the axis of the unit, and with the unit at the origin.

**879. Vertical distribution curve.** A polar curve representing the luminous intensity of a lamp, or lighting unit, in a plane passing through the axis of the unit, and with the unit at the origin. Unless otherwise specified, a vertical distribution curve is assumed to be an *average* vertical distribution curve, such as may in many cases be obtained by rotating the unit about its axis and measuring the average intensities at the different elevations. It

Digitized by Google

is recommended that in vertical distribution curves, angles of elevation shall be counted positively from the nadir as zero, to the zenith as 180 deg. In the case of incandescent lamps, it is assumed that the vertical distribution curve is taken with the tip downward.

**880. Mean horizontal candle-power** of a lamp—the average candle-power in the horizontal plane passing through the luminous center of the lamp.

It is here assumed that the lamp (or other light source) is mounted in the usual manner, or, as in the case of an incandescent lamp, with its axis of symmetry vertical.

**881. Mean spherical candle-power** of a lamp—the average candle-power of a lamp in all directions in space. It is equal to the total luminous flux of the lamp, in lumens, divided by $4\pi$.

**882. Mean hemispherical candle-power** of a lamp (upper or lower)—the average candle-power of a lamp in the hemisphere considered. It is equal to the total luminous flux emitted by the lamp, in that hemisphere, divided by $2\pi$.

**883. Mean zonal candle-power** of a lamp—the average candle-power of a lamp over the given zone. It is equal to the total luminous flux emitted by the lamp in that zone, divided by the solid angle of the zone.

**884. Spherical reduction factor** of a lamp—the ratio of the mean spherical to the mean horisontal candle-power of the lamp.*

**885. Photometric tests** in which the results are stated in candle-power should be made at such a distance from the source of light that the latter may be regarded as practically a point. Where tests are made in the measurement of lamps with reflectors, the results should always be given as "apparent candle-power" at the distance employed, which distance should always be specifically stated.

**886. The output of all illuminants** should be expressed in lumens.

**887. Illuminants should be rated** upon a lumen basis instead of a candle-power basis.

**888. The specific output of electric lamps** should be stated in lumens per watt; and the specific output of illuminants depending upon combustion should be stated in lumens per b.t.u. per hour. The use of the term "efficiency" in this connection should be discouraged.

When auxiliary devices are necessarily employed in circuit with a lamp, the input should be taken to include both that in the lamp and that in the auxiliary devices. For example, the watts lost in the ballast resistance of an arc lamp are properly chargeable to the lamp.

**889. The specific consumption** of an electric lamp is its watt consumption per lumen. "Watts per candle" is a term used commercially in connection with electric incandescent lamps, and denotes watts per mean horisontal candle-power.

**890. Life tests. Electric incandescent lamps** of a given type may be assumed to operate under comparable conditions only when their lumens per watt consumed are the same. Life-test results, in order to be compared, must be either conducted under, or reduced to, comparable conditions of operation.

**891. In comparing different luminous sources,** not only should their candle-power be compared, but also their relative form, brightness, distribution of illumination and character of light.

**892. Lamp accessories. A reflector** is an appliance, the chief use of which is to redirect the luminous flux of a lamp in a desired direction or directions.

**893. A shade** is an appliance, the chief use of which is to diminish or to interrupt the flux of a lamp in certain directions, where such flux is not desirable. The function of a shade is commonly combined with that of a reflector.

**894. A globe** is an enclosing appliance of clear or diffusing materials, the chief use of which is either to protect the lamp, or to diffuse its light.

* In case of a uniform point-source, this factor would be unity, and for a straight cylindrical filament obeying the cosine law it would be $\pi/4$.

**895. Table XIX.—Photometric Units and Abbreviations**

| Photometric quantity | Name of unit | Abbreviations, symbols and defining equations |
|---|---|---|
| 1. Luminous flux | Lumen | $F$. $\Psi$ |
| 2. Luminous intensity | Candle | $I=\frac{dF}{d\omega}$, $F=\frac{d\Psi}{d\omega}$, c-p. |
| 3. Illumination | Phot., foot-candle, lux | $E=\frac{dF}{dS}=\frac{I}{r^2}\cos\theta\beta$ |
| 4. Exposure | Phot-second | $t$ $E$ |
| 5. Brightness | Apparent candles per sq. cm.<br>Apparent candles per sq. in.<br>Lambert | $b=\frac{dI}{dS\cos\theta}$<br>$L=\frac{dF}{dS}$ |
| 6. Normal brightness | Candles per sq. cm.<br>Candles per sq. in. | $b_0=\frac{dI}{dS}$ |
| 7. Specific luminous radiation | Lumens per sq. cm.<br>Lumens per sq. in. | $E'=\pi b_0\beta'$ |
| 8. Coefficient of reflection | ..... | $m=\frac{E'}{E}$ |
| 9. Mean spherical candle-power | | scp |
| 10. Mean lower hemispherical candle-power | | lcp |
| 11. Mean upper hemispherical candle-power | | ucp |
| 12. Mean zonal candle-power | | zcp |

13. 1 lumen is emitted by 0.07958 spherical cp.
14. 1 spherical candle-power emits 12.57 lumens.
15. 1 lux = 1 lumen incident per sq. meter = 0.0001 phot = 0.1 milliphot.
16. 1 phot = 1 lumen incident per sq. cm. = 10,000 lux = 1,000 milliphot.
17. 1 milliphot = 0.001 phot = 0.929 foot-candle.
18. 1 foot-candle = 1 lumen incident per sq. ft. = 1.076 milliphot = 10.76 lux.
19. 1 lambert = 1 lumen emitted per sq. cm.*
20. 1 millilambert = 0.001 lambert.
21. 1 lumen, emitted, per sq. ft.* = 1.076 millilambert.
22. 1 millilambert = 0.929 lumen, emitted, per sq. ft.*
23. 1 lambert = 0.3183 candle per sq. cm. = 2.054 candles per sq. in.
24. 1 candle per sq. cm. = 3.1416 lamberts.
25. 1 candle per sq. in. = 0.4868 lamberts = 486.8 millilamberts.

**896.** (Deleted in the last revision of the Standardisation Rules.)

## STANDARDS FOR TELEPHONY AND TELEGRAPHY

**910.** After careful consideration, it does not seem that the time is yet ripe for a formal standardisation of terms and definitions used in telephony and telegraphy. Many of the terms commonly employed are used in more than a single way and, conversely, many pieces of apparatus and many constants which are essentially identical from a physical standpoint have been and are known by more than one designation.

**911. Damping of a circuit.** The damping, at a given point, in a circuit from which the source of energy has been withdrawn, is the progressive diminution in the effective value of electromotive force and current at that point resulting from the withdrawal of electrical energy.

**912. Damping constant.** The damping constant of a circuit depends upon the ratio of the dissipative to the reactive component of its impedance or admittance.

Applied to the admittance of a condenser or other simple circuit having capacity reactance, the damping constant for a harmonic electromotive

* Perfect diffusion assumed.

Digitized by Google

force of given frequency is the ratio of the conductance of the condenser or simple circuit at that frequency, to twice the capacity of the condenser at the same frequency.

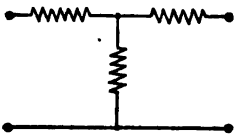
Applied to the reactance of a coil or other simple circuit having inductive reactance, the damping constant for a harmonic current of given frequency is the ratio of the resistance of the coil or circuit at that frequency, to twice the inductance at the same frequency.

**913. Equivalent circuit.** An equivalent circuit is a simple network of series and shunt impedances, which, at a given frequency, is the approximate electrical equivalent of a complex network at the same frequency and under steady-state conditions.

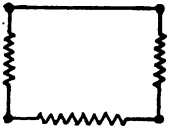
NOTE.—As ordinarily considered, the simple networks as defined are the electrical equivalents of complex networks only with respect to definite pairs of terminals, and only as to sending-end impedances and total attenuation. A further requirement is that the only connections between the pairs of terminals are those through the network itself.

**914. "T" equivalent circuit.** A "T" equivalent circuit is a triple-star or "Y" connection of three impedances externally equivalent to a complex network.

**915. "U" equivalent circuit.** A "U" equivalent circuit is a delta connection of three impedances externally equivalent to a complex network. It is also called a "Π" equivalent circuit.



Symbol for "T" equivalent circuit.



Symbol for "U" equivalent circuit.

## IMPEDANCE

**916. Mutual impedance.** The mutual impedance, for alternating currents, between a pair of terminals and a second pair of terminals of a network, under any given condition, is the negative vector ratio of the electromotive force produced between either pair of terminals on open circuit, to the current flowing between the other pair of terminals.

**917. Self impedance.** The self impedance between a pair of terminals of a network, under any given condition, is the vector ratio of the electromotive force applied across the terminals to the current produced between them.

## LINE CHARACTERISTICS

**918. Characteristic impedance.** The characteristic impedance of a line is the ratio of the applied electromotive force to the resulting steady-state current upon a line of infinite length and uniform structure, or of periodic recurrent structure.

NOTE.—In telephone practice, the terms (1) line impedance, (2) surge impedance, (3) iterative impedance, (4) sending-end impedance, (5) initial sending-end impedance, (6) final sending-end impedance, (7) natural impedance, and (8) free impedance have apparently been more or less indefinitely and indiscriminately used as synonyms with what is here defined as "characteristic impedance."

**919. Sending-end impedance.** The sending-end impedance of a line is the vector ratio of the applied electromotive force to the resulting steady-state current at the point where the electromotive force is applied.

NOTE.—See note under "Characteristic Impedance." In case the line is of infinite length, of uniform structure or of periodic recurrent structure, the sending-end impedance and the characteristic impedance are the same.

**920. Propagation constant.** The propagation constant per unit length of a uniform line, or per section of a line of periodic recurrent structure, is the natural logarithm of the vector ratio of the steady-state currents at various points separated by unit length in a uniform line of infinite length, or at successive corresponding points in a line of recurrent structure of infinite

Digitized by Google

length. The ratio is determined by dividing the value of the current at the point nearer the transmitting end by the value of the current at the point more remote.

**921. Attenuation constant.** The attenuation constant is the real part of the propagation constant.

**922. Wave-length constant.** The wave-length constant is the imaginary part of the propagation constant.

## LINE CIRCUITS

**930. Ground-return circuit.** A ground-return circuit is a circuit consisting of one or more metallic conductors in parallel, with the circuit completed through the earth.

**931. Metallic circuit.** A metallic circuit is a circuit of which the earth forms no part.

**932. Two-wire circuit.** A two-wire circuit is a metallic circuit formed by two paralleling conductors insulated from each other.

**933. Superposed circuit.** A superposed circuit is an additional circuit obtained from a circuit normally required for another service, and in such a manner that the two services can be given simultaneously without mutual interference.

**934. Phantom circuit.** A phantom circuit is a superposed circuit, each side of which consists of the two conductors of a two-wire circuit in parallel.

**935. Side circuit.** A side circuit is a two-wire circuit forming one side of a phantom circuit.

**936. Non-phantomed circuit.** A non-phantomed circuit is a two-wire circuit which is not arranged for use as the side of a phantom circuit.

**937. Simplexed circuit.** A simplexed circuit is a two-wire telephone circuit arranged for the super-position of a single ground-return signalling circuit operating over the wires in parallel.

NOTE.—In view of the use of the term "Simplex Operation" in telegraph practice, it is felt that the designation "Simplexed Circuit" as applied to the arrangement described is not a happy one.

**938. Composited circuit.** A composited circuit is a two-wire telephone circuit, arranged for the superposition on each of its component metallic conductors of a single independent ground-return signalling circuit.

**939. Quadded or phantomed cable.** A quadded or phantomed cable is a cable adapted for the use of phantom circuits.

NOTE.—The type of cable here defined has frequently been designated as "Duplex Cable"—a term which is objectionable, both on account of its lack of description and its widely different use in telegraph practice.

## LOADING

**950. Loaded line.** A loaded line is one in which the normal inductance of the circuit has been altered for the purpose of increasing its transmission efficiency for one or more frequencies.

**951. Series loaded line.** A series loaded line is one in which the normal inductance has been altered by inductance serially applied.

**952. Shunt loaded line.** A shunt loaded line is one in which the normal inductance of the circuit has been altered by inductance applied in shunt across the circuit.

**953. Continuous loading.** A continuous loading is a series loading in which the added inductance is uniformly distributed along the conductors.

**954. Coil loading.** A coil loading is one in which the normal inductance is altered by the insertion of lumped inductance in the circuit at intervals. This lumped inductance may be applied either in series or in shunt.

NOTE.—As commonly understood, coil loading is a series loading in which the lumped inductance is applied at uniformly spaced recurring intervals.

**955. Microphone.** A contact device designed to have its electrical resistance directly and materially altered by slight differences in mechanical pressure.

**956. Relay.** A relay is a device by means of which contacts in one circuit are operated under the control of electrical energy in the same or other circuits.

Digitized by Google

**957. Resonance.** Resonance of a harmonic alternating current of given frequency, in a simple series circuit, containing resistance, inductance and capacity, is the condition in which the positive reactance of the inductance is numerically equal to the negative reactance of the capacity. Under these conditions, the current flow in the circuit with a given electromotive force is a maximum.

**958. Retardation coil.** A retardation coil is a reactor (reactance coil) used in a circuit for the purpose of selectively reacting on currents which vary at different rates.

NOTE.—In telephone and telegraph usage, the terms "impedance coil," "inductance coil," "choke coil" and "reactance coil" are sometimes used in place of the term "retardation coil."

**959. Skin effect.** Skin effect is the phenomenon of the non-uniform distribution of current throughout the cross-section of a linear conductor, occasioned by variations in the intensity of the magnetic field due to the current in the conductor.

**960. Telephone receiver.** A telephone receiver is an electrically operated device designed to produce sound waves or vibrations which correspond in form to the electromagnetic waves or vibrations actuating it.

**961. Telephone transmitter.** A telephone transmitter is a sound-wave or vibration-operated device designed to produce electromagnetic waves or vibrations which correspond in form to the sound waves or vibrations actuating it.

**962. The coefficient of coupling of a transformer.** The coefficient of coupling of a transformer at a given frequency, is the vector ratio of the mutual impedance between the primary and secondary of the transformer, to the square root of the product of the self-impedances of the primary and of the secondary.

**963. Repeating coil.** A term used in telephone practice meaning the same as transformer, and ordinarily a transformer of unity ratio.

## APPENDIX I

## STANDARDS FOR RADIO COMMUNICATION

The following Par. **1000** to **1028** have been abstracted from the report of the Standardization Committee of the Institute of Radio Engineers, and are here included by permission as an Appendix, until further revised. For full particulars, see the I.R.E. Standardization Committee report.

**1000. Acoustic resonance device.** One which utilizes, in its operation, resonance to the audio frequency of the received signals.

**1001. Antenna.** A system of conductors designed for radiating or absorbing the energy of electromagnetic waves.

**1002. Atmospheric absorption.** That portion of the total loss of radiated energy due to atmospheric conductivity.

**1003. Audio frequencies.** The frequencies corresponding to the normally audible vibrations. These are assumed to lie below 10,000 cycles per second.

**1004. Capacitive coupler.** An apparatus which, by electric fields, joins portions of two radio frequency circuits, and which is used to tranafer electrical energy between these circuits through the action of electric forces.

**1005. Coefficient of coupling (inductive).** The ratio of the effective mutual inductance of two circuits to the square root of the product of the effective self-inductances of each of these circuits.

**1006. Direct coupler.** A coupler which magnetically joins two circuits having a common conductive portion.

**1007. Counterpoise.** A system of electrical conductors forming one portion of a radiating oscillator, the other portion of which is the antenna. In land stations a counterpoise forms a capacitive connection to ground.

**1008. A damped alternating current** is an alternating current whose amplitude progressively diminishes.

Digitized by Google

**1009. The damping factor** of an exponentially damped alternating current is the product of the logarithmic decrement and the frequency.

Let $I_0$ = initial amplitude
$I_t$ = amplitude at the time $t$
$\epsilon$ = base of Napierian logarithms
$a$ = damping factor
then $I_t = I_0 \epsilon^{-at}$

**1010. Detector.** That portion of the receiving apparatus which, connected to a circuit carrying currents of radio frequency, and in conjunction with a self-contained or separate indicator, translates the radio frequency energy into a form suitable for operation of the indicator. This translation may be effected either by the conversion of the radio frequency energy, or by means of the control of local energy by the energy received.

**1011. Electromagnetic wave.** A periodic electromagnetic disturbance progressing through space.

**1012. Forced alternating current.** A current, the frequency and damping of which are equal to the frequency and damping of the exciting electromotive force.

**1013. Free alternating current.** The current following any electromagnetic disturbance in a circuit having capacity, inductance, and *less* than the critical resistance.

**1014. Critical resistance of a circuit.** That resistance which determines the limiting condition at which the oscillatory discharge of a circuit passes into an aperiodic discharge.

**1015. Group frequency.** The number per second of periodic changes in amplitude or frequency of an alternating current.

NOTE 1.—Where there is more than one periodically recurrent change of amplitude or frequency, there is more than one group frequency present.

NOTE 2.—The term "group frequency" replaces the term "spark frequency."

**1016. Inductive coupler.** An apparatus which, by magnetic forces, joins portions of two radio frequency circuits and is used to transfer electrical energy between these circuits, through the action of these magnetic forces.

**1017. Linear decrement of a linearly damped alternating current** is the difference of successive current amplitudes in the same direction, divided by the larger of these amplitudes.

Let $I_n$ and $I_{n+1}$ be successive current amplitudes in the same direction, of a linearly-damped alternating current.

Then, the linear decrement, $b = \dfrac{I_n - I_{n+1}}{I_n}$

Also, $I_t = I_0 (1 - bft)$
Where $I_0$ = initial current amplitude
$I_t$ = current amplitude at time $t$
$f$ = frequency of alternating current

**1018. Logarithmic decrement** of an exponentially damped alternating current is the logarithm of the ratio of successive current amplitudes in the same direction.

NOTE.—Logarithmic decrements are standard for a complete period or cycle.

Let $I_n$ and $I_{n+1}$ be successive current amplitudes in the same direction.
$d$ = logarithmic decrement

Then $$d = \log_\epsilon \frac{I_n}{I_{n+1}}$$

**1019. Radio frequencies.** The frequencies higher than those corresponding to the normally audible vibrations, which are generally taken as 10,000 cycles per second. See also Audio Frequencies (Par. 1003).

NOTE.—It is not implied that radiation cannot be secured at lower frequencies and the distinction from audio frequencies is merely one of definition based on convenience.

**1020. Resonance** of a circuit to a given exciting alternating e.m.f. is that condition due to variation of the inductance or capacity in which the resulting effective current (or voltage) in that circuit is a maximum.

**1021–1023.** (Deleted in the last revision of the Standardization Rules.)

Digitized by Google

**1024. A standard resonance curve** is a curve the ordinates of which are the ratios of the square of the current at any frequency to the square of the resonant current, and the abscissas are the ratios of the corresponding wave length to the resonant wave length; the abscissas and ordinates having the same scale.

**1025.** (Deleted in the last revision of the Standardization Rules.)

**1026. Sustained radiation** consists of waves radiated from a conductor in which an alternating current flows.

**1027. Tuning.** The process of securing the maximum indication by adjusting the time period of a driven element. (See Resonance.)

**1028. A wave-meter** is a radio frequency measuring instrument, calibrated to read wave lengths.

**1029.** (Deleted in the last revision of the Standardization Rules.)

**1030. Decremeter.** An instrument for measuring the logarithmic decrement of a circuit or of a train of electromagnetic waves.

**1031. Attenuation, radio.** The decrease with distance from the radiating source, of the amplitude of the electric and magnetic forces accompanying (and constituting) an electromagnetic wave.

**1032. Attenuation coefficient of (radio).** The coefficient, which, when multiplied by the distance of transmission through a uniform medium, gives the natural logarithm of the ratio of the amplitude of the electric or magnetic forces at that distance, to the initial value of the corresponding quantities.

**1033. Coupler.** An apparatus which is used to transfer radio-frequency energy from one circuit to another by associating portions of these circuits.

## APPENDIX II

## ADDITIONAL STANDARDS FOR RAILWAY MOTORS

**1100.** In comparing projected motors, and in case it is not possible or desirable to make tests to determine mechanical losses, the following values of these losses, determined from the averages of many tests over a wide range of sizes of single-reduction single-geared motors, will be found useful, as approximations. They include axle-bearing, gear, armature-bearing, brush-friction, windage, and stray-load losses.

**Table XX.—Approximate Losses in D-c. Railway Motors**

| Input in per cent. of that at nominal rating | Losses as per cent. of input | Input in per cent. of that at nominal rating | Losses as per cent. of input |
|---|---|---|---|
| 100 or over | 5.0 | 40 | 8.8 |
| 75 | 5.0 | 30 | 13.3 |
| 60 | 5.3 | 25 | 17.0 |
| 50 | 6.5 | | |

**1101.** The core loss of railway motors is sometimes determined by separately exciting the field, and driving the armature of the motor to be tested, by a separate motor having known losses and noting the differences in losses between driving the motor light at various speeds and driving it with various field excitations.

**1102. Selection of motor for specified service.** The following information relative to the service to be performed, is required, in order that an appropriate motor may be selected.

(*a*) Weight of total number of cars in train (in tons of 2,000 lb.) exclusive of electrical equipment and load. (*b*) Average weight of load and durations of same, and maximum weight of load and durations of same. (*c*) Number of motor cars or locomotives in train, and number of trailer cars in train. (*d*) Diameter of driving wheels. (*e*) Weight on driving wheels, exclusive of electrical equipment. (*f*) Number of motors per motor car. (*g*) Voltage at train with power on the motors—average, maximum and minimum. (*h*) Rate of acceleration in miles per hr. per sec. (*i*) Rate of

Digitized by Google

braking (retardation in miles per hr. per sec.). (*j*) Speed limitations, if any (including slowdowns). (*k*) Distances between stations. (*l*) Duration of station stops. (*m*) Schedule speed including station stops in m.p.h. (*n*) Train resistance in pounds per ton of 2,000 pounds at stated speeds. (*o*) Moment of inertia of revolving parts, exclusive of electrical equipment. (*p*) Profile and alignment of track. (*q*) Distance coasted as a per cent. of the distance between station stops. (*r*) Time of layover at end of run, if any.

**1103. Stand-test method of comparing motor capacity with service requirements.** When it is not convenient to test motors under actual specific service conditions, recourse may be had to the following method of determining temperature rise.

**1104.** The essential motor losses affecting temperatures in service are those in the motor windings, core and commutator. The mean service conditions may be expressed, as a close approximation, in terms of that continuous current and core loss which will produce the same losses and distribution of losses as the average in service.

A stand test with the current and voltage which will give losses equal to those in service, will determine whether the motor has sufficient capacity to meet the service requirements. In service, the temperature rise of an enclosed motor (Par. **164**), well exposed to the draught of air incident to a moving car or locomotive, will be from 75 to 90 per cent. (depending upon the character of the service) of the temperature rise obtained on a stand test with the motor completely enclosed and with the same losses. With a ventilated motor (Par. **165** and **167**), the temperature rise in service will be 90 to 100 per cent. of the temperature rise obtained on a stand test with the same losses.

**1105.** In making a stand test to determine the temperature rise in a specific service, it is essential in the case of a self-ventilated motor (Par. **167**), to run the armature at a speed which corresponds to the schedule speed in service. In order to obtain this speed it may be necessary, while maintaining the same total armature losses, to change somewhat the ratio between the $I^2R$ and core-loss components.

**1106. Calculation for comparing motor capacity with service requirements.** The heating of a motor should be determined, wherever possible, by testing it in service, or with an equivalent duty cycle. When the service or equivalent duty-cycle tests are not practicable, the ratings of the motor may be utilized as follows to determine its temperature rise.

**1107.** The motor losses which affect the heating of the windings are as stated above, those in the windings and in the core. The former are proportional to the square of the current. The latter vary with the voltage and current, according to curves which can be supplied by the manufacturers. The procedure is therefore as follows:

**1108.** (*a*) Plot a time-current curve, a time-voltage curve, and a time-core loss curve for the duty cycle which the motor is to perform, and calculate from these the root-mean-square current and the average core loss.

**1109.** (*b*) If the calculated r.m.s. service current exceeds the continuous rating, when run with average service core loss and speed, the motor is not sufficiently powerful for the duty cycle contemplated.

**1110.** (*c*) If the calculated r.m.s. service current does not exceed the continuous rating, when run with average service core loss and speed, the motor is ordinarily suitable for the service. In some cases, however, it may not have sufficient thermal capacity to avoid excessive temperature rises during the periods of heavy load. In such cases a further calculation is required, the first step of which is to compute the equivalent voltage which, with the r.m.s. current, will produce the average core-loss. Having obtained this, determine, as follows, the temperature rise due to the r.m.s. service current and equivalent voltage.

Let $t$ = temperature rise
$p_c$ = $I^2R$ loss, kw.
$p_e$ = core loss, kw.
} with r.m.s. service current, and equivalent service voltage.

$T$ = temperature rise
$P_c$ = $I^2R$ loss, kw.
$P_e$ = core loss, kw.
} with continuous load current corresponding to the equivalent service voltage.

Then

$$t = T\frac{p_c + p_e}{P_c + P_e}, \text{ approximately.}$$

Digitized by Google

**1111.** (*d*) The thermal capacity of a motor is approximately measured by the ratio of the electrical loss in kw. at its nominal (1-hr.) capacity, to the corresponding maximum observable temperature rise during a 1-hr. test starting at ambient temperature.

**1112.** (*e*) Consider any period of peak load and determine the electrical losses in kilowatt-hours during that period from the *electrical* efficiency curve. Find the excess of the above losses over the losses with r.m.s. service current and equivalent voltage. The excess loss, divided by the coefficient of thermal capacity, will equal the extra temperature rise due to the peak load. This temperature rise added to that due to the r.m.s. service current, and equivalent voltage, gives the total temperature rise. If the total temperature rise in any such period exceeds the safe limit, the motor is not sufficiently powerful for the service.

**1113.** (*f*) If the temperature reached, due to the peak loads, does not exceed the safe limit, the motor may yet be unsuitable for the service, as the peak loads may cause excessive sparking and dangerous mechanical stresses. It is, therefore, necessary to compare the peak loads with the short-period overload capacity. If the peaks are also within the capacity of the motor, it may be considered suitable for the given duty cycle.

# SECTION 25

## GENERAL ENGINEERING ECONOMICS

BY FRANK F. FOWLE, S.B.

### GENERAL DEFINITIONS

1. **Engineering** is defined in its modern sense by Webster's New International Dictionary as, "The art and science by which the mechanical properties of matter are made useful to man in structures and machines." A broader and perhaps better definition is, "The art of organizing and directing men and of controlling the forces and materials of nature for the benefit of the human race." Telford defined an engineer as one who applies the forces of nature to the service of man (*Trans.* A. I. E. E., Vol. XXII, 1903, p. 620).

2. **Branches or subdivisions of engineering.** Originally engineering was regarded as having but two subdivisions or branches: (1) military engineering, or the design and construction of offensive and defensive military works; (2) civil engineering, or the design and construction of public works, roads, bridges, canals, tunnels, lighthouses, etc. This distinction has long since become obsolete, and engineering is now such an indispensable factor in our modern complex civilisation, that it is necessary to recognise a great many different fields or branches of it. To classify these in detail is difficult, because there is frequently no sharp line of demarcation between one field and another, and different fields frequently overlap one another.

The well-recognised major divisions of engineering are civil, mechanical, electrical, and chemical; each of these broad fields is subdivided into many branches and specialties, some distinct and some overlapping. Examples of these subdivisions are hydraulic, highway, structural, steam, refrigerating, illuminating, telephone, radio, electrochemical, sanitary, metallurgical, gas, aerial engineering, etc. These major and secondary classifications do not define all of the recognised fields, however, because there are numerous industries which are so important and so broad in their scope as to have created special engineering fields, combining in practically every case two or more of the major divisions or subdivisions given above. Among these can be named railroad, marine, mining, water-works, central station, municipal, industrial, naval, ordinance engineering, etc.

Thus there is no simple classification of the different branches of engineering which readily defines or embraces the whole field. Yet all the branches of engineering have much in common, in the respect that the underlying technical foundation in every case consists of a thorough knowledge of physics, chemistry and mathematics.

3. **Economics or political economy** is defined as the science of wealth, and is concerned with the general laws affecting the production, distribution, exchange and consumption of wealth. It is not in place to go into the abstract general principles of the subject here; several of the leading authorities are named below* for the benefit of any who wish to study the

* Walker, F. A. "Political Economy;" H. Holt & Co., New York, 3rd ed., 1888.

Hadley, A. T. "Economics;" G. P. Putnam's Sons, New York, 1897.

Ely, R. T. "Outlines of Economics;" The MacMillan Co., New York, 1908; rev. ed.; see Bibliography in Appendix B.

Taussig, F. W. "Principles of Economics;" The MacMillan Co., New York, 1911, 2 vol.

Seligman, E. R. A. "Principles of Economics;" Longmans, Green & Co., New York, 3rd. ed., 1907; see "Suggestions For Students and General References," pp. XVII to L.

Marshall, A. "Principles of Economics;" The MacMillan Co., New York, 1907; 5th ed.

Digitized by Google

general subject. Those principles of economics which are especially useful to the engineer are covered or touched upon in the succeeding treatment.

4. **Engineering economics** may be defined as that field or body of knowledge which is concerned with the *economic* results of engineering, and the application of the principles and laws of economics to engineering undertakings. Since the purpose of all engineering is avowedly utilitarian, it seems unnecessary to offer proof that engineering should invariably justify itself upon economic grounds. Obviously no contemplated engineering project can be reasonably sure of success, however sound it may be upon purely technical grounds, until it has been most carefully considered on economic grounds and the conclusion reached that barring unforeseen casualties it will become a paying and profitable enterprise.

5. **The fundamental elements of engineering economics** may be grouped into four broad classes, with certain subdivisions, as indicated below. This classification is here presented for the first time and hence it should be regarded as tentative. The main thought, however, is to make as clear as possible the principal economic considerations in engineering work as they exist to-day.

| | | |
|---|---|---|
| The Elements of Engineering Economics | Cost Analysis | Principles of accountancy<br>Capital and operating charges<br>Total annual charges<br>Costs per unit<br>Fixed and variable costs<br>Cost balance |
| | Social-Economic Investigations | Traffic analysis<br>Statistics of consumption<br>Probable future development |
| | Valuation of Property | Purchase or sale<br>Rate making<br>Taxation<br>Issuance of securities<br>Adjustment of book values |
| | Rate Making | Public utilities<br>Common carriers |

The skeleton definition of engineering economics given above should be interpreted in a somewhat liberal sense; the predominant idea to be emphasized is the unavoidable contact of the modern engineer with countless economic questions involving cost, price and value, and those social-economic questions, connected with the operation and development of engineering projects directly affecting the public or the public welfare.

The subsequent presentation of the subject is not offered in the sense that it is complete or exhaustive; on the contrary, it is somewhat fragmentary, but has been prepared with the object of making it as useful as possible.

## VALUE, PRICE AND COST

6. **Value** defined in the economic sense is power in exchange, or purchasing power. Ely states that value in the generally accepted sense is exchange value, or objective value as distinguished from subjective value. The measure of importance attached to a commodity or article by some one individual is subjective value, and obviously may differ in extreme degree from the value placed upon the same commodity or article by some other person. Hadley states that value is essentially an ethical term and therefore there may be as many theories of value as there are views of business ethics; he also points out that while the term value may be used in the sense of utility, it ordinarily means the proper and legitimate price, or an estimate of what the price ought to be. Walker drew a very careful distinction between value and utility, the latter being always present where there is value, whereas utility alone does not invariably imply value in the economic sense. Utility does not imply value in the economic sense until it is coupled with desire. Among other elements which go to comprise economic value, the factors of time, place, cost and demand are of major importance. Therefore in speaking of value it is essential to employ such qualifying adjectives or phrases as will serve to make clear the particular kind of value in mind. The term value should never be confused with the terms price or cost, since the several meanings are distinctly different,

Digitized by Google

**7. Price** is exchange value or purchasing power expressed in terms of some one article or commodity, which is usually money. It is important to recognize that price and value are not synonymous terms, although in ordinary commercial usage the term value is quite generally used in the sense of the reasonable price, or what the price ought to be under the ruling conditions. The natural or normal price is the price which is proportional to the cost of production; Adam Smith called the price in terms of money the nominal price, and the price in terms of units of labor or services the real price. Price and cost are not synonymous terms; for instance, the price paid for an article represents the cost to the purchaser, but not to the seller. It is therefore important to preserve this distinction in general. Generally speaking, price means the amount of money actually asked or paid for the article or thing in question.

**8. Competitive regulation of prices.** Except for those commodities or services vested with a public interest, the charges for which are regulated by statute, prices are regulated by the law of supply and demand, under free competition. In other words, prices are regulated by economic laws except for certain classes of things which have their prices regulated by statute.

**9. Price regulation by statute.** In the case of services or commodities which, generally speaking, are necessary to the public convenience and welfare, such as transportation, water supply, gas, electrical energy, communication, etc., it is now universally accepted that the public has the inherent right to regulate the prices or rates therefor. Such regulation is provided for under the Interstate Commerce Act and the public utility laws of the various states. The broad general principles involved in such regulation are three in number: (1) every price or rate is subject to the test of reasonableness, from the standpoint of all the parties involved; (2) under like conditions of service or supply there shall be no discrimination as to price; (3) all who come must be served. For references to the extensive literature on the subject of public utility regulation, see the Bibliography, Par. 88, 159.

**10. Cost** is what the owner of a thing actually paid for it, or his total outlay for the same, in wages, materials and expenses. When the term cost is employed in its broadest sense, it is commonly understood to include not only wages, materials and expenses, but such charges as interest, taxes, insurance and depreciation on the plant required to produce the article or service in question, and perhaps also a certain allowance for profits in addition to the foregoing. Thus it is very essential, in discussing the cost of a thing, or in comparing different costs, to define the elements which cost is understood to include. In most cases it is desirable to employ the term cost in connection with a prefix or adjective which defines it so clearly as to preclude confusion or misunderstanding; for example, labor cost, fuel cost, productive cost, selling cost, distribution cost, etc.

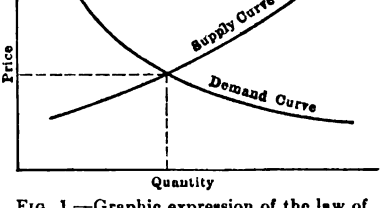

FIG. 1.—Graphic expression of the law of supply and demand.

**11. The law of supply and demand.** The term demand, in the economic sense, means the quantity of an article which will be purchased at a given price, assuming free competition among the buyers. If the price increases, the demand will diminish, and if the price decreases the demand will increase. This inverse relation is expressed by the demand curve in Fig. 1, which takes different positions and characteristics for different commodities.

The term supply, in the economic sense, means the quantity of an article which will be offered for sale, under a given price, assuming free competition among the sellers; it is therefore distinct in meaning from the stock of this article which the producers or distributers have on hand, available for offering

Digitized by Google

in the market. When the price increases, the supply will increase; and conversely, when the price drops, the supply will fall. This relation is expressed by the supply curve in Fig. 1, which occupies different positions for different commodities.

In a stable market the supply will equal the demand, at the normal price. If the price is forced upward, the demand will fall and the supply will increase; the attendant reaction will naturally tend to restore the normal conditions. If the price is manipulated downward the demand will increase, but the supply will diminish; and the attendant natural reaction is again such as to tend toward the restoration of normal conditions.

Should there come about a permanent condition in the market, resulting in greater normal demand, the position of the demand curve will shift in such manner that the demand at the former normal price will be greater than before. The result will be a higher normal price at increased normal quantity or sales. In like manner, a permanent reduction in demand will result in a lower normal price, at diminished normal quantity. A permanent change in the supply, such as might result from a decrease in the sources of raw materials, or, on the other hand, a discovery of new sources of raw materials, will likewise cause the supply curve to shift to a new position.

Generally speaking, a condition of gradually rising normal demand is closely succeeded by a rise in prices, until the demand reaches an even level. A falling demand is similarly followed by diminishing prices, until the demand strikes bottom. Such phenomena will be observed quite generally in studying the prices of any article through a series of years.

## CAPITAL, RENT AND INTEREST

**12. Wealth** in the economic sense may be defined as all property which possesses money value or economic utility. In the broadest possible sense it means an abundance of things which are objects of human desire, but especially an abundance of worldly estate or riches, such as land, goods, money and securities.

**13. Property** is defined by Webster as follows: The exclusive right to possess, enjoy, and dispose of, a thing; ownership; in a broad sense, any valuable right or interest considered primarily as a source or element of wealth; practically all valuable rights except, generally, those involved in public or family relations; various incorporeal rights, patents, copyrights, rights of action, etc.; anything, or those things collectively, in or to which a man has a right protected by law. Property is commonly regarded as comprising two kinds: real property, or land, buildings, fixed plant and improvements in connection therewith; personal property, or furniture, tools, implements, live stock, money, securities, etc. There is also a more modern distinction, as between tangible and intangible property: the former includes real and personal property which exists in tangible physical form; intangible property comprises rights, franchises, good will, going-concern value, patents, copyrights and contracts.

**14. Capital** may be defined in the economic sense as a stock of accumulated wealth; or the amount of property owned by an individual or a corporation at a specified time, in distinction from the income received during a given period. Capital may be in the form of money, or some readily salable article for which there is a constant and general demand, in which case it is said to be liquid capital; or it may be in the form of property which is not readily salable on sudden notice, such as land, buildings, or manufacturing plant, in which case it is termed invested capital. In other words, liquid capital can be readily and quickly converted into money if it is not already such, whereas invested capital usually cannot.

**15. Money** is a common medium of exchange, issued by duly constituted authorities, and, as such, is a commodity the same as any other article which passes frequently from hand to hand in trade or exchange. Therefore, being a commodity, the price of money is regulated by the law of supply and demand. Thus when money is scarce and the demand normal, or heavy, it will command a premium; conversely, if money is overplentiful and the demand low, it can be had at a discount. While true in theory, such fluctuations in the price of money from its face or par value, are disturbing to trade and therefore undesirable; one of the fundamental purposes of our present currency system is to provide elasticity in the supply of money, in order suitably to meet changes in the demand for it and avoid both premiums and

Digitized by Google

discounts. To the end that money may be kept on a stable basis, it is usually founded upon a standard comprised of one of the rare or precious metals; thus the gold standard of value is recognized in the civilized countries the world over, and is the basis of the money in our own country.

**16. Rent** is defined as the price paid for the services or use of land; this is the definition usually given in Economics. In the ordinary commercial sense, rent is the price paid for the use of real property, including land and the buildings and improvements thereon. Under the latter definition, the term rent includes both ground rent and capital rent. The term capital rent is synonymous with interest, defined in the next paragraph.

**17. Interest** is the price paid for the services or use of capital; or the rent for the use of capital. Economists distinguish two kinds of interest: loan interest, or the rent for borrowed capital; imputed interest, or that increment in the price paid for a commodity or a service which recompenses the vendor for the use of his capital in the operation. Universal custom has established the practice of basing the interest charge or rental on a certain percentage, per unit of time, applied to the principal or capital.

Ordinary interest is usually collected with the repayment of the principal, or at stated periods during the term of the loan, say annually, or semi-annually. Another form of interest is termed discount, or banker's discount; this differs from ordinary interest in the respect that it is collected in advance by deducting it from the principal of the loan when handed to the borrower.

**18. The risks of investment.** Capital, being a commodity in the economic sense, is subject to the law of supply and demand. Those persons possessing idle capital are always seeking a market for it, or some use in return for which it will yield interest; persons having business opportunities but lacking the necessary capital to embark in their ventures, are naturally seeking those who have capital to invest. The investor or loaner of capital is concerned with both the safety of his principal and the rate of interest yield, and naturally seeks the highest obtainable interest rate consistent with the risk he is willing to assume for the return of his capital at some stated time or on demand. It is a fundamental principle that the interest rate demanded by capitalists increases with the degree of risk assumed on the principal; and conversely, the less the risk, the lower is the interest rate tendered by borrowers. Thus it can be said, in general, that the commercial rate of interest charged for the use of capital contains two components; one of these is the true interest, and the other is virtually a premium on insurance against loss of the principal.

**19. Legal rates of interest** under the numerous state laws are given in the appended table.

| States and territories | Legal | Contract | States | Legal | Contract | States | Legal | Contract |
|---|---|---|---|---|---|---|---|---|
| Alabama | 8 | 8 | Kansas | 6 | 10 | New York | 6 | 6 |
| Alaska | 8 | 12 | Kentucky | 6 | 6 | N. Carolina | 6 | 6 |
| Arizona | 6 | any | Louisiana | 5 | 8 | Ohio | 6 | 8 |
| Arkansas | 6 | 10 | Maine | 6 | any | Okla. Ter. | 7 | 12 |
| California | 7 | any | Maryland | 6 | 6 | Oregon | 6 | 10 |
| Colorado | 8 | any | Mass. | 6 | any | Penna. | 6 | 6 |
| Conn. | 6 | 6 | Michigan | 5 | 7 | R. Island | 6 | any |
| Dakota, N. | 7 | 12 | Minnesota | 6 | 10 | S. Carolina | 7 | 8 |
| Dakota, S. | 7 | 12 | Mississippi | 6 | 10 | Tennessee | 6 | 6 |
| Delaware | 6 | 6 | Missouri | 6 | 8 | Texas | 6 | 10 |
| Dist. of Col. | 6 | 6 | Montana | 8 | any | Utah | 7 | any |
| Florida | 8 | 10 | Nebraska | 7 | 10 | Vermont | 6 | 6 |
| Georgia | 7 | 8 | Nevada | 7 | any | Virginia | 6 | 6 |
| Idaho | 7 | 12 | New Hamp. | 6 | 6 | Wash't'n | 6 | 12 |
| Illinois | 5 | 7 | N. Jersey | 6 | 6 | W. Virginia | 6 | 6 |
| Indian Ter. | 6 | 8 | N. Mexico | 6 | 12 | Wisconsin | 6 | 10 |
| Indiana | 6 | 8 | | | | Wyoming | 8 | 12 |
| Iowa | 6 | 8 | | | | | | |

**20. Interest rates** vary to a considerable extent, depending upon the class of investment. U. S. Government bonds pay different rates, from 2 per cent. to 4 per cent.; savings-banks deposits, from 3 to 4 per cent.; checking deposits in banks, above a certain minimum amount, frequently draw 2 per cent. on daily balances; certificates of bank deposit, or time deposits, 3 per cent.; railroad and public utility bonds, from 3.5 to 6 per cent.; industrial bonds, 5 to 7 per cent.; short-term notes of railroads and public utilities, 5 to 6 per cent.; real-estate mortgages, 5 to 6 per cent.; railroad and public utility stocks, whatever may be earned, but seldom in excess of 8 per cent.

**21. Compound interest** is based upon the computation of simple interest for stated periods and the addition of the interest to the principal at the end of each period, thus enlarging the principal for each consecutive period, progressively. Let

$P$ = the principal in dollars.

$n$ = the number of years for which the compound interest is to be computed.

$t$ = the ratio of 1 year to the period during which simple interest is computed; thus if compounded annually, $t = 1$ and if compounded semi-annually, $t = 0.5$.

$r$ = the annual percentage rate of interest expressed as a decimal; thus if the rate is 6 per cent., $r = 0.06$.

$S$ = the amount of $P$ dollars at compound interest for $n$ years, compounded at intervals of $t$ years, at the annual rate $r$

The formula for calculating $S$ is as follows:

$$S = P\,(1+tr)^{\frac{n}{t}} \qquad \text{(dollars)} \qquad (1)$$

This can also be expressed in another form

$$\log S = \log P + \frac{n}{t}\log.(1+tr) \qquad (2)$$

The latter form indicates the manner of calculating problems; in most cases the interest is compounded annually, which makes $t = 1$.

**22. Present worth of a future lump payment.** If the sum of $S$ dollars is due at the end of $n$ years, the amount which would have to be set aside at the present date, compounded at intervals of $t$ years at the annual interest rate $r$ (decimally expressed), is expressed by the following formula:

$$P = \frac{S}{(1+tr)^{\frac{n}{t}}} \qquad \text{(dollars)} \qquad (3)$$

This can also be expressed in a form suitable for numerical calculation:

$$\log P = \log S - \frac{n}{t}\log\,(1+tr) \qquad (4)$$

The symbols used have the same significance as stated in Par. **21.**

**23. Annuities.** An annuity is a fixed sum of money payable at equal intervals of time (see Wells, W. "College Algebra;" chapter on "Compound Interest and Annuities"). In most discussions of the subject it is assumed that the payments are made annually and the interest compounded annually. When an annuity is defined as beginning at a certain date, the first payment will fall due 1 year from that date.

**24. The present worth of an annuity** of $A$ dollars per annum, commencing at once and continuing for $n$ years, allowing interest compounded annually at the annual rate $r$ (decimally expressed), may be calculated from the following formula:

$$P = \frac{A}{r}\left[\frac{(1+r)^n - 1}{(1+r)^n}\right] \qquad \text{(dollars)} \qquad (5)$$

The present worth of a perpetual annuity, commencing at once, is equal to $A/r$.

The present worth of an annuity to commence after $m$ years and then continue for $n$ years, is expressed by the formula,

$$P = \frac{A[(1+r)^n - 1]}{r(1+r)^{m+n}} \qquad \text{(dollars)} \qquad (6)$$

Digitized by Google

The present worth of a perpetual annuity to commence after $m$ years, is

$$P = \frac{A}{r(1+r)^m} \qquad \text{(dollars)} \qquad (7)$$

**25. A sinking fund** is one to which equal annual payments are made, compounded at stated intervals, for the purpose of producing a certain predetermined sum at the end of a given period. Sinking funds are quite commonly established for the purpose of retiring bond issues or loans at maturity; they are also established occasionally for the purpose of creating depreciation reserves.

If it is desired to have a sum of $S$ dollars at the end of $n$ years, created from $n$ equal payments, one at the end of each year, compounded annually at the annual interest rate $r$ (decimally expressed), the amount of each annual payment must be that found from the following formula:

$$p = \frac{rS}{(1+r)^n - 1} \qquad \text{(dollars)} \qquad (8)$$

Such a fund does not accumulate uniformly, but at a progressively increasing rate, slowly at first, and rapidly toward the end of the period; this effect becomes more pronounced as the period lengthens. At the end of $m$ years the total amount in the fund bears to the ultimate fund ($n$ years) the ratio expressed by the formula,

$$\frac{(1+r)^m - 1}{(1+r)^n - 1} \qquad (9)$$

This formula is sometimes made use of in determining the percentage of present condition in appraising depreciated properties (Par. 64).

**26. Sinking-fund table.** The table given below is based on Eq. 8 in Par. 25, and shows the sum which must be set aside at the end of each year, for $n$ years, at various rates of interest, compounded annually, to produce the total sum of one dollar at the end of the period. The values given in the table were taken from a more comprehensive table given by Henry Floy in his work, "Valuation of Public Utility Properties" (McGraw-Hill Book Co., New York, 1912), Chap. VIII.

(Amounts stated in dollars)

| Years | Annual rate of interest; per cent. | | | | |
|---|---|---|---|---|---|
| | 2 | 3 | 4 | 5 | 6 |
| 1 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 |

## ANNUAL CHARGES

**27. Two general classes of costs.** In most enterprises there are two general classes of expenditures or costs, namely: (1) expenditures for plant or property, or improvements thereto, all constituting **additions to capital;**

Digitized by Google

(2) expenditures for salaries, wages, rents, taxes, insurance, depreciation, repairs, supplies, etc., all constituting charges to operation, or **operating expenses.** The distinction between these two classes of costs is fundamental in its importance.

**28. Cost comparisons** are of two kinds: (1) comparisons of capital costs, or construction costs; (2) comparisons of operating costs. When comparing one plant with another, as to overall results, it is necessary to reduce all costs to one basis; this is most frequently done by comparing the total annual charges (Par. **29**), but in some instances the operating expenses (excluding interest and profits) are capitalized at the prevailing interest rate and added to the capital or investment. The latter method is rarely used.

**29. The total annual charges** may be defined as the sum of all operating expenses (Par. **27**) plus interest and profit on the investment or capital; or the total charge for operation. The total annual charges may be classified as shown below.

- Total annual charges for operation
  - Investment costs
    - Taxes
    - Insurance
    - Depreciation
    - Maintenance
    - Interest
    - Profits
  - Production costs
    - Traffic
    - Transportation
    - Operating
    - Commercial
    - General

These charges are defined in the succeeding paragraphs.

**30. Taxes** constitute a charge based on the assessed value of the property and require no explanation. This charge varies from about 1 per cent. to 2 per cent. per annum on the capital invested in physical or tangible property.

**31. Insurance** can be defined as a cooperative method of distributing the burden of losses or casualties. The annual assessments or rates are determined by actuaries who apply the theory of probability to the problem of determining the probable risk of loss or damage, based upon the statistics of a large number of past losses. There are many different kinds of insurance, such as life, health, fire, boiler, accident, marine, employers' liability, automobile, plate glass, burglar, hurricane, cyclone, etc. The insurance rate is usually based on a percentage of the investment in insured property, or face value of the total risk, per unit of time or per annum.

**32. Depreciation** is fully covered in another portion of this section; see Par. **41**, *et seq.* It is quite as much an expense of operation as the cost of labor, supplies and other items which are currently paid by the day, week or month.

**33. Maintenance** defined in its broadest sense means upkeep of all kinds, including both repairs and renewals, but in the technical sense in which it is usually employed it means repairs exclusively. The repair charge is frequently reduced to terms of a percentage of the capital invested in plant, or the original cost of the plant.

**34. Interest** has been defined at length in Par. **17** to **20**, and need not be further considered here.

**35. Profits** represent a return on the investment over and above the normal rate of interest. For instance, a return of 8 per cent. has been held reasonable in the case of certain public utilities, on the theory that in addition to interest at a rate, say, of 6 per cent., the investor is entitled to a profit of 2 per cent. as an inducement to himself and others to engage in the particular class of business in question. The term profit is often employed, however, in the sense of including true interest in addition to true profit.

**36. Investment costs** are those, as the name implies, which bear some direct ratio or proportion to the investment. They are defined in Par. **29** to **35**, above. In the case of maintenance expense, there is probably some portion of it, but not all, which is more nearly a production expense than an investment expense; this seems to be obviously true, because of the fact that

Digitized by Google

certain repairs depend upon the amount of use, and increase therewith, as in the case of machinery. The investment costs are sometimes termed **fixed charges.**

**37. Production costs,** defined in Par. **29** as including traffic, transportation, operating, commercial and general expenses, can be said to include in general all other operating expenses not included under the definition of investment costs. The classification of production costs will follow, as a rule, the accounting classification for the utility or common carrier under consideration.

**38. How to determine the annual charges.** The determination of annual charges, for the purposes of cost analysis, rate making, or comparison, should be made as far as possible with the aid of the corporate accounts or books of the company, showing every detail of the business. This will usually insure that no element of cost is overlooked, and will substitute fact for assumption in every case where dependable facts are available. When the corporate books are not available, general experience and special knowledge of the class of business in question, are the only means at hand.

**39. Constant and variable expenses.** For the purposes of rate making it is frequently convenient to treat all operating charges as divisible into two classes: (1) constant expenses, or all expenses which do not vary with the rate of production or output; (2) variable expenses, or all expenses which change substantially in direct proportion with the output.

**40. Cost balance.** One of the most important problems in engineering economics is to determine whether a given operation or service is secured in the most economical manner. Otherwise expressed, this is the problem of determining the particular set of conditions which makes the total annual charge a minimum. Such a problem is usually complicated by the presence of numerous variables, and it becomes impracticable to lay down any brief general rules; each problem is likely to represent a class by itself.

A good example of this problem is that of determining the particular size of conductors which will insure the transmission of electrical energy, under a given set of conditions, at a minimum annual charge. This problem was first solved by Sir William Thompson (Lord Kelvin) and the theorem which he deduced is known as Kelvin's Law; see Sec. 11, 12 and 13.

## DEPRECIATION

**41. Depreciation is defined** by Webster* as follows: A falling of value; of money, a reduction or loss in exchange value or purchasing power, especially with reference to the face value; a lessening in price or estimated value, lowering of worth. In the case of property, there are some kinds whose exchange value seldom decreases, and is more likely, perhaps, to increase; there are other kinds which inevitably depreciate, and finally reach a certain small minimum value or possibly cease to possess any value whatever. The engineer is concerned for the most part with those kinds of property which are perishable, in the ultimate sense, and which deteriorate through physical causes, or through the loss of economical usefulness.

**42. The necessity for recognizing depreciation** is two-fold. In the first place, perishable property will ultimately reach a point at which it possesses only a certain minimum or residual value, or else it will cease to have any value whatever, in consequence of having outlived its usefulness. Then replacement will become necessary, and in order to provide the requisite funds without increasing the investment or drawing upon capital, or making an excessive charge against operating expenses, it is desirable to lay aside each year a uniform amount for the creation of a depreciation reserve which will equal the total cost of renewal at the end of the life period.

In the second place, when perishable property is bought or sold during its life period, it is not as a rule considered to be worth its original value, because it has depreciated in the meantime; the present worth, on any given date, is said to be the original worth less the accrued depreciation to such date.

The two phases of the depreciation problem are, therefore: (1) To ascertain the annual rate of depreciation; (2) to ascertain the accrued depreciation on any given date, or at any given age.

---

* New International Dictionary.

Digitized by Google

**43. The two classes of depreciation** usually recognized are physical depreciation and functional depreciation. These are defined in the next succeeding paragraphs.

**44. Physical depreciation** is the result of age, wear and tear, corrosion, and decay. This form of depreciation is constantly in progress; the rate of its progress depends upon the conditions of service or use, protection from ravaging elements, and the degree of care exercised in making prompt repairs when necessary. This rate of course varies greatly with different forms of machinery, apparatus, plant, etc.

**45. Functional depreciation** is the result of failure to function properly, in consequence of lack of adaptation to the service demanded. It has two principal causes, inadequacy and obsolescence.

**46. Inadequacy** is the result of unexpected or premature growth in the demand for service, requiring enlarged capacity which can be provided only by removing the old plant or equipment to make way for new before physical depreciation has run its full course. Depreciation resulting from this cause usually makes it imperative to replace equipment or plant sooner than otherwise, but the displaced equipment is sometimes useful for a further period if re-installed in a new location or in some other plant where its capacity is suited to the demands for service. One of the functions of sound engineering, of course, is to study the probable future demands and so arrange a plant or installation that new units can be provided as occasion may demand, without disturbing the units already in operation. In other words, part of the inherent economy in efficient engineering consists in securing if possible the maximum physical life from any piece of plant or apparatus, unless, of course, it appears conclusively that the total annual charges (Par. **29**) will be actually lessened by deviating to some other plan or policy. It is conceivable, for instance, that the maximum physical life will exceed the economical life, but this is predicated upon the assumption of a progressively diminishing efficiency with increasing age, attended by a marked increase in the total annual charges per unit of production or output before approaching the end of the maximum physical life.

**47. Obsolescence** is that form of functional depreciation which results from new inventions or radical improvements in the art, causing a set-back of present methods or machinery in the scale of efficiency, or creating new demands which it was not possible to serve under the past state of the art. Whether all forms of obsolescence, or allowances for their probable occurrence and effect, should be included in depreciation is perhaps an open question. Many advances in the art relate wholly to improvements in efficiency or reductions in the cost of production. When comparing a new and improved machine with one of obsolete type but not yet worn out in the physical sense, the question whether the new shall immediately supplant the old is usually regulated by the consideration whether the saving in total annual charges (Par. **29**) resulting from the substitution will extinguish the remaining service value of the old machine within a reasonable period, or much sooner than the expiration of the probable life period of the new machine. Thus there are certain types of cases in which obsolescence is not a proper charge against depreciation, but should be amortized (Par. **68**) through the application of those annual charges which represent the savings in operation secured by discarding obsolete machinery or plant. Cases of the latter type are probably typical, as a rule, of the greater number of advances in the art; whereas that type of obsolescence which makes it almost imperative to discard the old for the new, springs into existence with the relatively infrequent advances in the arts which are fundamental or revolutionary in character, as distinguished from those advances which can be classed as mere improvements of things which are already old in the arts.

**48. The insurance element in depreciation.** It is almost self-evident that any provision in depreciation for probable future inadequacy and obsolescence partakes of the nature of insurance to cover a risk. In this sense, therefore, provisions for future inadequacy and obsolescence are, in reality, insurance charges, and not depreciation in the technical sense—at least not in the physical sense. Such provisions should be based, therefore, upon the law of probability applied to the statistics of past occurrences with respect to the abandonment of plant or machinery strictly on account of inadequacy and obsolescence. This mode of procedure will develop the monetary

Digitized by Google

value of the risk, and the annual insurance charge in terms of a percentage of the investment or cost of the plant; the insurance charge should be added to the annual percentage charge for depreciation of a purely physical character.

Another element sometimes included in the gross charge for depreciation, is the insurance increment to cover losses from probable plant casualties, such as fires, floods, cyclones, storms, earthquakes, etc. This again involves the application of the law of probability, to the statistics of past casualties to plant; the necessary annual insurance charge, determined in terms of a percentage of the plant investment or cost, should be added to the other percentage elements comprising the gross annual allowance for depreciation. Of course these charges which partake purely of insurance, can be segregated from the charges for physical depreciation, if desired, and there would be some advantage in so doing, from the standpoint of cost keeping and business administration.

**49. The terms employed in discussing depreciation** are defined in the following Par. **50** to **60.**

**50. Original cost or investment** ($I$) means the total actual outlay or expenditure for the physical plant, installed and in readiness for service; it is also known as the physical cost. It includes as a rule all expenditures which can be classed as construction costs, but none of the so-called intangible property such as franchises, good will, patent rights, licenses, contracts, cost of establishing the business, or going value.

**51. Salvage or scrap value** ($S$) is the amount realised from the sale of worn-out or abandoned plant for what it will bring as junk or second-hand materials.

**52. Cost of removal** ($R$) is the cost of labor and other expense incidental to the removal of worn-out or discarded plant, to make way for the new plant which will replace it.

**53. Service or wearing value** ($W$) is the sum of the original cost plus the cost of removal, less the salvage value, expressed by

$$W = I + R - S \qquad \text{(dollars)} \qquad (10)$$

This is the net depreciable value of the plant, or the sum of money which will be required to replace the plant when it becomes useless, provided that the cost of labor, materials and equipment remains unchanged.

**54. Realized depreciation** is the term applied, in accounting, to the actual sum or amount charged to the depreciation reserve when plant is actually displaced or abandoned. In amount it is identical with the wearing value, $W$

**55. Accrued depreciation** ($A$) is the total or cumulative depreciation in the plant on any given date, expressed in the same units of value measure as the original cost, or in dollars. The accrued depreciation increases in amount as the plant grows older, and finally, at the end of the physical life, becomes equal to the wearing value, $W$.

**56. Present worth** ($P$) is the difference between the original cost ($I$) and the accrued depreciation ($A$), expressed by $P = I - A$.

**57. The life** ($l$) of a plant is always expressed in years. Unless otherwise qualified, the estimated life is usually stated for the conditions of service which the plant or apparatus in question will be required to meet. In some cases, the estimated life includes allowances for probable inadequacy and obsolescence, and in such instances will be less than the physical life which ought to be expected. For tables of **life expectancy** of different kinds of machinery and plant, see other sections of the Handbook dealing with the same; also Foster, H. A. "Engineering Valuation of Public Utilities and Factories;" and Floy, H. "Valuation of Public Utility Properties;" also see Sec. 10, subsection on "Power Plant Economics."

**58. The age** ($a$) of a plant is always expressed in years, and needs no definition except to say that it is usually reckoned from the date the plant or machine is a completed structure, installed and ready for service.

**59. Present condition** ($p$) is the ratio of wearing value less accrued depreciation, to wearing value. This can be expressed as

$$p = \frac{W - A}{W} = 1 - \frac{A}{W} \qquad (11)$$

Digitized by Google

**60. The annual depreciation charge** ($d$) is the ratio of the number of dollars which must be set aside every year and placed in the depreciation reserve, to the original cost or investment; it is usually expressed as a percentage. The yearly (or monthly) accretions to the **depreciation reserve** are calculated in such manner as to produce, at the end of the life expectancy, a total fund equal to the wearing value. The annual sum ($D$), in dollars, charged to expense and credited to the depreciation reserve, can then be expressed by $D = dI$.

**61. Segregation of plant into classes,** for the purpose of computing the annual depreciation charge, is very essential for the reason that different kinds and types of plant have different life expectancies, and therefore depreciate at different rates. After the segregation process is completed and the annual depreciation is determined for each class or type, the sum of the annual charges for all the classes, in dollars, will give the total charge in dollars; the latter sum divided by the original cost or physical value of the whole plant will give the **composite depreciation charge** for the physical property as a whole.

**62. Theories of depreciation.*** There is no agreement at present concerning the question as to how, or in what manner, depreciation accrues from year to year during the life period. The discussion centres for the most part, in this country, around two well-known theories, one known as the straight-line method and the other as the sinking-fund method. There is also the method of diminishing values or reducing balances, and the annuity method. The first two methods are presented briefly in the following paragraphs.

**63. The straight-line method** is based on the assumption that depreciation accrues according to a straight-line law, in the simple ratio of age to life, as shown in Fig. 2. The formulas expressing the several relationships among the foregoing quantities or values (Par. **50** to **60**) are as follows:

$$\left.\begin{array}{lll} d = \dfrac{W}{lI} \text{ (per cent.)}; & A = adI & \text{(dollars)} \\ p = 1 - \dfrac{a}{l} = 1 - \dfrac{A}{W} \text{ (per cent.)}; & P = I(1-ad) & \text{(dollars)} \end{array}\right\} \quad (12)$$

The values of $W$ and $I$ are expressed in dollars and $a$ and $l$ in years. This method, as ordinarily applied, depends in no way upon the amount or rate of interest earned by the depreciation reserves, pending their use for renewals. The straight-line method of computing depreciation is in wide use and has received the approval of several Public Utility Commissions.

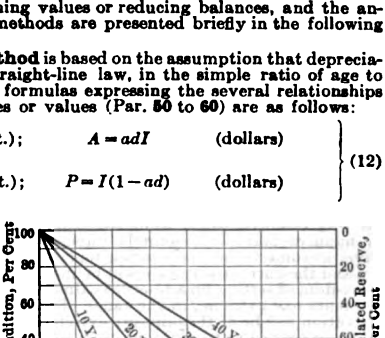

FIG. 2.—Depreciation diagram; straight-line theory.

**64. The sinking-fund method** is based on the assumption that depreciation accrues according to the law which expresses the accumulation of a sinking fund at compound interest (Par. **25**), as shown in Fig. 3. The formulas for use in this case are as follows:

$$\left.\begin{array}{ll} d = \dfrac{W}{I}\left[\dfrac{r}{(1+r)^l - 1}\right] & \text{(per cent.)} \\ p = \dfrac{(1+r)^l - (1+r)^a}{(1+r)^l - 1} & \text{(per cent.)} \\ A = W(1-p) & \text{(dollars)} \\ P = I - A = pW - R + S & \text{(dollars)} \end{array}\right\} \quad (13)$$

* Erickson, H. "Depreciation;" address before Central Water Works Association, Detroit, Mich., Sept. 25, 1912. Also see Bibliography, Par. **88.**

Digitized by Google

The values of $W$ and $I$ are expressed in dollars, $a$ and $l$ in years, and $r$ is the annual rate of interest on the fund, decimally expressed. This method requires that the depreciation reserves be left undisturbed for the entire period of life expectancy, in order that the full amount or sum required to extinguish the wearing value may be realised; otherwise the sums received as interest will be impaired. The sinking-fund method has been employed by the Railroad Commission of Wisconsin: also see Floy, H., "Valuation of Public Utility Properties;" New York, 1912; Chap. VIII.

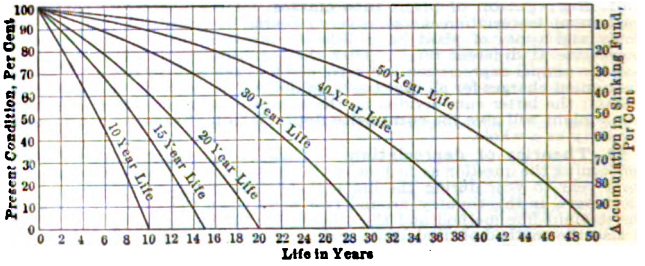

FIG. 3.—Depreciation curves; based on 5 per cent. sinking fund.

**65. The method of reducing balances** is rarely used in this country. It consists briefly in reducing the book value or worth of the plant each year by a fixed percentage. If this figure, for instance, is 10 per cent., the value at the commencement of the second year will be 90 per cent.; the third year, 81 per cent.; the fourth year, 72.9 per cent., etc. This method is interesting theoretically, but is not regarded as very practical.

**66. Reserves for accrued depreciation.** Expert opinions differ as to whether it is necessary to lay aside depreciation reserves for future use. In the case of a new property, just starting operations, there is no doubt that it is very essential to lay aside something for accruing depreciation, unless low finances make it absolutely impossible; unquestionably the time will arrive, at some future date, when replacements in this plant become necessary and the current revenues will be inadequate to meet the outlay, so that the wisdom of setting up a reserve is almost self-evident. The case just cited represents one extreme, in the range of possible or probable cases; the next illustration will be at the opposite extreme. Conceive a very large property, highly diversified as to different kinds and types of plant or equipment, and built up by piecemeal growth extending over a very long series of years; in this case the renewals from year to year probably will not vary to any great extent in number and cost, but perhaps increase slightly from year to year, on the whole, as the property increases in total bulk or size. There are many properties which are intermediate between these two extremes, and a reserve for accrued depreciation is therefore a very wise, if not a necessary provision; at the same time, this is not the universally accepted view.

From another standpoint, however, there is a very strong reason for creating depreciation reserves. Quite aside from the question as to whether a reserve is necessary in order to distribute the cost of renewals uniformly from year to year in the expenses of operation, it is unquestionably true that plants of practically every kind depreciate with age; that is to say, depreciation is always going on, beyond any power to prevent it. This being so, it becomes evident that the present worth of almost every kind of plant commences to decrease from the first day it enters service; therefore it is essential from the standpoint of the stockholder or investor, to protect the original investment by creating a reserve to offset the accrued depreciation. If the depreciation which accrues annually is offset by charging an equal sum to expenses and crediting it to the reserve, each year, and if the cost of renewals as they occur is charged to the reserve, the whole matter of protecting the investment will take care of itself, in theory. In other words, under this plan, the sum of the present worth of the property plus the total reserve on hand, at any date, will always equal the original investment; this will be

Digitized by Google

true, whether the property grows rapidly, or slowly, and without regard to the size of the expenditures for renewals, provided only that the life expectancy of each increment or fragment of the property is realized with substantial accuracy.

**67. Investment of depreciation reserves.** The proper disposition of depreciation reserves, pending their use for the purpose originally intended, is a subject which has received much discussion without evolving any hard-and-fast rule that meets with general approval. If the funds are not invested in some form of security, or in a business enterprise, they can hardly draw a rate of interest in excess of the usual rates on time deposits, or say 3 per cent. per annum. If invested in conservative bonds, the rate may be as high as 5 per cent. If the property is one which earns more than 5 per cent., there will be some advantage in investing the depreciation reserve, or some portion of it, in extensions of the plant. The last plan also possesses the advantage of reducing the requirements for fresh capital in extending the business; indeed, in some cases it has become the policy to invest the whole depreciation reserve in this manner.

When the depreciation reserve is set up on the basis that the total reserve should always equal the accrued depreciation on the entire property, and the entire reserve is invested in the property, there is one consequence which it is important not to overlook; namely, the present worth of the property will always be equal, in theory, to the total investment in it by the stockholders or owners, assuming that the property is free of debt of any kind. The propriety of investing the whole depreciation reserve in this manner is probably open to some question: in new plants just commencing operations, this procedure may possibly lead to financial embarrassment some years later, when extensive renewals become necessary during some particular year, and the necessary cash is not available except through the sale of new securities; in properties, however, of a highly diversified character as to types and kinds of plant, built up by piecemeal growth through a long series of years, the funds required for renewals during any particular year are not likely to exceed the total sum set aside that year for accrued depreciation, and therefore this plan is not very likely to lead to difficulties in such cases. Between these extremes, nevertheless, there are many intermediate situations, and the ruling local conditions in each instance must largely determine the best course to pursue.

In the case of public utilities, or quasi-public corporations, the depreciation reserve is virtually a trust fund created by public contribution through the assessments or charges for service, and the income from the fund is properly returnable to the fund and belongs thereto; but whether this income is treated as a credit against current charges (expense) for accrued depreciation, or whether it is treated as part of the total corporate income, makes no difference in fixing the amount of the reasonable return on the investment.

Those who are particularly interested in this question should read the literature which is to be found in the transactions of engineering societies, the technical press, the literature of accountancy and the authorities cited in the Bibliography, Par. **86**.

**68. Amortization** is a term used in finance and accounting in the sense of extinguishment; for example, to amortise a debt by means of a sinking fund (Par. **25**), or to amortize the principal of an issue of bonds, or an indebtedness represented by an issue of notes. The term should not be confused with depreciation. It can be correctly said, however, that the annual sums set aside for depreciation, and placed in a reserve fund, are for the purpose of amortising the wearing value. Amortisation means merely the extinguishment of a parcel of value or money equivalent, by means of periodical charges spread over a period of time.

**69. Depreciation accounting** is too extended a subject to explain briefly. In general, the periodical sums necessary to cover depreciation are charged to operating expenses and concurrently credited to the reserve for accrued depreciation. When plant is displaced, its original cost is credited to the fixed capital account and charged to the reserve; the reserve is also charged with the cost of removal and credited with the salvage, the latter being concurrently charged to supplies. The new plant, which displaces the old, is charged to the fixed capital account, under the appropriate sub-accounts. Some authorities hold that accrued depreciation should be

Digitized by Google

deducted from the plant investment, and the reserve for accrued depreciation carried as an asset; others hold that no deduction should be made, and that the reserve should be carried as a liability. The accounting rules of the Interstate Commerce Commission, and those of the State Public Service Commissions should be consulted by those who wish for more information, as well as the text-book authorities; also see files of the *Journal of Accountancy*, for articles on depreciation and its treatment in accounting.

**70. Appreciation** may be defined as an increase in worth or exchange value; the converse of depreciation. In the physical sense, most kinds of property depreciate; but in the sense of market value, when regulated by the law of supply and demand, many kinds of property may appreciate. A familiar example of appreciation is found in the case of land, in a fertile or productive country of increasing population. The market value of land which is useful for business purposes often rises very rapidly.

## SOCIAL-ECONOMIC INVESTIGATIONS

**71. General.** Lack of space forbids any extensive treatment of this subject, or more than a few references to its fundamental features. It forms the essential connecting link between engineering in the purely technical sense, and the social service rendered by engineering projects designed to satisfy public needs. Thus it occupies a position of the highest importance in every type of public utility engineering, and typifies the close relation of engineering, as a whole, to the social welfare.

**72. Traffic analysis** and considerations having to do with the handling of traffic, and the determination of traffic loads and delays, form an essential part of public utility and transportation engineering. Traffic questions are of prime importance in all forms of transportation and communication. In each type of case, the unit of traffic is different; it may be a passenger, or a unit of bulk or weight, or a message. But in every case the traffic itself may be defined as the flow of these units past a given point. The minute-to-minute or hour-to-hour variations in the flow constitute the traffic load curve, which is usually extended to further limits in order to reveal the day-to-day, week-to-week and month-to-month variations throughout a period of a year. Other types of curves show the delays to the traffic before it moves, and indicate the quality of the service in this particular.

Traffic data are fundamental, of course, in determining the required schedule of traffic vehicles, or the facilities needed to accommodate the traffic at any period. The volume of traffic, the quality of service and the net income on the investment are so intimately related that they cannot be independently considered in any successfully managed transportation or communication enterprise. For example, see a paper by the author, entitled, "Toll Telephone Traffic," *Proc.* A. I. E. E., June, 1914.

**73. Statistics of demand and consumption** are to electric, gas and water utilities what traffic analysis is to common carriers (transportation and communication). This analogy, while true in the broad sense, is somewhat imperfect as to detail. In the case of utilities, the statistics of demand and consumption relate wholly to the quantity of service, whereas the quality of the service depends upon both the quality of the delivered commodity and the continuity and uniformity of its supply. In other words, transportation and communication partake wholly of the nature of a service, whereas a utility furnishes both commodity and service. It is hardly necessary to dwell upon the importance of preserving continuous statistics of demand and consumption, from the standpoint of the financial results to the utility, because it is so evident. Electric central station statistics are given more elaborate consideration in another portion of this Section, see Par. 89 to 127.

**74. Probable future development** of the business of a public utility or a common carrier concerns itself with projecting or extrapolating the past and present experience into the future, for the purpose of forming a guide in shaping present policies of management. Investigations made for this purpose are sometimes termed development studies. The desired end in all such investigations is to forecast the probable future demand and consumption. The methods employed are sometimes elaborate, and lack of space forbids any attempt to go into details here. Passing reference will be made, however, to the usefulness of the law of probability in making investigations of this general character.

Digitized by Google

**75. Application of the law of probability.** Experience shows that demand and consumption fluctuate to some extent, under similar conditions as to time, locality, weather, etc., even when the periods compared are separated by no more than a day or a week intervening. Given a sufficient number of observations on demand or consumption, taken under precisely similar conditions but on successive occasions, it becomes quite evident that the mathematical law of probability may be useful in computing the most probable demand or consumption, and also in computing the probability that the demand or consumption will deviate by a specified amount from the most probable value. The theory of probability constitutes the entire foundation for the discussion of precision of measurements (Sec. 3), and has been applied in a number of other connections in engineering, among them being the analysis of telephone traffic. It also forms the whole basis, of course, of every form of insurance.

## VALUATION AND RATE MAKING

**76. General.** Valuation and rate making have become so important that at least five important and authoritative works dealing with this field have been published since 1911. Only the barest outlines of the subject can be given here, with references in the succeeding paragraphs and the Bibliography to some of the principal authorities. Central-station valuation and rate making are treated at some length in Par. **128 to 156**, which should also be consulted for a more detailed exposition of the fundamentals of the subject.

**77. Standards of value** by which to measure the fair value of a public utility have been the subject of extended discussion and litigation, without establishing up to this time any well-defined conclusions except of the broadest character. Although the matter is still in its formative phases, the general principle that investors in public utility enterprises are entitled to fair and reasonable treatment at the hands of the public is well recognised. An excellent discussion of the present status of the matter will be found in Dr. R. H. Whitten's "Valuation of Public Service Corporations;" Supplement, 1914, Chap. II.

The courts have held that original cost, estimated present reproduction cost, and outstanding securities issued against the property, are all competent evidence on the question of value; but the conclusion in every case must be tempered by a consideration of all the facts and circumstances. This is very well expressed by the decision in the Minnesota Rate Cases (230 U. S. 352, 33 Sup. Ct. 729, June 9, 1913), "It is not a matter of formulas, but there must be a reasonable judgment having its basis in a proper consideration of all relevant facts."

**78. Valuations under the cost-of-reproduction theory** resolve themselves into two main questions: (1) What is the value of the tangible property; (2) what is the value of the intangible property?

**79. Tangible property** consists of physical plant, such as right-of-way, land, buildings, machinery, distribution system, meters, etc., organization and engineering expense, interest and taxes during construction; supplies and materials on hand, and working capital.

**80. Intangible property** consists of franchises, licenses, rights, contracts, good will and going value. The modern rule is to allow nothing for **franchise value** unless something was or is actually paid for it, or unless some value for it has been capitalized in the past with public approval. Under monopoly, **good will** has been held to have no value for rate-making purposes. **Going value**, or going-concern value, has been extensively discussed by engineers and commissions, but no recognized or authoritative rule is yet in existence; an excellent summary of the theories of going value, and the tendencies of courts and commissions with respect thereto, is contained in Dr. Whitten's two volumes on "Regulation of Public Service Corporations." See also Par. **156**.

**81. Valuation of tangible property under the cost-of-reproduction theory** involves two separate steps or procedures: (1) The preparations of an **inventory** of the property; (2) the determination of **unit costs** and their application to the quantities in the inventory, for the purpose of computing the total reproduction cost-value, new or undepreciated. The unit costs should be those, if possible, determined from the actual current construction costs shown by the corporate books, unless known to be objectionable for

Digitized by Google

some good and sufficient reason, and therefore unreasonable for the purpose in hand. Unit costs which are unusually high or low by reason of exceptional prevailing prices for labor or materials should be avoided; for this reason average costs covering a period of several years past are sometimes employed.

**82. Deduction of accrued depreciation,** or cost new less depreciation, is the generally accepted rule in preparing valuations. This has no immediate relation to the question whether a reasonable return will be permitted on the cost new, or the same less accrued depreciation; the proper or reasonable course in connection with the latter question will develop in the subsequent consideration of the merits of each case.

**83. A reasonable return on the legitimate investment** in property used and useful in the public service, considering the risk involved and the usual return on other investments involving similar degrees of risk, must in the long run be the guiding rule in fixing rates. If less than a fair return, as determined by this rule, is allowed in fixing rates, the securities of public utility enterprises cannot compete successfully in the investment market with other classes of investment and money will not be forthcoming for the extensions of such properties. On the other hand, if more than a fair return is allowed, the price of service to the public or the consumers will be unjustly high.

**84. Theories of rate making.** There are two fundamental theories of rate making, known respectively as the value-of-service theory and the cost-of-service theory. There has been much controversy between the advocates of these theories, the literature of which is very extensive. Since the whole subject is yet in the formative stage, it seems unwise to attempt more than a brief statement of each theory, in the two succeeding paragraphs.

**85. The cost-of-service theory** is based on the declaration of principle that every rate for service shall be equal, no more or less, to the cost of rendering the service. This definition comprehends such an interpretation of the term cost as to include a reasonable return (interest and profit) on the investment, in addition to all the other elements of cost or expense embraced in the term total annual charge (Par. **29**). The correctness of this theory in its broader aspects is very generally recognised, but there are numerous differences of opinion as to how far it can be applied in determining individual or class rates.

**86. The value-of-service theory** is the older theory, and comes down from the early days before public utility regulation had become an accepted institution. Under this theory the rates are regulated by what the traffic will bear. Competition was largely relied upon, before the days of regulation, to prevent the rates from becoming oppressive. It is not contended at the present time that the total profits of a public utility should be regulated by the value-of-service theory, but it is frequently contended, however, that this theory should be employed to temper the cost-of-service theory, in fixing individual or class rates.

**87. Cost analysis for rate making** involves the problem of determining the cost of each class of service. The difficulties in this process are numerous and it is invariably necessary to adopt certain assumptions as to how different kinds or elements of cost should be distributed or prorated among different classes of expense. Those who are seeking detailed information should consult the extensive literature on the subject, including the opinions and decisions of Public Utility Commissions; also see the treatment of central-station rate making, Par. **128** to **152.**

# CENTRAL STATION ECONOMICS

**JAMES RALEY CRAVATH**

*Consulting Engineer and Public Utility Expert; Member American Institute Electrical Engineers; Illuminating Engineering Society; and Western Society of Engineers*

## CENTRAL-STATION FACTORS RELATING TO UTILIZATION OF INVESTMENT AND APPARATUS

**89. Definition.** In all engineering study of the economics of central stations for the supply of electric light and power for various purposes in a community, it is convenient and customary to use certain factors or unit values derived from other similar plants. The factors given here apply to electric generating and distribution systems only and do not include other utilities such as electric railways, water works, gas works, ice plants and steam heating systems sometimes operated in connection with electric light and power plants and included in their reports.

**90. Cost of plant per kw. of yearly maximum load.** Since the cost of a plant depends so much upon the maximum load it must carry, this is an important factor as showing the amount of money actually invested to create a plant sufficient to carry a given maximum load. This cost usually varies between $200 and $500 per kw. The average is probably somewhere between $250 and $300 per kw. Of this 50 to 75 per cent. is usually in the distribution systems leaving 25 to 50 per cent. for the power plant. The cost of the distribution system part will be highest with underground distribution or where the consumers are scattered, and will be the least with overhead construction or in those localities where the density of consumption per mile of distribution mains is greatest. The cost of steam power plants will be from $55 per kw. up to $150. The lower figure is for the largest steam-turbine stations in locations where land is cheap and there are no expensive preparations of the site. The higher figure is for reciprocating-engine plants on expensive land, with all refinements, so situated that the labor cost of construction is high. If a plant has a very large reserve amount of apparatus in excess of that required to carry the maximum load of the year, this first cost per kw. of peak load will, of course, be higher than if there is little or no reserve.

**91. Cost of plant per kw. of maximum capacity.** This item is similar to the foregoing item except that it is based on the maximum capacity of the plant rather than the maximum load on the plant. It will consequently vary within about the same limits as the previous item. In general it is not as useful a unit of comparison as the previous item because it is more likely to be affected by increase of the power plant from time to time in excess of the actual maximum demand.

**92. Gross annual earnings per kw. of yearly maximum load.** These usually are between the limits of $60 and $140. They are most frequently between $80 and $100. This factor indicates whether the gross

Digitized by Google

earnings are high or low for a given maximum load, and consequently whether the plant is selling its output to its best financial advantage. This factor is likely to be lowest when the annual load factor is lowest, hence the importance of improving the load factor.

**93. Gross yearly earnings per kw. of maximum plant capacity.** This factor is similar to the previous one except that it depends on plant capacity rather than the actual maximum load.

**94. Gross yearly earnings per $100 cost of plant.** This factor varies between $17 and $56. Assuming the plants under consideration to have been well managed and developed for a number of years, the lowest values will be found in some of the large plants where the operating expenses are correspondingly low but the investment is high on account of the expensive distribution system construction necessary to serve large areas. A low factor for this value may also be caused by overbuilding a plant for the territory it is to serve. The highest values are usually found in small and medium sized plants in new territory where the growth has been rapid, the construction inexpensive and the rates high. The operating expenses may be correspondingly high but this is not always the case.

**95. Operating expenses in per cent. of gross earnings.** Under operating expenses are here included all expenses except depreciation, interest dividends and new construction chargeable to plant or capital account. Operating expenses of central stations operated with water power or, occasionally, with very economically operated steam-turbine plants may be as low as 45 per cent. Good practice usually ranges between 50 and 65 per cent.

**96. Connected load per kw. of maximum station load.** This is a combination of the demand and diversity factors. These factors (treated in Par. 106 to 115) are chiefly of practical importance in making rates, as they show the maximum demand made upon the station and consequently the relative amount of investment required by different classes of business. The total connected load per kw. of maximum station load, ranges from 1.5 to 3.6. On the majority of systems it will range between 2 and 3 corresponding to a combined demand and diversity factor of 33 to 50 per cent.

**97. Kilowatts of transformer capacity per kw. of maximum station load in an alternating-current system,** usually ranges from 1 to 2. It is lowest in systems where transformers are large and serve a large number of customers each. It is highest where the transformers are small and serve only a few customers each. In the majority of central stations if the transformer arrangement is well planned it is not necessary to have this factor more than 1.2 to 1.5 kw.

**98. Kilowatts of maximum load per employee** in all departments. In a large number of stations this ranges from 30 to 70. It seldom exceeds 100 excepting where a considerable output is sold wholesale. That the large stations do not show figures much higher than the small ones is probably due to the fact that the number of employees engaged on the distribution system and in looking after the wants of consumers and the perfection of the service is greater in proportion in the large than in the small systems.

**99. Per cent. of kilowatt-hours lost and unaccounted for.** This factor is the difference in per cent. between the kilowatt-hours sent out from the station bus bars and the kilowatt-hours registered on meters or otherwise accounted for. This loss includes loss in lines, loss in slow meters, core and copper losses in transformers and leakage through defective insulation. This seldom is less than 15 per cent., and it is most commonly between 20 and 30 per cent. It may be over 30 per cent. in alternating-current systems with a large number of small transformers and with a very small amount of energy sold per mile of line and per transformer. Obviously if a system were operated without selling any electrical energy, these losses would be 100 per cent.

**100. Yearly load factor.** This is the average load of the year divided by the maximum load and expressed in per cent. A purely lighting load in a small town will yield a yearly load factor under 20 per cent. In a large city it will be under 25 per cent. Addition of motor and heating appliance load has improved these low load factors from year to year during the history of the central station business. A load factor between 30 and 35 per cent.

Digitized by Google

is now common in the smaller plants having a moderate amount of power business. In some manufacturing cities load factors over 50 per cent. have sometimes been attained, but such cases are rare. A combination of lighting, power, and railway loads in a large city gives a load factor between 40 and 45 per cent. The load factor indicates the percentage of time which the plant apparatus is lying idle, and it is the constant aim of central station companies to increase the load factor and reduce the idle time, because interest must be paid on the investment whether the apparatus is in use or not.

## CENTRAL STATION FACTORS RELATING TO TERRITORY SERVED BY SYSTEM

**101. Gross yearly earnings per capita of population.** This factor varies through a large range. Ten dollars per capita may be considered near the maximum at the present writing. This factor is usually higher in the Western part of the United States than in the Eastern. Some engineers in making preliminary estimates on the possibilities of future gross earnings, adopt a step-by-step schedule which increases from East to West. Gross earnings of $6 to $7 per capita may now be considered reasonably attainable under ordinary conditions in most towns on the western side of the Mississippi Valley.

**102. Cost of plant per capita.** This is a factor used by some engineers to indicate whether an excessive amount of plant has been put in for the population to be served. Aside from this it is evidently dependent upon the gross earnings per capita and the degree to which the territory has been developed for electric service. An investment of $40 per capita in an electric plant might be justified if the gross earnings were $10 per capita. In practice we find this varying from $3 to $35 per capita.

**103. Watts maximum load per capita.** This factor is also an indication of the extent to which the territory has been developed. If excessive in proportion to gross earnings per capita, it would indicate bad management. It usually ranges from 30 to 100.

**104. Population per consumer.** This will range from 5 to an indefinite figure. Of course 5 represents near saturation. Such a condition can only be attained in a prosperous country or suburban town.

**105. Gross earnings per consumer.** This factor when taken in connection with a knowledge of the territory served may help to indicate whether the large manufacturing power business or the small residential business has been neglected. This factor may vary between $18 and $159, but its most usual range is between $40 and $70.

**106. Demand factor.** This is the actual maximum demand divided by the connected load, expressed in per cent. It may be applied to a system, a group of consumers or any individual consumer. It is useful in determining the apparatus which must be provided and the rates which can be made for serving any given class of business. These factors can be determined only by actual measurement for different classes of customers with maximum-demand meters.

For example, suppose we find by inserting maximum-demand meters in the services supplying a number of drug-stores that the total maximum demand made by these stores during a year is 75 per cent. of what it would have been had the total connected load been turned on by each consumer at some time during the year. We would then say that the demand factor of these drug-store consumers is 75 per cent. In figuring on the amount of apparatus needed to serve other drug-stores we would multiply the connected load by the demand factor which would give the probable maximum demand.

Mr. E. W. Lloyd in a paper entitled "Compilation of Load Factors," before the National Electric Light Association in 1909, gave the results of the experience of the Commonwealth Edison Co. of Chicago with a large number of consumers equipped with maximum-demand meters. The demand factors of some of the most important classes of small and medium lighting consumers given by Mr. Lloyd are shown by the table in Par. 107, where the classification is according to business, without regard to the size of the installation. Some of the more important demand factors of power consumers taken from the same paper are also given in Par. 109, where the classification is by size of installation. The load and demand factors of a number of larger consumers using both power and light as given by Mr. Lloyd appear in Par. 108.

Digitized by Google

Some years ago all consumers in Chicago were served through maximum-demand meters. This practice was later changed so that consumers having less than 1 kw. connected have their maximum demands estimated according to a table prepared by averaging the previous experience of the company with consumers of this class. A table in Par. 110 gives the demand factors used for estimating maximum-demand in Chicago for such small commercial and residence-lighting customers.

This paper by Mr. Lloyd gives curves showing that the demand factor of residence customers having more than 1 kw. in lamps connected, falls gradually from about 47 per cent. with 1.5 kw. connected load to about 35 per cent. with 4.5 kw. connected load. Small stores and offices are shown to have a demand factor of about 63 per cent., with 1.5 kw. connected load, which gradually falls to about 50 per cent. at 4.5 kw. connected load. The curve in both cases following a straight line from 1.5 to 4.5 kw.

The Wisconsin Railroad and Public Service Commission in rendering its decision in the case of the Madison Gas and Electric Company's rates in 1910 assumed demand factors as indicated by the table in Par. 111. These demand factors, in turn, were derived from figures obtained by tests in Madison, taking also into consideration demand factors compiled by companies using Wright demand meters, summarized in Par. 112.

### 107. Demand Factors and Load Factors of Small and Medium Lighting Customers in Chicago, Classified by Business

(E. W. Lloyd)

| Kind of business | Load factor | Demand factor (ratio of maximum to connected load) |
|---|---|---|
| | Per cent. | Per cent. |
| Banks | 16.1 | 66.8 |
| Churches | 12.4 | 56.0 |
| Hotels | 24.4 | 28.0 |
| Houses | 7.8 | 43.0 |
| Offices (business) | 9.2 | 64.2 |
| Offices (professional) | 6.7 | 64.0 |
| Pool and billiards | 17.4 | 64.5 |
| Printers and engravers | 14.7 | 59.0 |
| Restaurants | 23.4 | 52.3 |
| Saloons | 20.8 | 62.6 |
| Shops (barber) | 11.5 | 70.4 |
| Shops (machine) | 8.7 | 37.2 |
| Shops (tailor) | 8.4 | 59.3 |
| Stables (livery) | 22.2 | 52.3 |
| Stores (book and stationery) | 11.7 | 66.4 |
| Stores (cigar) | 16.8 | 64.7 |
| Stores (dry goods) | 8.2 | 76.5 |
| Stores (drug) | 19.3 | 78.8 |
| Stores (furniture) | 6.0 | 69.7 |
| Stores (grocery) | 10.3 | 73.0 |
| Stores (hardware) | 10.6 | 40.0 |
| Stores (house furniture) | 7.8 | 52.0 |
| Stores (jewelry) | 15.0 | 64.1 |
| Stores (shoe) | 9.8 | 66.5 |
| Stores (clothing) | 6.6 | 52.9 |
| Small hotels and rooming houses | 26.0 | 67.4 |
| Laundries | 10.3 | 67.5 |
| Theatres | 17.2 | 49.0 |
| Warehouses | 12.0 | 41.4 |
| Wholesale houses | 19.4 | 46.6 |
| Manufacturers | 9.5 | 53.5 |
| Hospitals | 12.5 | 42.3 |
| Flats | 6.9 | 54.1 |

| Clubs | 28 | Blacksmith shops | 66 |
| Schools | 37 to 52 | County and federal building | 33 to 31 |

**113. Diversity factor,** as here used is the maximum simultaneous demand of a number of individual services for a specified period, such as 1 hr., divided by the sum of the individual maximum demands of these services for the same period, this result being expressed in per cent. For example, suppose two consumers each have a maximum demand of 50 kw. The sum of their maximum demands would therefore be 100 kw. Suppose, however, these maximum demands do not occur at the same time so that a maximum demand indicator connected to supply both services would indicate a maximum of only 75 kw. The diversity factor would then be 75 kw. divided by 100 kw. or 75 per cent. In other words, the actual maximum demand on a feeder or power plant supplying these two consumers would be only 75 per cent. of their combined maximum demands.

If the consumer's maximum demand is known and the diversity factor for that class of business is also known, the maximum effective demand of the consumer at a given point (such as transformers or power station) is determined by multiplying the consumer's actual maximum demand by the diversity factor (expressed in per cent.) between the consumer and the point under consideration.

The diversity factor is a most important element in central station electric supply; in fact it is one of the economic foundation stones upon which the central station industry is built. But for the fact that the various combined maximum demands of various consumers do not coincide, greater plant capacity would be required to serve them and rates for service would necessarily be high, because of the higher investment required. One hundred per cent. less the diversity factor represents the percentage of apparatus which can be dispensed with by combining the supply of the consumers onto one system.

Thorough study of diversity factors can be made only where maximum-demand meters are used for each consumer. Mr. H. B. Gear, distribution engineer of the Chicago central-station system has reported the results of such investigations at various times as indicated in the Bibliography at the end of this section. The accompanying table gives a summary of Mr. Gear's figures on diversity factors for lighting and power loads (Par. 115).

**114. Classification of diversity factor.** In an electric light and power distribution system there is first a diversity factor between the individual consumers and the transformer serving a group of such consumers because the maximum demands of the individual consumers do not come at the same time. There is next a diversity factor between different transformers and their feeders for similar reasons. Going back another step there is a diversity factor between various feeders entering a power-house or substation and the bus bars and on large systems there is a diversity factor between various substations, and the power station bus bars.

Par. 115 gives the diversity factor for each step from the consumer to the generating station in the first four items, while the last four items give the diversity factors step by step from consumer to generator.

To combine the demand and diversity factors so as to determine the maximum demand on a transformer, feeder or station, as caused by a given connected load, multiply the diversity factor by the demand factor and multiply their product by the connected load.

The yearly diversity factor between lighting and power load, and electric street and elevated railway loads in Chicago is reported by Mr. Samuel

Digitized by Google

Insull as allowing a saving in generating equipment of 8.1 per cent. for the period of heavy winter load of 1911 and 1912, by combining their sources of power supply. The diversity factor in this case would thus be 100 per cent.—8.1 per cent. or 91.9 per cent.

**115. Diversity Factors**
(H. B. Gear)

| | Residence light, per cent. | Commercial light, per cent. | General power, per cent. | Large users, per cent. |
|---|---|---|---|---|
| Between consumers..... | 29.8 | 68.5 | 69.5 | ..... |
| Between transformers..... | 77.0 | 77.0 | 74.0 | 87.0 |
| Between feeders..... | 87.0 | 87.0 | 87.0 | 87.0 |

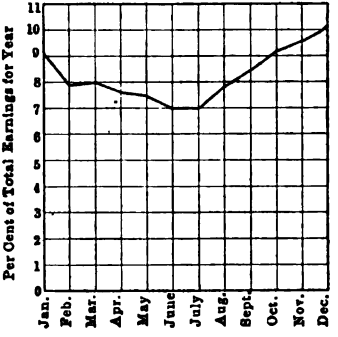

FIG. 4.—Variation of central station station earnings by months.

**116. Variations in earnings from month to month** by a central station are caused by increased demand for light during the winter season. In making estimates for the future it is frequently desirable to know about how these monthly variations run. The curve of Fig. 4 shows how the earnings vary from month to month as taken from a number of typical electric light and power systems of various sizes, with normal yearly growth.

**117. Yearly increase in output.** The output and consequent generating capacity of the central stations of the United States as a whole is such as to double about every 5 years. This corresponds to an increase each year of about 15 per cent. over the year previous. This being an average figure, due allowance must be made for local conditions in making estimates.

## TYPICAL EARNINGS OF ELECTRIC LIGHT AND POWER COMPANIES

**118. Finances.** The following typical earnings of electric light and power companies in the United States are given as showing in a general way the relative values of capital account, gross income, operating expenses, depreciation, and net earnings available for interest and dividends, in electric light and power companies of several sizes, not operated in connection with any other public utility. While the figures given are typical of the sizes of plants named, considerable variation from them is found in practice. Some plants make a better showing than indicated in these typical cases, while others make a less favorable showing.

**119. The item of intangible value** in the cases given represents whatever market value there may be in the plant over and above first cost of the physical property. It includes working capital, expenses of getting business started and worked up to a profitable basis, and any reasonable losses in connection therewith such as are allowed under the head of **going value** by the Wisconsin Commission. It may in some cases include some value based altogether on earning power. The intangible value of a property when determined for rate-making purposes by a public service commission is

Digitized by Google

usually the amount of capital, over and above the cost of the physical plant, upon which the property will be permitted to pay common current interest or dividend rates.

**120. The market value of such a property**, if it has such value over and above its physical value, is evidently its value to a prospective purchaser, and the purchaser usually pays a price based on present and prospective earnings. What these earnings will be depends on the possibilities of the territory served and if there be a rate regulating public service commission, it will also depend on the rate of return on the investment which will be allowed by the public service commission.

**121. Central-station operation in connection with ice plant.** As many of the smaller light and power central stations are operated in connection with ice plants the effect upon the first cost and earnings by adding such a plant is given in two cases. The amount of ice manufactured per year, which determines the gross and net income, depends so much on the latitude in which the plant is located that considerable allowance must be made for this fact.

Ice plants, such as are mentioned in cases 4 and 5 (Par. **126** and **127**), might earn double the gross and about double the net earnings if located in the extreme southern part of the United States. The income from ice depends also a great deal on whether it is sold wholesale or retail, or whether it simply supplies the population in its own town, or in addition ships to other nearby points.

In comparing the typical cases given for the various sizes of plants, it will be seen that in general the gross earnings per $100 invested are larger in the successful small plants than in the large ones, but in the smaller plants the operating expenses are likely to be a larger percentage of the gross receipts. The larger plants can also obtain capital at a lower rate of interest.

The larger the plants the smaller the ratio of gross earnings to capital invested. This is mainly due to the higher cost of transmission and distribution plants necessary to serve the larger territories supplied from the larger generating stations. In some cases it is also due to the higher cost of underground as compared to overhead distribution, and to a more substantial character of construction.

**122. Type of plant affecting various items.** The typical examples given are for steam-driven stations where the cost of fuel is near average. Higher fuel cost will, of course, raise the percentage of operating expenses, or, if more expensive machinery is put in to keep the fuel cost down, the capital account will be increased per kilowatt of peak load. Hydroelectric plants operating central-station lighting and power systems frequently involve higher first cost per kilowatt of peak load, and a consequent low ratio of gross earnings to capitalisation. Such high first cost, of course, can only be justified by the decreased operating expenses caused by fuel saved by water power operation.

**123. Typical earnings of central stations. Case 1.**

| | | |
|---|---|---|
| First cost of physical property | | $37,500 |
| Intangible value | | 12,500 |
| Total capitalisation | | $50,000 |
| Gross earnings (40 per cent. of capital) | $20,000 | |
| Operating expenses (60 per cent. of gross) | | $12,000 |
| Depreciation at 6 per cent. on physical value | | 2,250 |
| Net earnings for interest or dividends | | 5,750 |
| | $20,000 | $20,000 |

**124. Typical earnings of central stations. Case 2.**

| | | |
|---|---|---|
| First cost of physical property | | $75,000 |
| Intangible value | | 25,000 |
| Total capitalisation | | $100,000 |
| Gross earnings (33 per cent. of capital) | $33,000 | |
| Operating expenses (58 per cent. of gross) | | $19,140 |
| Depreciation at 6 per cent. on physical value | | 4,500 |
| Net earnings for interest or dividends | | 9,360 |
| | $33,000 | $33,000 |
| Peak load of plant 300 kw. | | |
| Gross income per kw. of peak | | $110 |

Digitized by Google

**125. Typical earnings of central stations. Case 3.**

| | | |
|---|---|---|
| First cost of physical property | | $750,000 |
| Intangible value | | 250,000 |
| Total capitalization | | $1,000,000 |
| Gross earnings | $230,000 | |
| Operating expenses (50 per cent. of gross) | | $115,000 |
| Depreciation at 6 per cent. on physical property | | 45,000 |
| Net earnings for interest or dividends | | 70,000 |
| | $230,000 | $230,000 |

**126. Typical earnings of central stations. Case 4.**

Effect of 10-ton ice plant with electric plant like that in Case 1. Ice sold at wholesale. Latitude of central Mo. Compression plant.

| | | |
|---|---|---|
| Cost of ice plant | | $9,000 |
| Gross income from ice | $5,800 | |
| Extra operating expenses for ice | | $3,600 |
| Depreciation at 6 per cent | | 540 |
| Net for interest and dividends | | 1,660 |
| | $5,800 | $5,800 |

NOTE.—With sufficient cooling water available an absorption plant could be put in and would operate with much greater coal economy. Its first cost would be considerably higher.

**127. Typical earnings of central stations. Case 5.**

Effect of 15-ton ice plant operated with electric plant like that in Case 2. Ice sold at wholesale and retail. Latitude of southern Iowa.

| | | |
|---|---|---|
| First cost of ice plant | | $13,000 |
| Gross earnings, ice | $13,000 | |
| Extra operating expenses for ice | | $6,500 |
| Depreciation at 6 per cent | | 780 |
| Net for interest and depreciation | | 5,720 |
| | $13,000 | $13,000 |

## PRINCIPLES OF RATE MAKING

**128. Determining factors.** The rates for service charged by a corporation giving central station electric light and power service must be such as to yield a gross revenue sufficient to pay operating expenses, interest, depreciation, and a fair profit on the enterprise. This constitutes the general problem of rate making. There are two general theories which have been used as a basis of rate making; these are given in Par. **129** and **130**.

**129. The value-of-service theory** of rate making is that the rate of charge should be based on the value to the consumer of the service rendered. In railroad rate making this theory has been commonly referred to as "**Charging what the traffic will bear.**" Under this theory if a consumer is unable to obtain service except from some other very costly source, the rate to such a consumer could be made very high because of the absence of competition. Other consumers might be able to serve themselves or to get other services at such a low rate that their business could not be obtained except at a very close margin of profit for the central station, and to such a very low rate would be given. The value-of-service theory has undoubtedly had much to do with the making of central-station rates in the past, but present tendencies are to abandon this theory in favor of the cost-of-service theory, explained later. The value-of-service theory, or charging what the traffic will bear, if carried to an extreme logical conclusion might, in some cases, result in the central-station enterprise deriving an unreasonable profit from some of its customers and insufficient profit from others. In ordinary lines of trade and industry where there is free competition, the value of service theory is necessarily the basis of prices. An electric central station, however, is a public utility which is in the majority of cases a monopoly, at least as far as electric service in a given community is concerned. Because of the fact that it is a monopoly, both public sentiment and public service commissions generally are opposed to the principle of allowing a larger profit from one class of consumers than from another. For this reason the value-of-service theory is being abandoned. Its use in the past has not given

Digitized by Google

rise to so great abuses in the rates of central station enterprises as might be at first supposed, because, although the central station frequently has a monopoly of electric service in a community, it has on every hand to meet the competition of other methods. Electric lighting comes into competition with gas and oil, and electric power with gas, steam and oil engines. However, as electric service becomes more and more of a necessity and less of the nature of a luxury, the tendency to regulate its rates in accordance with the cost of service to the producer rather than according to the value of service to the more or less helpless consumer, becomes stronger.

**130. The cost-of-service theory** of rate making is that all rates should be proportioned among the various consumers according to the cost of serving them. The term "Cost" in this case is assumed to include a reasonable profit. The cost-of-service theory is the one now generally used by the various public service commissions intrusted by law with the work of regulating and adjusting the rates of public service enterprises. The theory upon which the majority of such commissions are proceeding is that, on account of the monopolistic character of a public utility, its rates should be regulated in accordance with the cost of service including a fair return upon the capital invested in the public utility.

**131. Definitions.** The following definitions used in connection with electric central-station rates have been adopted by the Rate Research Committee of the National Electric Light Association. (Examples of all the forms of rates defined are given in Par. **151**.)

**Flat rate.** The term "Flat rate" is applicable to any method of charge for electric service which is based on the consumer's installation of energy-consuming devices or on a fixed sum per consumer. Meters are not used.

**Demand rate.** The term "Demand rate" is applicable to any method of charge for electric service which is based on the maximum demand during a given period of time. The demand is expressed in such units as kilowatts or horse-power. Maximum-demand indicators or graphic meters are used.

**Meter rate.** The term "Meter rate" is applicable to any method of charge for electric service which is based on the amount used. This amount is expressed in units, as kilowatt-hours of electricity. Integrating meters or graphic meters are used.

**Consumer's output rate.** The term "Consumer's output rate" is applicable to any method of charge for electric service based on the consumer's output. The unit of the consumer's output may, for example, be a gallon of water pumped, a barrel of flour, or a ton of ice made.

**Two-charge rate.** The term "Two-charge rate" is applicable to any method of charge for electric service in which the price per unit of metered electric energy for each bill period is based upon both the actual or assumed quantity of electric energy consumed and the actual or assumed capacity or demand of the installation.

**Three-charge rate.** The term "Three-charge rate" is applicable to any method of charge for electric service in which the charge made to the consumer for each bill period consists of, (a) a sum based upon the quantity of electric energy consumed, (b) a sum based upon the actual or assumed capacity or demand of the installation, (c) a charge per consumer.

**Straight line.** The term "Straight line," as used in connection with and as applied to any method of charge, indicates that the price charged per unit is constant, *i.e.*, does not vary on account of any increased or decreased number of units. The total sum to be charged is obtained by multiplying the total number of units by the price per unit.

**Block.** The term "Block," as used in connection with and as applied to any method of charge, indicates that a certain specified price per unit is charged for all or any part of a block of such units, and reduced prices per unit are charged for all or any part of succeeding blocks of the same or a different number of such units, each such reduced price per unit applying only to a particular block or portion thereof. The total sum to be charged is obtained by multiplying the number of units in the first block by the price per unit for that block and adding thereto the number of units in the second block times the price per unit for that block, and so on until the sum of the units falling within the different blocks equals the number of units to be charged for.

**Step.** The term "Step," as used in connection with and as applied to

Digitized by Google

any method of charge, indicates that a certain specified price per unit is charged for all or any part of a specified number of units, with reductions in the price per unit based upon increases in the number of units according to a given schedule. The total sum to be charged is obtained by multiplying the total number of units by the price applying for this number of units, or by the primary price, and deducting the discount applying for this number of units.

**133. The flat rate** consisting usually of a fixed rate per month per lamp was the common rate in the early days of the electric-lighting industry. Its chief advantage is simplicity, as it requires no meter. It is still used generally for street-lighting contracts where a flat rate per lamp per year is charged. It is also used to a limited extent for other classes of business where the kilowatt-hours used can be definitely determined from the hours at which the supply is turned on and off or where the consumers connected load is too small to justify a meter. It is also used to some extent where there is no check upon the consumption of electricity but its use in this way can hardly come under the head of scientific rate making as it has no justification on economic grounds.

**133. The straight-line meter rate,** that is a rate under which a uniform price per kilowatt-hour is charged to all consumers, regardless of the quantity used or the conditionsof use, was at one time popular and is still used in many places but is now recognized as being utterly unfair because it takes no account of the great differences in the cost of serving different classes of consumers. The reason for these differences is explained later under the Two Charge or Hopkinson Rate (Par. **135**). In effect it makes some consumers pay the loss incurred in the supply of other consumers. Furthermore it has a very dwarfing effect upon the growth of the central-station business because of the impossibility of building up a large power business or securing large customers with such a uniform rate in vogue. Failure to secure such consumers means that the existing consumers must be charged higher rates than if a larger business were conducted by the central station.

**134. The block meter rate and the step meter rate** have been used to a considerable extent and represent an unsuccessful attempt to adjust properly the cost of service among different consumers by giving the consumers of a large number of kilowatt-hours per month a lower price per kilowatt-hour than the consumers of a smaller number of kilowatt-hours. These two rates are based upon the general law of commerce that it costs less to handle large or wholesale quantities of any commodity than to handle small retail quantities. However, these rates fail to take into account certain factors of the central-station supply business which affect the cost of service even more than quantity, as explained in Par. **135**. Their principle advantage is that they are easier to understand than some of the rates scientifically based on cost of service. They are used as a matter of expediency, legal necessity or ignorance. They cannot be classed as scientific rates under the cost-of-service theory.

**135. Hopkinson two-charge rate.** Dr. John Hopkinson in an address before the Junior Engineering Society in England, 1892, appears to have been the first to publish and make clear a thorough analysis of the various elements which should go to make up a rate based upon the cost of service. The Hopkinson method of estimating rates is now generally recognised by all authorities as correct where rates are to be based on cost of service. Various modifications and refinements of Hopkinson's original analysis have been introduced from time to time as mentioned later. The Hopkinson rate is one which would come under the head of a two-charge rate under the foregoing definitions.

The two-charge or Hopkinson rate is based on the facts that some of the costs of rendering service to a given customer are fixed annual expenses regardless of the kilowatt-hours actually consumed by such customer, while there are other costs which vary in accordance with the kilowatt-hours taken by the customer. As a simple example, take a consumer who makes a maximum demand of 1 kw. at the time of the maximum or peak load on the central-station plant. To serve this consumer a generating plant and distribution system must be provided, sufficient to supply that 1 kw. maximum to the consumer. To accomplish this end requires a certain investment upon which interest and a fair profit must be paid continually, and upon which depreciation is continually taking place. There are, also, other minor

Digitized by Google

fixed items, such as taxes and insurance, which are dependent entirely upon the size of the plant and which go on continually without regard to the kilowatt-hours output of the plant. Such fixed charges are evidently proportional to the maximum demand of the customer without any regard to his consumption of electrical energy. If we find, for example, that the cost of the power station and distribution system per kw. of maximum load is $300, then that consumer who requires 1 kw. maximum should pay continuously, per month or per year, the interest, profit, taxes, depreciation, insurance, etc., upon this $300 investment. This should be paid without regard to whether he uses a large or small amount of electrical energy in kilowatt-hours, because the investment has been made to serve him. In addition to this he should pay a meter rate or charge per kilowatt-hour. This latter is to pay for the variable cost, principally fuel and labor, which varies according to the output of the station. As a matter of fact there are some labor and fuel costs which are dependent more upon the peak load of a station than upon the kilowatt-hours output and some authorities would include some of these costs in the fixed yearly or monthly maximum demand charge. However these are details aside from the main principle involved. Plant conditions change with increasing load and it is more customary to count these fuel and labor items as variable in proportion to the kilowatt-hours output than as charges in proportion to the maximum demand. We see then that the cost of serving a customer is divided into two distinct elements, viz., maximum demand, and kilowatt-hours, which should be combined in making up a rate. The **demand charge** is sometimes called a **readiness to serve charge.**

Following up our specific example; in the case of the customer making a maximum demand of 1 kw. upon the system at the time of maximum system load, the fixed or maximum demand charges against such a customer might then be found to be per year as follows:

| | |
|---|---|
| Interest and profit on $300 per kilowatt plant and distribution system investment at 8 per cent. | $24.00 |
| Taxes and insurance, 2 per cent. on $300 | 6.00 |
| Depreciation at 6 per cent. on $300 | 18.00 |
| Total fixed annual charges per kilowatt demand | $48.00 |

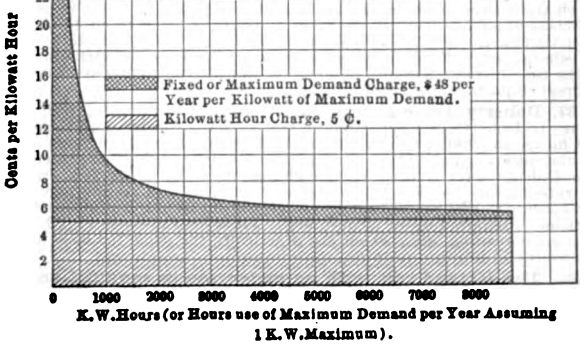

FIG. 5.—Typical form of cost curve for electrical energy supply.

Digitized by Google

We will assume without itemising that the variable expenses such as labor, fuel, etc., amount to 5 cents per kw-hr. of output. That is to say, the variable expenses divided by the kilowatt-hours output equal 5 cents. We then have the two elements of the cost which in practice are either billed to the consumer as separate items or added together and converted into a charge per kw-hr. If we desire to determine the total cost of the two charges per kw-hr. it is determined by taking the sum of the maximum demand and kilowatt-hour charges and dividing this by the number of kilowatt-hours used.

The cost curve, Fig. 5, shows the sum of the maximum demand and kilowatt-hour charges under the foregoing assumptions of a demand charge of $48 per kilowatt maximum demand plus 5 cents per kw-hr, for the equivalent of various numbers of hours use per year of a 1-kw. maximum demand. It will be noted that the fixed or maximum-demand charges constitute a very large proportion of the total when the electrical energy is used but a short time per day or per year, while with electrical energy used continuously the maximum-demand portion is relatively small because it is divided among a large number of kilowatt-hours. This cost curve form is typical of all cost curves for electric supply.

In order to overcome the objections of many consumers, especially small consumers, to paying a fixed maximum-demand charge per month regardless of whether any electrical energy is used or not, it is common practice to accomplish practically the same ends by combining in some way, the maximum-demand and kilowatt-hour or output charges. The most common method of doing this is to charge a relatively high rate per kw-hr. until a given consumer has used enough electrical energy per month to pay for most of his maximum-demand charges plus the output charges, and after this amount or block of electrical energy has been used to make a much lower rate for additional blocks. This might be technically designated as a two-charge block rate.

**136. The Wright demand rate is such a two-charge block rate.** Mr. Arthur Wright put such a rate in force in Brighton, England, and described it in 1896 before the Borough Electrical Engineers' Convention. He invented a simple meter for measuring the consumer's maximum demand, which has been extensively used on Chicago consumers. This meter is not used, however, in the majority of cases where a two-charge block rate is in force.

An example of a common way of stating such a Wright demand or two-charge block rate is as follows: 14 cents per kw-hr. until the consumer has taken an amount of electrical energy equivalent to 30 hr. use per month of his maximum demand and 7 cents per kw-hr. for all electrical energy used in excess of aforesaid amount. Of course such a rate does not guarantee to the central station a minimum payment by the consumer per month sufficient to cover the fixed maximum-demand charges which the customer should justly pay but in practical effect it provides a sufficient annual revenue in the great majority of cases to cover these costs even though there is a loss on some consumers. In connection with any two-charge rate the determination of the consumer's maximum demand at the time of the maximum demand on the central station system becomes of great importance and this is discussed later.

**137. Doherty three-charge rate.** The Doherty rate, proposed by Henry L. Doherty in a paper before the National Electric Light Association at Chicago in 1900, differs from the Hopkinson rate or two-charge rate only by the addition of a third element commonly called a consumer charge. The Doherty rate is thus a three-charge rate. In Doherty's analysis of the rate-making problem he recognized that there is a certain fixed expense per consumer without regard to either the maximum demand or the kilowatt-hours required by such consumer. These are the expenses of bookkeeping, meter reading, etc., which are practically the same for large and small consumers.

**138. The demand rate with no meter rate in conjunction has its principal application** in sale of wholesale power from some hydroelectric plants where the investment and operating costs are fixed or constant, regardless of the number of kilowatt-hours used per year. The kilowatt-hour output in some cases is immaterial to the owner of the plant and the sum of the simultaneous demands of the different consumers at time of station maxi-

Digitized by Google

mum load determines the amount of business which can be carried and the consequent gross revenue. A demand rate in effect is very similar to a flat rate. The only difference is that the consumer's maximum demand instead of being contracted for in advance is measured continuously and can be varied by the consumer from time to time without violation of contract.

**139. Demand factor or the maximum demand made by the consumer** is determined for rate-making purposes in various ways. The most common method with small consumers is to assume the consumer's demand factor or in other words to assume that the consumer's maximum demand is a certain percentage of the connected load. Such demand factors may be determined for different classes of consumers by test of a sufficient number of consumers with maximum demand meters and the results of such tests then taken as the basis of assumptions for all similar consumers. Such a method is of course somewhat inaccurate but it avoids the investment expense of a maximum demand meter for each consumer; which is an important item with small consumers. Demand factors as determined by various authorities for some classes of business are given in Par. **107** to **112**.

With large consumers it is frequently the practice to measure the maximum demand for a comparatively short period of time by means of an indicating instrument inserted at times of greatest load and assume that the maximum demand thereafter is the same as that measured.

**140. Maximum-demand meters.** In the Wright demand system of charging (Par. **136**) the maximum demand is determined by a **Wright demand meter** kept continuously in circuit alongside the kilowatt-hour meter. The Wright demand meter is an instrument for recording the maximum current which has passed and operates by the expansion and pouring over of a liquid by the heating effects of the current. It measures maximum amperes, not kilowatts.

**A printing attachment on a recording watt-hour meter** can be arranged to print at regular intervals the reading of the meter at that instant. The difference between two succeeding readings divided by the hours elapsed between readings gives the average demand in kilowatts between readings. By arranging the instrument to print at intervals of a few minutes, peak loads of very short duration can be measured. Such an instrument also shows the time at which the maximum demand is taken, thus showing whether at the time of the maximum load on the system or not; which in some cases is important as explained later in connection with off peak or limited hour rates. The paper rolls need be removed but once a month.

**Watt-hour meters with attachments for recording maximum demand** are available, such attachments depending upon the torque exerted upon the meter at any instant; this torque being proportional to the maximum demand.

**A curve-drawing watt-meter** which draws a curve of the load upon a roll of paper is sometimes used for determining maximum demand where the meters can be looked after with sufficient frequency. It is usually considered practicable only in large installations.

**141. The maximum demand in the case of residences is sometimes assumed to be proportional to the room area** or to the number of certain kinds of rooms in a house. This is sometimes called the **Detroit system**, having been first used in America at Detroit. Under this system the residence consumer's maximum demand is assumed to be a certain number of watts for each different kind of room. Not all rooms are counted as only those rooms termed active are included and the number of watts per room is varied according to a schedule believed from experience to correspond to the average actual demand of such rooms. While such a method of figuring maximum demand would appear peculiar at first sight it is nevertheless probably as fair as an assumption that the maximum demand is a certain proportion of the connected load. Basing assumed maximum demand upon connected load in a residence has the serious drawback that it practically puts a penalty on the wiring of a house with a large number of closet lights and similar conveniences. These have but little influence upon the maximum demand but are nevertheless very convenient for the consumer and have much to do in persuading him to use electric light. Basing the maximum demand upon the active rooms in a house or upon the size of the house eliminates this unfairness and helps to cultivate the residence business.

Digitized by Google

In England the **taxable (rateable) value** of a residence has been taken as a basis for the assumed demand in a few cases.

Where the maximum demand is assumed rather than measured it is customary in residence business under a two-charge block rate to include no electric heating devices, vacuum cleaners, washing-machine motors and the like in the connected apparatus counted as the basis of maximum demand. This is done upon the theory that such devices are not ordinarily used during the maximum or peak load of the station, or of the residence distribution system, so that there need be no investment or maximum-demand charge against them. The practical effect of such a policy is to give such heating devices a low rate because the ordinary residence consumer will consume enough electricity for lighting to exceed the primary or high-rate portion of his bill so that electricity used for heating and other household conveniences comes in on the low-rate portion of the bill.

**142. Active-room-socket method of estimating maximum demand. (Cleveland method.)** A further modification of the active-room plan of estimating demand, used at Cleveland, consists in counting the demand as being a certain number of watts per lamp socket connected in the active rooms. This is called the active-room-socket system.

**143. Diversity of maximum demand, affecting investment charges.** So far we have considered only the simple case of a consumer whose maximum demand comes at the same time as the peak load on the station or system. If the consumer's maximum demand is at a different time the problem is much more elaborate.

The maximum demands of different consumers do not all coincide as explained in Par. **113**. On account of the diversity between the demands of different consumers it must not be assumed that each consumer should be charged with the full station investment per kw. corresponding to the maximum kilowatt demand of such consumer. In order to determine definitely how much power-station investment should be charged against a given consumer, it is essential to know the diversity factor between the consumer and the power station or the maximum demand of such a consumer at the time of the maximum load upon the power station. As far as the power-station size and investment is concerned, the maximum demand of the consumer at times other than that of maximum power-station load is immaterial. Likewise, to determine the amount of feeder investment which should be charged against a consumer, it is essential to know the maximum demand of certain consumers at the time of the maximum load upon the particular feeder on which the consumer is located. The same process must be applied to mains and transformers.

A study of demand and diversity factors is therefore essential to scientific rate making in order that the proper relative amount of investment be charged against a given class of consumer. Demand and diversity factors are given in Par. **106** to **115**.

**144. To determine the investment which should be charged against the service of a given consumer** the method of applying demand and diversity factors is as follows: We will assume the case of a consumer with a connected load of 10 kw. We will also assume that the following demand and diversity factors have been found to apply to this class of consumers.

(a) Demand factor 80 per cent.
(b) Diversity factor consumers to transformers 70 per cent.
(c) Diversity factor transformers to feeders 80 per cent.
(d) Diversity factor feeders to power station bus bars 90 per cent.

The investment required for various parts of the plant to serve this consumer will then be as follows:

10 kw. in connected load × 80 per cent. demand factor = 8 kw. maximum demand at consumer's service, or 8 kw. meter investment.

8 kw. in consumer's demand × 70 per cent. diversity factor, consumer to transformer = 5.6 kw. transformer investment.

5.6 kw. in transformers × 80 per cent. diversity factor, transformers to feeders = 4.48 kw. feeder investment.

4.48 kw. feeders × 90 per cent. diversity factor, feeders to power-station bus bars = 4.03 kw. power-station investment. It is of course necessary in such an analysis that the cost of the various parts of the system from the power station to the consumer be known, and the more exact such an analysis of cost the more equitable the rates that can be calculated there-

Digitized by Google

from. It is not however customary to attempt to charge each consumer with the exact feeder investment necessary to serve him. Some consumers are a considerable distance from the power station and others are near, and making an exact analysis would complicate matters to such an extent that it is customary to take the complete feeder and pole-line equipment reduced to a cost per kw. of demand basis and to charge this investment equally among all consumers.

**145. Off-peak rates, sometimes called limited rates** are sometimes made for classes of business where the maximum demand of the consumer is limited to certain hours of the day so that all or a large portion, of the consumer's load is turned off during the hours of maximum central station load. In this way the power station and distribution system investment which is installed to provide for the demands of ordinary consumers can be made to do double duty and the demand charge is considerably reduced. There is a difference of opinion among rate experts as to how much of the demand charge should be borne by the off-peak consumer in such cases. Some argue that, inasmuch as the station and meter capacity are already installed for serving the peak-load consumer, it is proper to eliminate a considerable percentage of the demand charge for the off-peak consumer, because the power-station capacity service supplied to such a customer is in the nature of a by-product which would not otherwise be utilised. The general practice is to divide such charges between the peak and the off-peak consumers. However, in cases where it is necessary for competitive reasons to remove the demand charge of the off-peak consumers in so far as it applies to investment already made for peak consumers, and allow it to be borne altogether by the peak consumers, the by-product theory offers an excellent argument. Further, the taking on of such off-peak business, even though it bears but a small percentage of the maximum-demand charge, increases the net income of the company and assists in a more economical production, so that ultimately reduced rates can be instituted for all consumers. As a general policy the leaders of the central-station industry as well as public service commissions recognise fully that any rates which help to increase and build up the volume of central-station business help ultimately to reduce the cost of service to all consumers.

**146. The practical deviations of rates from the cost-of-service theory** are necessarily numerous. It is not feasible to determine the exact investment required to serve each consumer. Consumers must rather be taken by classes. Furthermore, the rate per kw-hr. to each consumer using electricity but a few hours per month based upon the cost of service, would be astonishingly high. If the rates charged on this business were based strictly on cost of service, there would be so much public protest that both central-station companies and rate-regulating commissions apparently have concluded that it is best to allow this class of business to be taken at a loss and let the losses be made up by other consumers, inasmuch as the gross revenue from such business is a small proportion of the whole.

**147. Limited-demand flat rates** are sometimes used for small residence lighting where it is desired to cut out the expense of meter investment, meter readings and bookkeeping. Such rates also appeal to a certain class of small consumers who wish to know definitely what their lighting bills will be per month without the uncertainty of a meter. One trouble with flat rates has been that consumers put in larger lamps or other devices than they contract to pay for. Under the limited-demand flat rate system the consumer is served through a limiting device of some sort which periodically interrupts the current and flickers the lamps whenever the contracted maximum demand is exceeded. The consumer is thus warned to turn off one or more lamps and prevented from using an excess demand over that contracted for.

The limited-demand flat rate has some of the disadvantages of all flat rates namely that consumers waste electrical energy by keeping lights on when not needed. Where such rates are in use, however, this tendency is somewhat restricted by making the consumer pay for lamp renewals, and if lamp renewals are sufficiently expensive there is some incentive to turn out lamps when not needed in order to save renewal costs. However such flat rates must always be made high enough to allow for considerable waste on the part of the consumer. The principal use for such a rate is in the supply of very small residences where the cost of bookkeeping, meter reading and

Digitized by Google

meter maintenance would be a considerable percentage of the total monthly bill. A very common rate for this class of business in the United States for small residences is 1 cent per watt of demand per month. In calculating such rates it must be remembered that the diversity factor of this class of business as expressed in per cent. is higher than for ordinary residence business, because when service is supplied through a meter lamps are turned on and off as needed by the various consumers. The peaks of the various consumers thus do not coincide. Under the flat rate system there is likely to be but little diversity between consumers because the lights are left on continuously during the evening. The maximum demand of a group of such flat rate consumers per kw. of connected load will therefore be considerably more than for a group of consumers served through meters.

**148. Rates for energy supplied for power purposes** to electric motors are generally lower than those paid for electric lighting purposes. The scientific justification of such a policy is usually found in the fact that the maximum demand for electric power does not coincide with the maximum demand for electric light and the maximum demand for electric light is at the time of the maximum demand on the central station system. The motor load is, therefore, to a certain extent, an off-peak business even though it be not definitely stipulated in the contract that motors are not to be operated during the peak-load hours of the system.

**149. Free lamp renewals.** Some central-station companies give free lamp renewals of certain kinds of lamps and the cost of lamp renewals is included in the kilowatt-hour lighting rate.

**150. A minimum bill or minimum charge per month** is generally recognized as just by public service commissions and courts. These minimum charges are in the nature of a consumer charge to cover the cost of meter reading, meter and service maintenance and bookkeeping and to serve as a partial offset to the losses which inevitably occur under most rate schedules where the consumer uses electricity but a short time each month. Minimum charges are from $1.50 per month down for small consumers where such charges are in force. Some companies have no minimum charge, believing it is a deterrent to some would-be consumers, and the loss on some small consumers is assumed as a part of the expense of developing the business, popularizing the service, and securing public good will.

**151. Examples of rate schedules.** The following rate schedules are given as specific examples of the rates defined and discussed in this section. The actual figures given are simply selected at random but they are within the range of ordinary practice and a number of the rates given are those actually in force in various cities.

**Flat rate.** One dollar per month for each 50-watt incandescent lamp or equivalent in commercial service. Fifty cents per month for each 50-watt incandescent lamp or equivalent in residence service.

**Flat rate for street lighting.** Seventy-five dollars per arc lamp (type of lamp being specified) per year, operating all-night every-night schedule, or about 4,000 hr.

**Demand rate.** Fifty dollars per kw. of maximum demand per year; the maximum demand being measured by a curve-drawing watt-hour meter.

**Straight-line meter rate.** Ten cents per kw-hr. for all electrical energy used. No discounts for quantity.

**Consumers' output rate.** Six cents per 1,000 gals. of water pumped. (In such a case the conditions of pumping are of course definitely known in advance of the contract. This is a form of rate sometimes used for waterworks pumping.)

**Two-charge rate** also known as the **Hopkinson rate.** Thirty-six dollars per year per kw. of maximum demand plus 6 cents per kw-hr. for electrical energy consumed.

**Two-charge block meter rate** with measured demand; also known as **Wright's demand rate.** A primary rate of 14 cents per kw-hr. for electricity used up to an amount equivalent to or less than the first 30 hr. use per month of the maximum demand, and a secondary rate of 8 cents per kilowatt-hour for additional electrical energy.

Where the maximum demand is not actually measured the following is a typical form of expression of the two-charge block meter rate: Primary rate, 14 cents per kw-hr. for energy used up to an amount equivalent to or less

Digitized by Google

than the first 30 hr. use per month of the active connected load. Secondary rate, 8 cents per kw-hr. for additional energy used. (In this case the active connected load is the assumed maximum demand.)

Where the active room plan is used as a basis of estimating maximum demand of residences, the following is an example of one method of estimating: multiply the number of rooms in the house by 0.04 kw., but do not count bathrooms, basements, cellars, porches, stairways, attics, store rooms, small halls, entrances, woodsheds, or barns.

**Three-charge rate.** Six dollars per year per consumer (as a consumer charge) plus $30 per year per kw. of maximum demand (as a demand charge sometimes called a readiness to serve charge) plus 6 cents per kw-hr. for electrical energy used.

**Block meter rate.** For the first 250 kw-hr. monthly consumption, 10 cents per kw-hr.; for the next 250 kw-hr. monthly consumption, 9 cents per kw-hr.; for the next 250 kw-hr. monthly consumption, 8 cents per kw-hr.

**Step meter rate.** For the first 250 kw-hr. of monthly consumption 12 cents per kw-hr.; for a monthly consumption between 250 and 500 kw-hr., 11 cents per kw-hr.; for a monthly consumption between 500 and 750 kw-hr., 10 cents per kw-hr. (Note that under the foregoing schedule a consumer of 249 kw-hr. per month would pay more than a consumer of 251, in actual dollars and cents. There is evident injustice in this and also in the fact that the discount is applied in sharp steps rather than gradually.)

**152. Discounts for prompt payment** are sometimes allowed and as the majority of consumers will take advantage of such discount the rate should be adjusted so that they will yield the owners of the property a fair profit after the discount is taken off. In order that a discount for prompt payment may be legally sustained it is necessary that it should not be a very large discount. About 10 per cent. is common. Discounts in excess of this are in danger of being set aside by courts or commissions as being unfair to the consumer who does not take advantage of the discount.

## VALUATIONS FOR RATE-MAKING PURPOSES

**153. Classification of purposes for which valuations are made.** The laws of many states where public service or public utility commissions have been created for the purpose of public-utility regulation, provide for the valuation of public utility properties for purposes of establishing reasonable rates. The theory upon which these laws are based (although it is not always expressly so stated) is that of allowing the investor in public utility properties a fair and reasonable rate of return (interest and profit) upon his investment.

Valuations made for rate-making purposes may be very different from valuations made for other purposes. If a property is to be appraised or valued for the purposes of an ordinary business purchase, the fundamental question to be solved is the probable earning power of the property both present and prospective. In valuations for rate making, however, the earning power of the property should receive no consideration, because the earning power is dependent upon the very rates which it is proposed to regulate, and to value a property on its earnings would defeat the entire end in view.

**154. The purpose of a valuation to be used in rate making,** should be to determine as nearly as possible the actual fair investment in the property to the end that rates may be so adjusted that a fair annual return (interest and profit) will be made to the investor upon the amount invested in the property after all expenses are paid. If this end were kept constantly in view many of the disputes and discussions in connection with such valuations would be obviated.

If the actual cost of a public-utility property could always be obtained from the construction or property accounts, the problem would be simple. However, it is frequently the case that construction costs are not kept in such shape that they can be accepted unquestionably by the appraiser. It may also happen that part of the books and records of the enterprise is destroyed or unavailable. In any case the engineer making the valuation must be prepared by knowledge of other plants to check the accuracy of any figures submitted to him or even to value a plant entirely in accordance with costs of similar plants elsewhere if no figures whatever are available on the actual cost of the plant under consideration. The value of a public utility property is usually classified under two heads, tangible and intangible.

Digitized by Google

**155. The tangible physical property** can be seen and appraised by an engineer familiar with the costs of similar plant and equipment as installed ready to run. As we are seeking for the actual first cost of such plant and equipment, the cost of building the plant at the time and in the manner in which it was actually built must be sought, rather than the cost of reproduction of such a plant at the present time. In this connection a reasonable allowance may be made for ever present minor mistakes in construction, and the cost of their correction, unless such mistakes are such as to show a lack of ordinary good business judgment or management on the part of the constructor and investor. Depreciation should be deducted.

**156. Intangible values** are those not represented by visible, or tangible physical property. They are a prolific source of controversy. Keeping in mind the fundamental principle of allowing a fair interest and profit on actual cost of a property we see that under intangible value should be included all money put into the property at any stage of its development for whatever purpose, from whatever source, after deducting that coming under the following descriptions:

(A) Cost less depreciation of tangible property already listed.

(B) Interest, profits or dividends paid in the past in excess of a fair rate of return.

(C) Money invested as a result of extravagance, dishonesty, bad management or lack of ordinary reasonable business judgment.

Note that if these deductions are large enough to leave no intangible value the tangible property cost less depreciation becomes the fair value upon which a fair return should be paid. In such a case the owners would either have had the amount spent on intangibles, including an amount equal to the depreciation, returned to them in dividends or the intangible value including depreciation would have vanished through dishonesty or bad management.

Under the foregoing method of arriving at intangible value (termed **going value** by the Wisconsin Commission) the investors are permitted a return on money put into a plant to pay operating losses before getting it on a paying basis as well as money put into permanent plant, providing the money was honestly and carefully spent as before specified, and provided they have not already been reimbursed for such losses. Manifestly, to determine such intangible or going value, an investigation must be made, not only of present conditions but of the financial history of the enterprise.

Among items of intangible or going value which are fairly allowable are discounts on sale of bonds, notes and stock and all reasonable expenses of financing and promotion, and interest during construction. Sufficient working capital must be provided to pay running expenses pending the collection of income and a fair rate of annual return should be allowed upon such working capital as well as upon the capital permanently invested in plant and equipment.

After intangible or going value is determined it may either be figured in as a part of the capital upon which a fair interest and profit should be perpetually earned, or it may not be figured in as a part of the permanent investment and sufficient net earnings may be allowed the investors to amortise or wipe out such intangible or going value at the end of a period of years. Both methods are in vogue.

**157. Treatment of depreciation.** In such valuations a determination of the actual depreciation as well as a fair depreciation on properties of this class are of much importance for the following reasons. If the owners have been receiving dividends or interest in excess of a fair interest and profit and these excess dividends were taken out of funds which should have been put back into the plant to make up depreciation and maintain the property is an unimpaired condition which would represent full security for the capital invested, such excess dividends should be deducted from the valuation of the plant, because this amount of value has already been returned to the owners. Depreciation due to gross carelessness or neglect or mismanagement will not ordinarily be allowed, but a fair rate of depreciation should be allowed and set aside or spent in renewals and if the enterprise has not been able to earn enough to pay such fair depreciation plus a fair profit under reasonably good management any such deficit can be reasonably put in as a part of the intangible or going value of the plant. In other words depreciation is simply one of the expenses of the operation which should be recognized and provided for, even though part of it is not

Digitized by Google

payable until some time in the future (see Par. 42). If the earnings in the past have not been sufficient to pay all such expenses and a loss has resulted from operation, such losses should be included in intangible or going value after making the proper deductions as stated.

**158. The per cent. upon the investment which a public utility is allowed to earn** as a fair and reasonable annual interest and profit upon its value as taken for rate-making purposes is a matter for commissions and courts to decide in accordance with the prevalent or market interest rate upon investments in similar securities. Public utility securities must compete in the financial market with other securities or they will not be sold. These are financial rather than engineering questions, but, since the engineer must frequently deal with them in the course of his business, the following points are given as presenting current practice.

Where part of the money to pay for the construction of a plant is raised by a bond issue, it is customary to sell the bonds at a discount below par, a part or all of which discount is taken by the bond broker as his commission for finding purchasers for the bonds. As the bonds must be redeemed at par when they are due, the discount upon the bonds must be added to the total annual interest paid on the bonds, in order to determine the actual annual cost to the public utility for the use of the money. This is a point sometimes overlooked in figuring the fixed charges which a public utility must carry. The principal question is to determine what rate of interest and profit a public utility must pay after discounts or commission on sale of securities are included. It is not a question of theory but of market conditions.

Mr. Halford Erickson member of the Railroad and Public Service Commission of Wisconsin in a public address 1914 (see Bibliography) gives the following figures as to rates actually paid by public utilities for money: Ten representative first mortgage bond issues covering electric-lighting and street-railway plants, brought out in 1913 and bearing interest at 5 per cent. on par value, were placed on the market at prices at which they would yield the investor an income of from 5 to 6 per cent. The cost to the issuing company of obtaining this capital amounted to from 1 per cent. minimum to over 11 per cent. maximum for discount and about 3 per cent. for selling expenses. The total average was about 6.2 per cent. During the same period 10 representative second mortgage bond issues covering gas, electric-lighting, and railway plants, bearing interest at 5 per cent., were offered at prices that would net investors an income of 5 to 6.2 per cent. On these issues the discount varied from 1 to over 12 per cent. and the selling expense stood at about 3 per cent. The total cost to the companies for this financing ranged from 5.2 to about 7 per cent., the average being about 6.4 per cent. Twelve note issues were offered to the public at prices which placed them upon a 6.2 per cent. income basis to the investors. When the discounts and selling expenses were taken into account, the cost to the companies of the bonds thus obtained was found to be about 9.4 per cent. per annum. In this case the discounts ranged from less than 1 to about 2.34 per cent. The selling costs, however, were rather heavy since they appear to have ranged from about 5 to over 8 per cent. Five preferred-stock issues were sold on a basis whose average yield to the investor was about 7.3 per cent. Since the discounts varied from 3 to 12.5 per cent. and the selling expense also had to be met, the cost to the companies was, of course, much greater than the price to the public. For about 40 plants in Wisconsin whose appraised value varied from about $20,000 to about $2,000,000 per plant, the bonds, when discounts and selling expenses are included, have of late years been selling at prices under which the cost of financing on the plant ranges from about 5.5 to fully 6.5 per cent. per annum. In these cases the bonds covered from 50 per cent. to more than 85 per cent. of the values of the plants and their business, while the net earnings of the plant did not amount to less than twice as much as the interest on the bonds.

In further explanation of Mr. Erickson's figures it should be said that this is in a state where most of the public utility companies are protected from competition as a recompense for commission regulation of rates and service, and that such securities, therefore, would present to the investor the minimum amount of hasard to be found in public utilities of any given size. Mr. Erickson's figures probably represent minimum interest rates obtainable by the public-utility properties in the United States of the kind and at the times stated.
